Overall, SSRIs usually decrease the frequency of panic attacks by about 80% and decrease associated anticipatory anxiety. The response rate may be lower for patients with more severe symptoms. Previous unsuccessful treatment with GABA-positive allosteric modulators (PAMs), formerly denoted as benzodiazepines, does not diminish the efficacy of SSRIs. When introduced, the daily doses of SSRIs should be half the usual starting doses used for the treatment of MDD. If not, the frequency of panic attacks may initially increase before abating, thereby possibly leading to early dropout from treatment. When stopping SSRIs in patients with panic disorder, a slower decrease in dose is recommended, as they may be more sensitive to discontinuation symptoms than patients with other disorders.

Social Anxiety Disorder (SAD)

SSRIs have been successfully used for the treatment of SAD. Improvement may be achieved slowly, becoming evident during the second month of treatment and continuing to increase until the third month. The combination of SSRIs and cognitive-behavior therapy (CBT) is more rapid and more complete than the use of an SSRI alone, as can be the case in other disorders.

Premenstrual Dysphoric Disorder (PMDD)

SSRIs are effective in alleviating the symptoms of PMDD. Improvement may be seen during the first week of treatment. Mood, irritability, and anxiety improve. Physical symptoms, such as swelling, bloating, and breast tenderness, are less responsive to treatment. Intermittent treatment (i.e., for the last 2 weeks of the menstrual cycle) can be as efficacious as continuous administration. Interestingly, this cyclical treatment does not produce SSRI discontinuation symptoms.

Post-Traumatic Stress Disorder

Placebo-controlled studies have confirmed the efficacy of SSRIs for PTSD. Discontinuation of the successful treatment after 6 months may result in the return of the PTSD symptoms in about half of patients.

Bulimia Nervosa

Fluoxetine (Prozac) 60 mg per day is FDA-approved for the treatment of bulimia nervosa. Trials have shown that fluoxetine is effective in decreasing episodes of binge eating and vomiting. No SSRI is FDA-approved for the treatment of anorexia nervosa.

Bipolar Depression

Fluoxetine, in combination with olanzapine (Symbyax), is FDA approved for the treatment of depression associated with bipolar I disorder.

Other Uses

SSRIs have been used off-label for several indications, including premature ejaculation. In this case, paroxetine may be the most useful of these drugs. However, continuous daily treatment is required to delay ejaculation significantly. SSRIs have also been used for the treatment of neuropsychiatric symptoms, agitation in neurocognitive disorders, and for the treatment of paraphilic disorders with inconsistent results.

PHARMACODYNAMICS

All SSRIs bind to and inhibit the action of 5-HT transporters. This raises 5-HT levels in the central nervous system (CNS) and throughout the body. The SSRIs act not only on the 5-HT transporter on 5-HT neurons but also at other sites, some well characterized, others not as clearly delineated (see below for individual medications). It is not clear whether the degree of SSRI selectivity offers any therapeutic benefit. One must be cautious, however, in extrapolating group effects to those of an individual patient, given that clinical experience reveals that patients who fail to respond to one may respond to another of these drugs. However, the equivalency of doses at the 5-HT transporter, drug compliance, and late responses should be taken into consideration when observing such differential responsiveness.

Medications other than the SSRIs that demonstrate significant inhibition of the 5-HT transporter include clomipramine (Anafranil), duloxetine

(Cymbalta), milnacipran (Savella, available in the United States only for the treatment of fibromyalgia), levomilnacipran (Fetzima), venlafaxine (Effexor), desvenlafaxine (Pristiq), vilazodone (Viibryd), vortioxetine (Trintellix), and trazodone (Desyrel). Most SSRIs are essentially devoid of any clinically significant degree of receptor antagonism properties at muscarinic, cholinergic, H_1, α_1, α_2, β-adrenergic, 5-HT_1, and 5-HT_2 receptors. Paroxetine has the greatest affinity for muscarinic cholinergic receptors of the available SSRIs and therefore produces, in a small percentage of patients, dry mouth, constipation, blurred vision, or urinary hesitancy. However, the affinity of paroxetine for muscarinic receptors as measured by inhibition of [^{3}H]quinuclidinyl benzilate binding. It is 15-fold less potent than that of amitriptyline, and its anticholinergic properties. This may thus explain its lack of side effects such as diarrhea and loose stools observed with other SSRIs, as well as its occasional sedating properties. Sertraline and fluvoxamine act as sigma-1 receptor agonists. The clinical relevance of this property remains to be fully understood, but some evidence suggests that it may contribute to therapeutic benefits in psychotic depression.

Positron emission tomography (PET) studies of the effect of SSRIs have been used for in vivo confirmation of in vitro and ex vivo derived hypotheses of mechanisms of action as well as for clinical dose findings. For example, PET imaging assessing occupancy of 5-HT reuptake sites by citalopram, fluoxetine, sertraline, paroxetine, or extended-release venlafaxine at minimum therapeutic doses revealed about 80% occupancy of 5-HT reuptake sites in the striatum. Similar quantitative results have been shown for the cingulate cortex. Higher regimens of SSRIs lead to greater occupancy of 5-HT transporters in the striatum. Notably, lower occupancy with a minimal effective dose of escitalopram has been reported in the orbitofrontal cortex, a brain region more intimately involved in OCD than for MDD. The latter observations help us understand why higher doses are commonly necessary for the treatment of OCD than depression. Taken together, these findings suggest that a threshold of 5-HT transporter occupancy is necessary to increase 5-HT transmission. That an increase in 5-HT transmission underlies the antidepressant action of SSRIs is indicated by the reappearance of depressive symptoms in patients who had responded to an SSRI when subjected to a tryptophan depleting paradigm (to decrease 5-HT synthesis). Further more, rapid return to their prior state with tryptophan administration (tryptophan is the amino acid precursor of 5-HT) confirmed the role of 5-HT in the therapeutic action of SSRIs.

Basis for the Delayed Onset of Therapeutic Effects of SSRIs

SSRIs penetrate the brain within hours, but their onset of action is delayed by at least 2 weeks. This can be accounted for by the initial decrease in the firing rate of 5-HT neurons because 5-HT$_{1A}$ autoreceptors on their cell bodies become overactivated as a result of the inhibition of the activity of 5-HT transporters. Since the release of 5-HT is directly proportional to the firing rate of 5-HT neurons, there is no sustained initial increase in 5-HT release in postsynaptic areas even though 5-HT reuptake is blocked. After prolonged SSRI administration, the 5-HT$_{1A}$ autoreceptors desensitize and allow recovery of the firing rate of 5-HT neurons in the presence of sustained 5-HT reuptake inhibition, at which time there is a net increase in 5-HT transmission. Also contributing to this enhanced 5-HT transmission is the desensitization of 5-HT$_{1B/D}$ autoreceptors on 5-HT terminals. The delay for the autoreceptors to desensitize (14 to 21 days) is consistent with the protracted onset of action of SSRIs in MDD. Importantly, the terminal autoreceptors in the orbitofrontal cortex desensitized after eight but not three weeks of SSRI administration, which is consistent with the longer delay of action of SSRIs in OCD than in MDD. These observations were made in rodent brains and can be translated to humans because the 5-HT system is nearly identical in mammalians.

Each of the SSRIs is structurally unique (Fig. 33.5a.1–1), although escitalopram is the *S*-enantiomer of the racemic mixture that is citalopram, and there are differences in their selectivity of reuptake inhibition, drug–drug interactions, and pharmacokinetic profiles. Studies of the reuptake inhibitory potencies of the SSRIs in vitro have been performed. Although different studies show different values, in general, the affinity (K_i) values are of the same relative ordering across studies. When interpreting in vitro data and attempting to extrapolate findings regarding relative degrees of reuptake inhibition to in vivo predictions, pharmacokinetic data such as steady-state concentrations, protein binding, molecular weights, and the presence or absence of active metabolites must all be accounted for.

TOLERABILITY

Both the therapeutic and adverse event profiles of SSRIs are the result of their blockade of the 5-HT transporter function. They eventually raise 5-HT levels in the CNS, as described above, but not necessarily to the same extent throughout the body, with a rapid action being particularly evident in the gastrointestinal (GI) tract. This is because 90% of the 5-HT in the body is in the periphery, where the degree of regulation is not as tightly controlled by autoreceptors. As a group, the SSRIs possess the adverse effects listed in Table 33.5a.1–2.

Escitalopram

FIGURE 33.5a.1–1. Structures of selective serotonin reuptake inhibitors.

When reviewing product information for the SSRIs, the frequency, severity, and duration of side effects need to be considered.

Gastrointestinal Effects

Nausea occurs in at least 25% of patients and can range from mild discomfort to, in some patients, vomiting. It is the most common early side effect of SSRIs and most often diminishes during the first to 2 weeks of treatment. Nausea at the initiation of treatment is generally dose-related. Accordingly, typical starting doses that are used to reduce this side effect are half of the usual starting dose. After 1 to 2 weeks at the lower doses, or when GI side effects resolve, the dose can be optimized. The disappearance of the GI side effects may be due to a desensitization of 5-HT_3 receptors. This is supported by the observations that GI side effects can be blocked by 5-HT_3 antagonists such as ondansetron (Zofran) and mirtazapine (Remeron).

Table 33.5a.1–2.
Selected Treatment-Emergent Adverse Events

- **Autonomic nervous system disorders**
  - Dry mouth
  - Increased sweating
- **Central and peripheral nervous system disorders**
  - Dizziness
  - Emotional blunting
  - Mild forgetfulness
- **Gastrointestinal disorders**
  - Nausea
  - Diarrhea
  - Constipation
  - Indigestion
  - Abdominal pain
- **Psychiatric disorders**
  - Insomnia
  - Somnolence
  - Decreased appetite
  - Decreased libido
- **Respiratory system disorders**
  - Rhinitis
  - Sinusitis
- **Urogenital**
  - Ejaculation disorder
  - Impotence
  - Anorgasmia
- **General**
  - Influenza-like symptoms
  - Fatigue
  - Yawning
  - Rash

Sexual Dysfunction

Sexual dysfunction, such as delayed ejaculation, delayed orgasm or anorgasmia, and diminished libido, is a common side effect of 5-HT reuptake inhibition. SSRI-associated sexual dysfunction is the most frequent side-effect–associated cause of premature medication discontinuation. Package insert data, almost always derived from phase III clinical trials, have underestimated the true incidence of sexual dysfunction, which occurs in clinical practice in about half of patients. Reliable estimates of the incidence and severity of untoward experiences involving sexual desire, performance, and satisfaction are difficult to obtain in part because patients and physicians may be reluctant to discuss them. Accordingly, estimates of the incidence of untoward sexual experience and performance cited in product labeling are underestimated in their actual incidence, as revealed by questionnaires on sexual function used in subsequent studies.

In some but not most instances, sexual dysfunction appears to be a dose-related effect, and occasionally decreasing the dose might be helpful. There have been a number of other strategies suggested to deal with this important adverse effect, including drug holidays for shorter half-life SSRIs (potentially associated with discontinuation symptoms or even a relapse) or the addition of buspirone, amantadine, yohimbine, cyproheptadine, stimulants, or bupropion. Anecdotally, selective inhibitors of cGMP-specific phosphodiesterase type 5, such as sildenafil (Viagra), have been reported by some patients to be helpful. A randomized controlled trial that used sildenafil as a treatment of sexual dysfunction in women taking SSRIs found that its use was associated with a reduction in sexual side effects. These observations lack solid replication, and, in fact, none of these approaches have been successful in completely reversing sexual side effects. Therefore, gradual switching to a medication not associated with sexual dysfunctions is often the most successful strategy. These include bupropion, mirtazapine, low-dose vortioxetine, vilazodone, or moclobemide (after an SSRI washout).

Sweating

Excessive sweating is not uncommon while being treated with SSRIs. The sweating is unrelated to ambient temperature. Nocturnal sweating may rarely drench bed sheets and require a change of night clothes. Terazosin, 1 or 2 mg per day, is often effective in counteracting sweating.

Discontinuation Syndrome

5-HT reuptake inhibitors have the potential to produce a discontinuation syndrome if stopped abruptly. However, it is important to emphasize that individuals treated with SSRIs do not develop addictions to these drugs. These drugs do not cause cravings, and individuals do not feel the need to increase the dose to get the same effect. Longer durations of treatment appear to be associated with a higher probability of discontinuation syndrome than shorter treatment periods (i.e., intermittent treatment in PMDD). In general, good clinical practice dictates a gradual tapering down of a therapeutic regimen after successful treatment.

Typical symptoms include asthenia, anxiety, agitation, GI distress, myalgias, sometimes a flu-like syndrome but with the absence of a fever, disequilibrium, and, in extreme cases, an experience described as electrical shocks coursing through the arms and legs. When discontinuing the medication, it should be done over the course of weeks rather than days. Drug taper can be problematic when the last dose is stopped. This problem can be managed by prescribing fluoxetine 20 mg per day for 1 to 2 weeks and then stopping that medication. The longer half-lives of fluoxetine and norfluoxetine help counter the discontinuation effects to a significant degree.

Bleeding

Both case reports and epidemiologic studies confirm that SSRIs alone may increase bleeding risk in some patients. There have been numerous case reports and case series describing abnormal bruising, bleeding, and heavy menses in patients taking SSRIs. Serotonin is released from platelets following vascular injury. It promotes vasoconstriction and a change in the shape of the platelets that lead to aggregation. Platelets cannot themselves synthesize 5-HT, so SSRIs deplete 5-HT in the platelets, which may decrease coagulation, theoretically leading to excessive bleeding diathesis in some patients. Other physiologic mechanisms may also be involved. There is an additive increase in bleeding risk when SSRIs are used concurrently with other drugs that can cause bleeding. SSRIs, for example, increase the incidence of serious bleeding in patients taking warfarin. Risk is also increased with concurrent use of nonsteroidal anti-inflammatory drugs, aspirin, or clopidogrel. A large general practice database search of data involving nearly 400,000 patients found that the number needed to harm (NNH) for upper GI bleeding with SSRI treatment in a low-risk population was 3,177, and in a high-risk population, it was 881. Thus, this risk associated with SSRI use is modest, requires monitoring and should not preclude their use in the presence of another predisposing factor.

Hyponatremia

There is an increased risk of hyponatremia in patients taking SSRIs. Risk factors include older age, female gender, volume depletion, and use of other medications or medical conditions causing hyponatremia like diuretics. SSRI-induced hyponatremia typically begins during the first weeks of treatment. This may be secondary to the syndrome of inappropriate antidiuretic hormone.

Cardiovascular Effects

All SSRIs can potentially lengthen the QT interval in otherwise healthy people and cause drug-induced long QT syndrome, possibly leading to torsade de pointes when taken in overdoses. In 2011, the FDA issued a safety warning about high-dose citalopram treatment. It made the following recommendations regarding citalopram use:

- 20 mg/day is the maximum recommended dose for patients with hepatic impairment, who are older than 60 years of age, who are CYP2C19 poor metabolizers, or who are taking concomitant cimetidine.
- No longer prescribe at doses greater than 40 mg/day.
- Do not use it in patients with congenital long QT syndrome.
- Correct hypokalemia and hypomagnesemia before administering citalopram.
- Monitor electrolytes as clinically indicated.
- Consider more frequent EKGs in patients with chronic heart failure, bradyarrhythmias, or patients on concomitant medications that prolong the QT interval.

This was based on a QT study assessing the effects of 20- and 60-mg doses of citalopram on the QT interval in adults compared with placebo. The study found a maximum mean prolongation in the individually corrected QT intervals of 8.5 milliseconds (ms) for 20 mg citalopram and 18.5 ms for 60 mg. For 40 mg, the estimated prolongation of the corrected QT interval was 12.6 ms.

Regulatory bodies in the United Kingdom and in Canada issued a similar safety warning about high-dose escitalopram treatment, with a maximal recommended dose of 10 mg/day in some populations considered at higher cardiac risk.

Antepartum use of SSRIs is sometimes associated with QTc interval prolongation in exposed neonates. A comparative study matched 52 newborns exposed to SSRIs in the immediate antepartum period with 52 controls. The mean QTc was significantly longer in the neonates exposed to SSRIs compared with the control group (409 ± 42 vs. 392 ± 29 ms; $p = .02$). Five neonates (10%) exposed to SSRIs had a prolonged QTc interval >460 ms compared with none in the controls. The longest QTc interval among exposed neonates was 543 ms. All the repolarization abnormalities associated with SSRIs normalized in subsequent electrocardiographic tracings, and no serious adverse effects occurred.

Comments

A 2013 study done at the Ann Arbor VAMC and the University of Michigan looked at the records of more than 600,000 VHA patients who received citalopram prescriptions between 2004 and 2009. This study did not show an increased risk for arrhythmias or death associated with daily doses of more than 40 mg. Citalopram daily doses greater than 40 mg were actually associated with slightly lower risks of all-cause mortality, noncardiac mortality, and ventricular arrhythmia compared with daily doses ≤20 mg. A subsequent study from the University of Minnesota in 35,848 patients whose regimens of citalopram were or were not reduced to 40 mg/day or less from a mean daily dose of 62 mg showed that reduction to the new safety limit was associated with a significantly higher rate of all-cause hospitalizations or death, as were hospitalizations for depression. Taken together, these findings raise questions about the legitimacy of the FDA warning.

Weight Gain

During early treatment, some patients may lose weight. Over time, many patients regain this weight, and it is not uncommon to see a significant increase in weight over the following months. The exact mechanism for this problem is unclear, but one should consider that appetite may increase as depression and/or anxiety abate. In some instances, it becomes difficult for patients to reverse this weight gain, even with rigorous dietary measures and exercise.

Diabetes

Population-based studies have shown that SSRIs may increase the risk of diabetes. An analysis was done based on three large well-known US datasets: the Nurses' Health Studies I and II and the Health Professionals Follow-up Study, a total of 139,000 women and 30,000 men. During over 1.6 million person-years of follow-up, the analysis documented a total of 6,641 new cases of type 2 diabetes and found that self-reported use of medications for depression was associated with an approximately 10% to 30% excess risk of developing diabetes. This association was robust despite adjustment for age, ethnicity, marital and living status, smoking habits, alcohol intake, physical activity, family history of diabetes, diet, body mass index, and major comorbidities (e.g., hypertension and dyslipidemia) and their treatment. There needs to be additional evidence that this increased risk is due to associated factors or SSRI treatment, but these findings suggest that it is prudent to monitor patients periodically for increased glycosylated hemoglobin (HbA1C).

Sleep Disturbances and Daytime Somnolence

Up to one-fourth of persons taking SSRIs note trouble sleeping, excessive somnolence, or overwhelming fatigue. Bruxism is another possible side effect. Nocturnal motor activity, including nocturnal myoclonus, may be increased during SSRI treatment. Some persons taking SSRIs report recalling extremely vivid dreams or nightmares. They describe sleep as "busy." Some persons benefit from taking their SSRI dose before going to bed, but others prefer to take it in the morning. SSRI-induced insomnia can be treated with Z drugs, trazodone, or other sedating medicines. Significant SSRI-induced somnolence often requires switching to another SSRI or bupropion.

Emotional Blunting

Emotional blunting or indifference are largely overlooked side effects associated with long-term SSRI use. Patients report an inability to cry in response to emotional situations, a feeling of apathy or indifference, or a restriction in the intensity of emotional experiences. This side effect is related to the inhibitory effect of 5-HT on the firing of dopamine and noradrenaline neurons. This side effect often leads to treatment discontinuation even when the drugs provide relief from depression or anxiety. The frequency of this side effect is unknown. It has a delayed onset, appears to be related to dosing, and may resolve with a dose reduction.

Extrapyramidal Symptoms

SSRIs rarely cause akathisia, dystonia, tremor, cogwheel rigidity, torticollis, opisthotonos, gait disorders, and bradykinesia. Rare cases of tardive dyskinesia have also been reported. Some people with well-controlled Parkinson disease may experience acute worsening of their motor symptoms when they take SSRIs, as 5-HT exerts an inhibitory effect on the firing of dopamine neurons.

Manic Switch

A switch in mood polarity has been reported following the initiation of SSRI in unipolar depression, although this adverse effect appears rare. Product monographs recommend screening for personal and family history of bipolar affective disorder before introducing an SSRI monotherapy. Except for the combination of fluoxetine with olanzapine, SSRIs are not FDA-approved for the treatment of bipolar depression.

Fractures

A recent meta-analysis found an increased risk of fracture among older adults treated with SSRIs (relative risk = 1.67, 95% confidence interval [CI] = 1.56–1.79). The authors reported an NNH of 19 for one additional fracture to occur over 5 years in SSRI-treated versus non-SSRI–treated individuals.

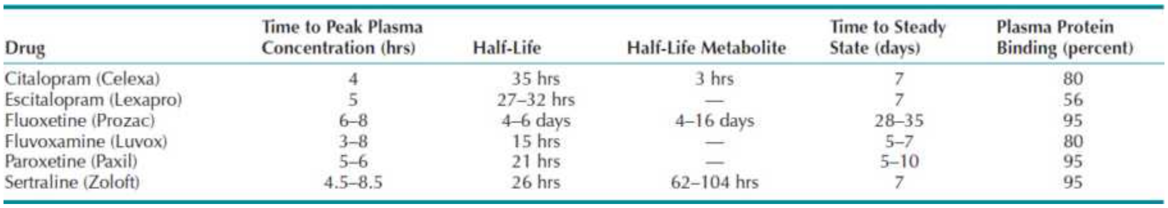
Laboratory Interferences

SSRIs do not interfere with any laboratory measures.

CHEMISTRY AND PHARMACOKINETICS OF INDIVIDUAL SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The SSRIs as a class exhibit a broad range of chemical structures and serum half-lives ranging from hours to days. There is no evidence that the structure of the drug molecules differentiates the clinical benefits and risks of the drugs in any meaningful way. The wide range of serum half-lives does manifest clinically. This is true not only in terms of time to steady state and the time required for the drug to exit the body after it is stopped but also in differing potentials for discontinuation syndrome on stopping the SSRI or, more commonly, after missing occasional doses. The SSRIs demonstrate moderate to high protein binding. Table 33.5a.1–3 summarizes the pharmacokinetic properties of the SSRIs. The contribution of protein binding to potential drug–drug interactions is unclear. The only fraction of the drug that is available to exert biologic activity is the free drug in the plasma. The amount of free drug can enter the CNS but is also subject to being metabolized. SSRIs, such as paroxetine, sertraline, and fluoxetine, are tightly protein-bound, and only approximately 1/20 of the drug in the system exists as a free drug, the balance being nonspecifically bound to serum proteins. It remains unknown whether clinically significant displacement of protein binding by the SSRIs occurs during concomitant therapy with other medications, such as warfarin (Coumadin). It can be argued that clinicians should actively look for such drug–drug interactions following the addition of one drug with high protein-binding characteristics to another, especially when functional assays (such as with warfarin) are available. Another area that requires exploration is the determination of the level at which protein binding becomes saturated, and the accumulation of free drug becomes a nonlinear process. This may have important implications for agents that demonstrate different mechanisms of action across low-to-high dosing ranges. The chemical structures of the individual SSRIs are illustrated in Figure 33.5a.1–1, and their pharmacokinetic profiles are shown in Table 33.5a.1–3.

Table 33.5a.1–3.
Pharmacokinetic Profiles of the Selective Serotonin Reuptake Inhibitors



Drug	Time to Peak Plasma Concentration (hrs)	Half-Life	Half-Life Metabolite	Time to Steady State (days)	Plasma Protein Binding (percent)
Citalopram (Celexa)	4	35 hrs	3 hrs	7	80
Escitalopram (Lexapro)	5	27–32 hrs	—	7	56
Fluoxetine (Prozac)	6–8	4–6 days	4–16 days	28–35	95
Fluvoxamine (Luvox)	3–8	15 hrs	—	5–7	80
Paroxetine (Paxil)	5–6	21 hrs	—	5–10	95
Sertraline (Zoloft)	4.5–8.5	26 hrs	62–104 hrs	7	95

FLUOXETINE

Chemistry

Fluoxetine's empirical formula is $C_{17}H_{18}F_3NO \cdot HCl$, and it has a molecular weight of 345.79. Its chemical designation is (±)-*N*-methyl-3-phenyl-3-[(α–α–α-trifluoro-*p*-toylyl)-oxy]-propylamine hydrochloride.

Pharmacologic Actions

Absorption. Fluoxetine is well absorbed orally, with 72% to 90% systemic availability, reflecting the combination of almost complete absorption and first-pass metabolism by liver hepatocytes. Maximum plasma concentration is achieved within 6 to 8 hours of ingestion after a single 40-mg dose. Peak plasma concentrations are not affected by food, but absorption may be delayed 1 to 2 hours. The delayed-release, enteric-coated preparation of once-weekly fluoxetine also demonstrates peak plasma levels 6 to 8 hours after absorption, although absorption does not begin until entry into the portion of the GI tract where the pH exceeds 5.5. There is more variability of peak and trough levels with the once-weekly preparation compared to once-daily dosing. In addition, the C_{max} after administration of the 90-mg, once-weekly preparation one day after 20-mg, once-daily dosing was 1.7 times higher than the C_{max} observed with once-daily dosing. When the transition to once-weekly dosing was delayed by 1 week after the last once-daily dose was given, the observed C_{max} was approximately equal. Fluoxetine is available as pulvules (10, 20, or 40 mg), tablets (10 mg), an oral concentrate (20 mg/5 mL), and in an enteric-coated, delayed-release, once-weekly form (90 mg).

Distribution. In vitro, fluoxetine is approximately 95% bound to serum proteins (albumin and α_1–acid-glycoproteins) at concentrations of 200 to 1,000 ng/mL. The volume of distribution for fluoxetine and norfluoxetine, the biologically active metabolite, ranges from 20 to 45 L/kg. The rate of plasma clearance is 20 and 9 L/hr for fluoxetine and norfluoxetine, respectively. Fluoxetine is widely distributed, including excretion into breast milk.

Metabolism and Elimination. Fluoxetine is a racemic mixture of *R*-fluoxetine and *S*-fluoxetine in equal proportions. Both are approximately equipotent in 5-HT reuptake inhibition activity, although the *S*-fluoxetine enantiomer is more slowly eliminated and is, therefore, the predominant form in plasma at a steady state. Fluoxetine undergoes demethylation in the liver to norfluoxetine and to a number of other unidentified minor metabolites, although norfluoxetine is the only metabolite identified that possesses biologic activity. In animals, the *S*-enantiomer of norfluoxetine is essentially equivalent in activity to that of *R*- or *S*-fluoxetine, but *R*-norfluoxetine has significantly less activity. The kidneys excrete inactive metabolites produced by hepatic metabolism.

The elimination half-life of fluoxetine is 1 to 3 days after acute administration and 4 to 6 days after chronic administration. Norfluoxetine has an elimination half-life of 4 to 16 days, independent of the duration of administration. Steady-state levels of fluoxetine are higher than would be predicted based on single-dose administration, as the drug inhibits its own metabolism.

Individuals who are deficient in CYP 2D6 activity—so-called poor metabolizers—constitute 6% to 8% of the Caucasian population and metabolize *S*-fluoxetine at a slower-than-expected rate. In contrast, the metabolism of *R*-fluoxetine is normal. Owing to the slower metabolism of *S*-fluoxetine, it is present at higher-than-expected concentrations, but *S*-norfluoxetine is found at lower concentrations. The sum total of *S*-fluoxetine and *R*-fluoxetine and *S*-norfluoxetine and *R*-norfluoxetine are approximately equal between poor metabolizers and those with a full complement of CYP 2D6 activity. The percentage of individuals with ultra-rapid status at the 2D6 varies geographically in the world: between about 1% (Scandinavia) to 20% in northeast Africa and Arabian Peninsula. A major dose adjustment of fluoxetine is likely not necessary as it inhibits its own metabolism, and these individuals would theoretically be transformed into slow metabolizers.

Impairment of hepatic function is associated with impaired metabolism of fluoxetine. In a series of subjects with cirrhosis of the liver, the mean half-life of fluoxetine was increased to 7.6 days, compared to 2 to 3 days for healthy subjects. The half-life of norfluoxetine was similarly increased to a mean of 12 days, compared to 7 to 9 days for healthy subjects. This would indicate the necessity of a dose reduction in individuals with significant liver disease.

Renal disease does not appear to impair the metabolism of fluoxetine or norfluoxetine in single-dose studies. One small study (*N* = 12) of patients on dialysis receiving fluoxetine at 20 mg per day for 2 months found steady-state fluoxetine and norfluoxetine levels close to those observed in patients with intact renal function.

Patients 60 years of age and older who were depressed demonstrated normal fluoxetine levels of 209 ± 86 ng/mL after dosing 20 mg per day for 6 weeks.

Children with OCD or MDD (six to less than 13 years of age; *N* = 10), compared to adolescents (13 to less than 18 years of age; *N* = 11), receiving fluoxetine at doses of 20 mg per day showed steady-state (60 days) fluoxetine levels of 171 and 86 ng/mL, respectively. Norfluoxetine levels were also higher in children than in adolescents, 195 and 113 ng/mL, respectively. These differences appear to be primarily related to relative body mass differences and the levels normalized when this was considered.

SERTRALINE

Chemistry

The empirical formula of sertraline is $C_{17}H_{17}NCl_2 \cdot HCl$; it has a molecular weight of 342.7. The structure of sertraline is distinct from that of other 5-HT reuptake inhibitors, and it is a naphthylamine derivative. The chemical designation is (1*S*-*cis*)-4-(3,4-dichlorophenyl)-1,2,3,4-tetrahydro-*N*-methyl-1-naphthalenamine hydrochloride.

Pharmacologic Actions

Absorption. Sertraline is well absorbed orally, with equivalent absorption observed with tablets and oral concentrate. Maximum systemic concentration is achieved within 4.5 to 8.4 hours of ingestion after 14 days of dosing in the range of 50 to 200 mg daily. When administered with food, the mean peak plasma concentration is increased by 25% with the tablet preparation, and the peak plasma concentration is achieved in 5.5 hours after ingestion, compared to 8 hours when given without food. Whether this food-related increase in sertraline plasma levels is clinically significant in terms of adverse events is unclear, although many clinicians advocate the initial administration of sertraline, like other SSRIs, after a meal. Administration of the oral concentrate preparation of sertraline with food is associated with a delay in the time to peak plasma concentration of from 5.9 to 7.0 hours.

Distribution. In vitro, sertraline is approximately 98% bound to serum proteins at concentrations of 20 to 500 ng/mL. The volume of distribution for sertraline is approximately 20 L/kg, and the rate of plasma clearance is 96 L/hr. The extent of the distribution of sertraline in breast milk has been studied in detail. The data indicate that sertraline is present in breast milk and in infant serum, albeit in much lower concentrations.

Metabolism and Elimination. Sertraline undergoes demethylation in the liver to *N*-desmethylsertraline. The half-life of sertraline is 26 hours, and the half-life of *N*-desmethylsertraline is 62 to 104 hours; however, the metabolite is 5 to 10 times less potent in inhibiting 5-HT reuptake than the parent compound, but still in the range of that of fluvoxamine. Desmethylsertraline displays a five- to ninefold increase in area under the curve (AUC) and peak and minimum plasma concentrations after 14 days of sertraline administration. In healthy volunteers, sertraline demonstrates linear pharmacokinetics over the range of 50 to 200 mg per day. Based on the use of radiolabeled sertraline in two healthy male subjects, unchanged sertraline was found to constitute less than 5% of the plasma radioactivity. After nine days, 40% to 45% of the radioactivity was recovered in urine, but no unchanged sertraline was detected. Another 40% to 45% was recovered in feces, of which 12% to 14% was unchanged sertraline.

Liver disease is associated with impaired metabolism of sertraline. In a series of subjects with mild, stable cirrhosis of the liver, the mean half-life of sertraline was increased to 52 hours, compared to 22 hours for normal subjects. This suggests the necessity of dose reduction or increased intervals between doses in individuals with hepatic impairment.

The presence of renal impairment (mild, moderate, or severe) does not appear to affect the multiple-dose pharmacokinetics of sertraline. This is perhaps due to renal excretion providing a relatively minor pathway for the elimination of the unchanged drug.

Aging is associated with a decrease in sertraline clearance. In 16 older adult patients treated with sertraline (100 mg per day for 14 days), the clearance of sertraline was 40% lower than that observed in younger subjects (25 to 32 years of age). The establishment of steady-state drug levels is delayed in this group to a time frame of 14 to 21 days of medication administration. Desmethylsertraline clearance was decreased in older men but not women.

The pharmacokinetics of sertraline in children (6 to 12 years of age) and adolescents (13 to 17 years of age) are similar to those seen in adults when adjustments are made based on body mass. Pediatric patients with MDD or OCD who were administered sertraline (42 days of sertraline therapy, of which at least the final 11 days were at a dose of 200 mg per day) had a mean C_{max} (maximal concentration) and half-lives of 165 ng/mL and 26 hours and 123 ng/mL and 28 hours for children and adolescents, respectively. In comparison, a separate study involving healthy adults who received sertraline (200 mg per day for 30 days) had a mean C_{max} of 142 ng/mL and a half-life of 27 hours. Children and adolescents have a smaller (by approximately 22%) AUC with sertraline than adults, also suggesting the potential for more rapid metabolism in the younger age group. Even so, initial dosing strategies should typically be adjusted downward for younger patients, who typically have a lower body mass than adults.

PAROXETINE AND PAROXETINE CR

Chemistry

Paroxetine is the hydrochloride salt of a phenylpiperidine compound and is structurally distinct from other medications for depression. Paroxetine is designated as (–)-trans-4*R*-(4′-fluorophenyl)-3*S*-([3′,4′-methylenedioxyphenoxy]methyl) piperidine hydrochloride hemihydrate. The empirical formula is $C_{19}H_{20}FNO_3 \cdot HCl \cdot \frac{1}{2}H_2O$, and the molecular weight of the free base is 374.8. Paroxetine constant release (CR) is the same salt as the immediate-release (IR) formulation but is in a degradable polymeric matrix with an enteric coating that delays drug release until the tablet has left the stomach.

Pharmacologic Actions

Absorption. Paroxetine is well absorbed orally, and food does not alter absorption. Maximum systemic concentration is achieved approximately 5 hours and 6 to 10 hours after ingestion for the IR and CR formulations, respectively. The CR formulation demonstrates a decrease in bioavailability of approximately 25% compared to the IR preparation, and thus equivalent doses of paroxetine IR and CR would be 10.0- and 12.5-mg, 20.0- and 25.0-mg, and 30.0- and 37.5-mg tablets, respectively.

Distribution. Paroxetine, like sertraline and fluoxetine, is tightly bound to serum proteins in vitro, with binding of 95% and 93% at plasma levels of 100 and 400 ng/mL, respectively. Paroxetine has not been reported to alter the in vitro protein binding of warfarin or phenytoin (Dilantin). The volume of distribution is approximately 15 L/kg, and the rate of plasma clearance is close to 79 L/hr. Most individuals achieve steady-state plasma concentrations within 5 to 10 days of dosing of the IR formulation and within 2 weeks with paroxetine CR.

Metabolism and Elimination. The principal path of metabolism for paroxetine is oxidation and methylation. A number of major metabolites have been identified, although none appears to be any greater than 1/50 as potent as the parent compound in the in vitro reuptake inhibition of 5-HT. A single test dose of paroxetine (30 mg) was recovered as 64% in the urine (2% as the parent compound and 62% as metabolites over 10 days). In the feces, 36% was excreted, with less than 1% as the parent compound.

Paroxetine saturates the CYP 2D6 isozyme of the CYP system and therefore exhibits nonlinear pharmacokinetics. Steady-state plasma maximal and minimal concentrations were elevated 6 and 14 times, respectively, over single-dose values after reaching a steady state. This translates into a 24-hour AUC value close to eightfold higher at a steady state than would be predicted from a single dose. Pharmacokinetic data showed that the half-life of 2D6 substrates is prolonged in the presence of paroxetine in normal metabolizers but is not further prolonged in slow metabolizers. As for fluoxetine, a major increase in dose may not be necessary for ultra-rapid metabolizers.

In older adult patients, dosing of paroxetine at 20, 30, or 40 mg per day produced plasma concentrations approximately 70% to 80% greater than those observed in younger patients. Patients with a creatinine clearance of less than 30 mL/min demonstrated a fourfold elevation in plasma levels compared to healthy controls. Patients with moderate renal impairment (creatinine clearance of 30 to 60 mL/min), as well as patients with moderate hepatic impairment, had a twofold increase in plasma concentrations. All the previously mentioned groups should receive reduced starting doses of paroxetine, for example, 10 mg per day of paroxetine or 12.5 mg per day of paroxetine CR.

FLUVOXAMINE AND FLUVOXAMINE CR

Chemistry

Fluvoxamine is a member of the 2-aminoethyloxime ethers of the aralkylketone family. The empirical formula of fluvoxamine is $C_{15}H_{21}O_2N_2F_3 \bullet C_4H_4O_4$, and it has a molecular weight of 434.4. The chemical designation is 5-methoxy-4′-(trifluoromethyl)valerophenone-(E)-*O*-(2-aminoethyl)oxime maleate (1:1).

Pharmacologic Actions

Absorption. The bioavailability of fluvoxamine maleate is 53% by oral administration, and its absorption is essentially unaffected by food. At a steady state, maximal plasma concentrations are achieved 3 to 8 hours after dosing.

Distribution. In vitro assays demonstrate protein binding, predominantly albumin, of approximately 80% for fluvoxamine at concentrations of 20 to 2,000 ng/mL. The volume of distribution for fluvoxamine is approximately 25 L/kg. Breast milk concentration was reported to be about a third of the mothers’ plasma, thereby leading to low exposure to the babies.

Metabolism and Elimination. The primary route of metabolism for fluvoxamine is oxidative demethylation and deamination in the liver. The main human metabolite, as determined by radiotracer studies, is fluvoxamine acid, which, along with its *N*-acetylated analog, accounts for approximately 60% of urinary products. In this same assay, fluvoxethanol comprised approximately 10%. Fluvoxamine acid is 10- to 100-fold less potent in an in vitro assay of 5-HT reuptake inhibition than the parent compound.

Fluvoxamine demonstrates nonlinear pharmacokinetics. In 30 normal volunteers receiving fluvoxamine at 100, 200, or 300 mg per day over 10 days, the maximum plasma concentration was 88, 283, and 546 ng/mL, respectively. This represents increases of 160% and 207% for the 200-

and 300-mg doses, respectively, over what would have been predicted from the lowest dose. The mean plasma half-life at a steady state is 16 hours in young, healthy volunteers receiving 100 mg per day and 14 hours in those receiving 50 mg per day. After repeated dosing, the half-life increases to 17 to 22 hours. Steady-state is typically achieved in approximately 7 days.

Hepatic dysfunction is associated with an approximately 30% decrease in fluvoxamine clearance compared to healthy controls. In contrast, renal impairment (creatinine clearance of 5 to 45 mL/min) was not associated with decreased clearance.

Older adult patients show a prolongation in the half-life of fluvoxamine. Compared to younger patients, in the older adults, the half-life at 50 mg per day goes from 14 to 17 hours, and it goes from 16 to 26 hours for dosing of 100 mg per day.

Similarly to adults, children (6 to 11 years of age) and adolescents (12 to 17 years of age) display nonlinear, multiple-dose pharmacokinetics with fluvoxamine. Steady-state plasma concentrations of fluvoxamine were two- to threefold higher in children than in adolescents after administration of 100 mg twice a day. The AUC, C_{max}, and minimum drug concentration (C_{min}) were similarly elevated in children compared to adolescents. Female children, in a small sample ($N = 3$), displayed higher plasma levels than male children. Adolescents are similar to adults with regards to the pharmacokinetic profile of fluvoxamine and thus may require higher doses than those necessary for the treatment of children.

CITALOPRAM AND ESCITALOPRAM

Citalopram was a late addition to the U.S. market when it received approval for the treatment of MDD in 1998. Racemic citalopram is a 50–50% mixture of the S- and R- isomers. Escitalopram is the *S*-enantiomer of racemic citalopram. The S-enantiomer is the active component that blocks the 5-HT recapture. The R-citalopram binds to the allosteric site of the transporter and counteracts the therapeutic effects of the S-citalopram. Hence, doses of racemic citalopram more than twice those of S-citalopram are needed to produce similar therapeutic benefits.

Chemistry

Citalopram is the hydrobromide salt of a racemic mixture of a bicyclic phthalane derivative designated chemically as (±)–1-(3-dimethylaminopropyl)–1–(4-fluorophenyl)–1,3-dihydroisobenzofuran-5-carbonitrile, HBr. The molecular formula is $C_{20}H_{22}BrFN_2O$, and it has a molecular weight of 405.35.

Escitalopram is the oxalate salt of the *S*-enantiomer of racemic citalopram.

Pharmacologic Actions

Absorption. Citalopram is well absorbed orally, and absorption is unaffected by food. The bioavailability of oral citalopram (40 mg, single dose) is approximately 80% of that observed after intravenous (IV) administration. Maximum systemic concentration is achieved approximately four hours after ingestion. Peak serum levels of escitalopram are seen approximately 5 hours after ingestion.

Distribution. Citalopram has less protein binding than some of the other SSRIs, with citalopram and its two primary metabolites, demethylcitalopram (DCT) and didemethylcitalopram (DDCT), displaying in vitro protein binding of 80%. The volume of distribution of citalopram is 12 L/kg, and the clearance rate is 19.8 L/hr, of which approximately 20% is renal clearance. The half-life of citalopram is approximately 35 hours, and most patients should achieve steady-state concentrations in approximately 1 week.

Escitalopram has protein binding of approximately 56%, measured in vitro. The clearance rate of escitalopram is 36 L/hr, with approximately 7% due to renal clearance. The volume of distribution is not well characterized. The mean terminal half-life is approximately 27 to 32 hours, so steady-state concentrations should be achieved after approximately 7 days of dosing.

Metabolism and Elimination. The principal pathway of metabolism for citalopram is by *N*-demethylation to DCT, and the primary CYP isozymes involved are CYP 3A4 and CYP 2C19. Citalopram is the compound found in the highest concentrations in humans, with DCT and DDCT present at concentrations of approximately 50% and 10%, respectively, of that of citalopram. The metabolites DCT and DDCT possess only approximately one-eighth the potency of inhibition of the 5-HT transporter that citalopram does and likely contribute little, if at all, to the therapeutic activity. Two other compounds are products of citalopram metabolism in addition to DCT and DDCT; these are citalopram-*N*-oxide and a deaminated propionic acid derivative. Citalopram displays linear and dose-proportional pharmacokinetics for single and multiple doses in the dose range of 10 to 60 mg per day.

Citalopram pharmacokinetics have been studied in different population subgroups. Normal controls 60 years of age and older in a single-dose study exhibited increases in AUC and half-life by 30% and 50%, respectively. The same population had increases of 23% and 30%, respectively, thus, 20 mg is the recommended daily dose in the geriatric population.

Patients with reduced hepatic function have demonstrated a 37% decrease in clearance of orally administered citalopram and a doubling of half-life. The recommended dose for patients with hepatic impairment is 20 mg per day.

Mild to moderate renal impairment is associated with a decreased clearance rate of 17% compared to healthy controls. The effect of severe renal impairment on citalopram clearance is not well characterized.

Escitalopram is metabolized to *S*-demethylcitalopram (*S*-DCT) and *S*-didemethylcitalopram (*S*-DDCT). Similar to the metabolism of citalopram, escitalopram is the predominant compound found in human plasma, with *S*-DCT being present at approximately 30% of the concentration of the parent compound. The level of *S*-DDCT is typically below the limits of detection. Escitalopram inhibition of the 5-HT transporter in vitro is at least 7 and 27 times more potent than inhibition displayed by *S*-DCT and *S*-DDCT, respectively. The primary CYP isozymes thought to be involved in escitalopram metabolism are CYP 2C19 and, to a lesser extent, CYP 3A4. Escitalopram displays linear and dose-proportional pharmacokinetics for single and multiple doses in the dose range of 10 to 30 mg per day.

Examination of escitalopram clearance in subjects 65 years of age and older in single-dose and multiple-dose studies showed increases of approximately 50% in AUC and half-life. Thus, 10 mg is the recommended daily dose in the geriatric population. The effect of reduced renal or hepatic function on escitalopram clearance is poorly characterized, but dose adjustments are extrapolated from data available for the racemic compound citalopram.

DRUG INTERACTIONS

SSRIs can produce pharmacodynamic or pharmacokinetic interactions with other medications. Categories of potential pharmacokinetic interactions between the SSRIs and other agents are enzyme inhibition through the CYP isozyme system and protein binding. Fortunately, the majority of drug–drug interactions are not critical, but they may insidiously compromise the patient’s quality of life or overall tolerability of a therapeutic regimen. It is not simply an issue of whether drug–drug interactions are seen in a particular area of practice; it is often a question of whether they are recognized, given that they do occur on a regular basis. Ultimately, it is the subsequent pharmacodynamic consequence that dictates the importance of the pharmacokinetic interaction.

Interactions involving SSRIs are particularly relevant clinically because MDD often requires more than one step of treatment to elicit remission of symptoms. Frequently, a second medication is added to augment the first. A combination of an initial SSRI with several other agents, psychotropic and otherwise, is standard practice. The STAR*D study looked sequentially at the “next-step” benefits of switching medications or adding on to citalopram. The results found that among patients who do not have a remission during up to 14 weeks of an initial SSRI or who could not tolerate such therapy, switching to another SSRI, an SNRI, bupropion, or a combination of citalopram with another agent resulted in similar symptom remission within each step. Of note, clinical experience suggests that switching to another class after failing an SSRI trial is often more useful than switching to another SSRI. This is somewhat supported by a large meta-analysis that found modest benefits of switching classes, with a number needed to treat (NNT) of about 22 to achieve one additional remission compared to switching to another SSRI. Factors to consider when switching or combining treatments include efficacy, tolerability, the burden of side effects, interactions among drugs, dosing convenience, adherence, and cost. Nevertheless, paramount to any subsequent step following monotherapy is using an efficacious dose to ensure adequate target engagement. The question of whether to use combinations from treatment initiation in an attempt to achieve greater remission rates within a first trial still needs more documentation. Indeed, there have been both positive studies and a large negative trial, but the latter may have been hampered by suboptimal dosing in a single-blind design. A recent meta-analysis actually showed that combining a monoamine reuptake inhibitor with a presynaptic α_2-antagonist (such as mirtazapine) from treatment initiation was associated with better efficacy outcomes compared to monotherapy (Standardized mean difference = 0.64; 95% CI = 0.12–1.15) and did not result in more dropouts due to side effects.

Pharmacodynamic Interactions

The most dreaded outcome of pharmacokinetic interactions involving SSRIs is the 5-HT syndrome or 5-HT toxicity. Serotonin syndrome is a life-threatening syndrome that can lead to autonomic instability, abdominal pain, diarrhea, confusion or delirium, increased motor activity, myoclonus, hyperpyrexia, cardiovascular shock, or death.

Serotonin-related problems occur on a continuum. For instance, mild elevation of the synaptic 5-HT at a therapeutic dose of an SSRI, is associated with common serotoninergic side effects such as GI discomfort or nausea. A real 5-HT syndrome is rare and occurs when dramatic levels of 5-HT are in the synapse. This syndrome is mostly mediated by the postsynaptic 5-HT_{2A} and 5-HT_{1A} receptors. 5-HT levels in the synapse increase significantly via three major mechanisms most often involved in 5-HT toxicity: 5-HT reuptake blockade, MAO inhibition, and increased 5-HT release from presynaptic neurons. A 5-HT syndrome is expected when a combination of these mechanisms occurs. For instance, 5-HT toxicity is expected when SSRIs are combined with MAOIs. Hence, this combination should never be prescribed. In the vast majority of cases, it is not expected that SSRIs alone in overdose would trigger a real 5-HT syndrome, as the MAO would prevent dramatic 5-HT increases. A review found that SSRI overdoses up to 30 times the typical daily dose resulted in minor or no symptoms. Combining two SSRIs is not an evidence-based strategy for treatment-resistant depression. However, such an approach would not lead to serotonin toxicity. Tryptophan (5-HT precursor) in combination with SSRIs also has the potential to produce serotonergic side effects. Again, real 5-HT toxicity is very rare when the MAO is not inhibited.

SSRIs must not be administered within 14 days of discontinuing treatment with an irreversible MAOI. When switching from an SSRI to an irreversible MAOI, clinicians must wait for five to seven half-lives after the SSRI has been stopped before introducing the MAOI.

Treatment of the 5-HT syndrome consists of removing the offending agents and promptly instituting comprehensive support care. Some benefits of pharmacologic interventions such as cyproheptadine and chlorpromazine have been suggested, but further research on this topic is needed.

A frequent drug combination in clinical practice is the use of a triptan to treat migraine along with an SSRI. Concurrent use of a triptan and an SSRI is normally uneventful, but significant reactions may occur. In response to multiple reports of serious reactions, in 2006, the FDA issued a Public Health Advisory warning of the possibility of 5-HT syndrome when triptans and SSRIs are taken together. According to the FDA advisory, physicians prescribing a triptan and SSRI should weigh the potential risk of 5-HT syndrome against the expected benefit of using a triptan with an SSRI. They should follow patients closely if a triptan and an SSRI are used together, particularly during treatment initiation, with dose increases, or with the addition of another serotonergic medication. It is important to remember that migraines on their own can produce severe physical and neurologic symptoms. Furthermore, most triptans do not cross the blood–brain barrier, and even if they did gain access to the CNS during a migraine attack (presumably due to increased permeability), they would decrease 5-HT release because of their agonistic effect at inhibitory 5-HT$_{1D}$ autoreceptors on 5-HT terminals. Therefore, patients who take a triptan and an SSRI together should be advised to seek medical attention only if they experience symptoms that they do not usually experience.

Because SSRIs may reduce dopamine turnover, their use in combination with dopamine-receptor antagonists can raise prolactin levels, even causing breast enlargement and galactorrhea, and produce extrapyramidal side effects.

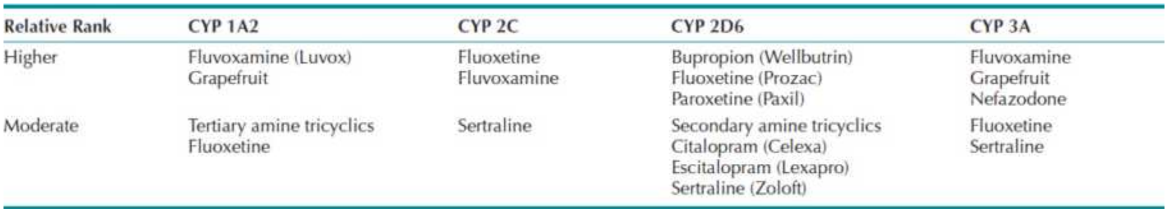
Pharmacokinetic Interactions

The ability of medications for depression to exert a pharmacokinetic effect by enzyme inhibition is dependent on the extent of inhibition that is produced. Classification schemes of medications for depression denote individual drugs as high, medium, or low or minimal potential for isozyme inhibition, as shown in Table 33.5a.1–4.

Predicting the potential clinical relevance of isozyme inhibition requires knowledge of not only the potential inhibitory properties of drugs but also the clinically relevant substrates for the isozymes. Examples of commonly prescribed medications and the isozymes that metabolize them are listed in Table 33.5a.1–4. The combination of a substrate and a potential inhibitor does not contraindicate their simultaneous use.

Fluoxetine is a relatively potent inhibitor of the CYP 2D6 and CYP 2C19 isozymes but with no appreciable activity in the CYP 3A4 isozyme system, although norfluoxetine does demonstrate some inhibition of the CYP 3A4 isozyme in vitro.

Table 33.5a.1–4.
Cytochrome P450 (CYP) Inhibitory Potential of Commonly Prescribed Medications for Depression



Relative Rank	CYP 1A2	CYP 2C	CYP 2D6	CYP 3A
Higher	Fluvoxamine (Luvox) Grapefruit	Fluoxetine Fluvoxamine	Bupropion (Wellbutrin) Fluoxetine (Prozac) Paroxetine (Paxil)	Fluvoxamine Grapefruit Nefazodone
Moderate	Tertiary amine tricyclics Fluoxetine	Sertraline	Secondary amine tricyclics Citalopram (Celexa) Escitalopram (Lexapro) Sertraline (Zoloft)	Fluoxetine Sertraline

Fluoxetine, paroxetine, sertraline, and citalopram inhibit the CYP 2D6 isozyme, albeit the latter do so only in their upper therapeutic ranges. Coadministration of these drugs with other medications that are substrates of the CYP 2D6 isozyme should be approached cautiously with an awareness of potential increases in serum concentrations of drugs that primarily use the CYP 2D6 pathway for metabolism. Examples of CYP 2D6 substrates include the type 1C antiarrhythmics—encainide (Enkaid), flecainide (Tambocor), propafenone (Rythmol), and mexiletine (Mexitil)—and β-blockers—labetalol (Normodyne), metoprolol (Lopressor), propranolol (Inderal), and timolol (Blocadren). Atenolol (Tenormin), a cardioselective β-blocker, is renally excreted and exhibits no pharmacokinetic interactions. Tamoxifen (Soltamox) is a prodrug that requires metabolism through the CYP 2D6 to be activated; hence coadministration with a drug that inhibits CYP 2D6 may reduces the effectiveness of Tamoxifen. Codeine is inactive as an analgesic and requires metabolism to morphine via the CYP 2D6 isozyme to be effective in reducing pain. Inhibition of the CYP 2D6 pathway can result in loss of analgesic properties.

There exists the potential for drug–drug interactions for an extended period after discontinuation, particularly with fluoxetine. Fluoxetine has a significantly longer half-life than the other SSRIs. A study was carried out to determine the onset and offset of CYP 2D6 inhibition. The 50% onset of

2D6 inhibition was 7 ± 2 days for fluoxetine 20 mg per day, 3 ± 2 days for paroxetine 20 mg per day, and 3 ± 3 days for sertraline 50 mg per day for 3 days, then 100 mg per day. The 50% offset of 2D6 inhibition after discontinuation was 63 ± 6 days (extrapolated time to baseline) for fluoxetine, 20 ± 6 days for paroxetine, and 25 ± 11 days for sertraline.

Fluoxetine may produce hypoglycemia in patients with diabetes who are treated with insulin or oral hypoglycemics. Dose reduction of the hypoglycemic or insulin may be required.

Paroxetine is a relatively potent inhibitor of the CYP 2D6 isozyme system but appears to be without clinically significant effects in the CYP 1A2, CYP 2C, or CYP 3A4 isozyme systems.

Citalopram and escitalopram are modest inhibitors of the CYP 2D6 isozyme based on in vivo testing. Coadministration of citalopram (40 mg per day) for 22 days resulted in a doubling of the plasma levels of metoprolol. In addition, coadministration of citalopram (40 mg per day) for 10 days along with a single dose of imipramine (Tofranil) (100 mg) did not alter the plasma concentrations of imipramine but did increase plasma levels of the primary metabolite, desipramine (Norpramin), by 50%. Similarly, escitalopram (20 mg per day) for 21 days resulted in increases in $C_{\max}$ (50%) and AUC (82%) of metoprolol given as a single dose of 100 mg. Likewise, escitalopram (20 mg per day) for 21 days resulted in increases in $C_{\max}$ (40%) and AUC (100%) of desipramine given as a single dose of 50 mg. In vitro enzyme assays suggest that citalopram is not an inhibitor for the CYP 3A4, CYP 2C9, or CYP 2E1 isozymes but is a weak inhibitor for CYP 1A2 and CYP 2C19, in addition to the data presented previously for the CYP 2D6 isozyme. Escitalopram does not appear to have in vitro inhibition of the CYP 3A4, CYP 1A2, CYP 2C9, CYP 2C19, and CYP 2E1 isozymes, although in vivo data are needed to confirm this.

Fluvoxamine is an inhibitor of the CYP 1A2, CYP 2C9, and CYP 3A4 isozyme systems. Theophylline, aminophylline (Phyllocontin), warfarin, propranolol, clozapine (Clozaril), and caffeine metabolism are inhibited through the CYP 1A2 isozyme by fluvoxamine. Warfarin metabolism is also inhibited through the CYP 2C9 isozyme system. GABA_A PAMs, including alprazolam (Xanax), clonazepam (Klonopin), triazolam (Halcion), and midazolam (Versed), are metabolized by hepatic oxidation via the CYP 3A4 isozyme. Approximately twofold elevations in serum concentrations of alprazolam have been observed after coadministration of fluvoxamine. Increased serum levels of carbamazepine (Tegretol), clozapine, methadone (Dolophine), propranolol, amitriptyline, clomipramine, and imipramine have been reported after the addition of fluvoxamine treatment. Thioridazine should not be combined with fluvoxamine owing to the potential drug–drug interaction and the potential for cardiac QTc interval prolongation secondary to the inhibition of thioridazine metabolism.

In premarketing trials, smokers demonstrated a 25% increase in fluvoxamine metabolism compared to nonsmokers, presumably through induction of the CYP 1A2 isozyme.

Fluoxetine, sertraline, and paroxetine are tightly bound to serum proteins and may displace other tightly protein-bound drugs, such as warfarin or digitoxin (Digitaline). Good clinical practice dictates checking serum levels or activity when medication with high protein binding is added to a tightly protein-bound drug with a low therapeutic index. Most assays do not differentiate between bound and free drugs, so functional assays, such as prothrombin time with warfarin, are a better indicator. Citalopram has a lower degree of protein binding (80%) than many other SSRIs, and escitalopram has an even lower degree of protein binding at approximately 56%. Thus, protein-binding interactions would not appear to be a problem with citalopram or escitalopram for most patients, although the clinical trials for these two compounds, as with other SSRIs, are typically done in a relatively healthy population, and the pharmacokinetics of SSRIs, when combined with multiple other agents is an under-researched area. The combination of citalopram with a highly protein-bound drug, such as warfarin resulted in a prolongation of prothrombin time by only 5%. Fluvoxamine has moderate protein binding and may be less likely to produce displacement of tightly protein-bound drugs than some of the others in this class.

DOSING AND ADMINISTRATION

The therapeutic dose ranges for the SSRIs have been well established, however, therapeutic effects are not dose related. There are only limited data that suggest that the presence of therapeutic levels of SSRIs correlates with plasma levels and subsequent clinical response. Nevertheless, patients may vary considerably in the amount of medication they need to derive clinical benefit. Consequently, dose optimization must be considered when the SSRI is well tolerated without inducing an adequate clinical response. Determination of the pharmacogenomic profile of patients with regards to transporters and receptors does not necessarily add to the effectiveness of SSRIs regimens, given their tolerability.

Fluoxetine

Fluoxetine is available in 10- or 20-mg pulvules, as 10-mg tablets, as 90-mg enteric-coated capsules for once-weekly administration, and as an oral concentrate of 20 mg/5 mL. The suggested starting dose of fluoxetine in patients with MDD is 20 mg per day. Effective doses for the treatment of MDD have been reported, ranging from 5 to 80 mg per day in dose-finding trials. Owing to the long half-life, achieving a new steady state after dose adjustment takes longer than that seen with most other medications. Pausing treatment for a few days to eliminate emerging side effects and then restoring the regimen at a lower dose, particularly if it has been several weeks since initiation of treatment or the last dose adjustment, is a reasonable approach to managing side effects.

Trials of fluoxetine in bulimia nervosa showed efficacy greater than placebo at 60 mg per day. Treatment of OCD is also usually at higher doses than those used in MDD, with commonly dosing up to 80 mg per day. However, SSRIs take longer to reduce OCD symptoms than symptoms of depression, so the drug should be given time on typical doses. The long half-life of fluoxetine and norfluoxetine does make interpretations of what may be the minimal therapeutic dose somewhat complicated. Fortunately, because fluoxetine is generally well tolerated, this becomes less of an issue than it might be with older medications.

Treatment of panic disorder is often initiated at 5 or 10 mg per day with gradual upward dose titration. Treatment of SAD or PMDD is often started at 10 to 20 mg per day. The dose is adjusted upward as needed.

A starting dose of 10 mg per day are often used in treating children, adolescents, or older adult patients. Dose increase is based on clinical response and tolerance of side effects.

Paroxetine

Paroxetine HCl is available as 10-, 20-, 30-, and 40-mg-size tablets. The 20-mg-size tablets are scored. Paroxetine CR is available in 12.5-, 25-, and 37.5-mg tablets. Paroxetine is also available in an oral suspension at a concentration of 10 mg/5 mL. Paroxetine mesylate is available as 10-, 20-, 30-, and 40-mg tablets.

The recommended starting dose for paroxetine is 20 mg per day for all approved indications, except in panic disorder, for which an initial dose of 10 mg per day is suggested. Starting paroxetine at 10 mg per day is also suggested for the older adults, medically ill, or those with significant renal or hepatic impairment. Paroxetine CR starting dose recommendations are similar, with 25 mg per day in MDD and 12.5 mg per day in patients with panic disorder, the older adults, the medically ill, or those with significant renal or hepatic impairment. Many clinicians find starting the more anxious or somatically preoccupied patient at a dose of 10 mg of paroxetine or 12.5 mg of paroxetine CR for a few days to be of benefit.

Taking paroxetine with meals, at least initially, reduces the incidence of nausea, and if present, the majority of patients describe nausea, to be a transient side effect. Patients with MDD who do not respond to 20 mg per day of paroxetine or 25 mg per day of paroxetine CR can have their doses increased by 10-mg (paroxetine) or 12.5-mg (paroxetine CR) intervals to as much as 50 mg per day (paroxetine) or 62.5 mg per day (paroxetine CR). In studies that established paroxetine to have efficacy in maintenance treatment, patients received a mean dose of approximately 30 mg per day.

The target dose of paroxetine in the treatment of OCD is 40 mg per day, with most responders receiving 40 to 60 mg per day. Presumably, doses of paroxetine CR need to be approximately 25% higher. The patient’s response to treatment of OCD is often slower than what is seen in MDD.

Patients with panic disorder usually tolerate the side effects of paroxetine if started at a lower dose than those used in treating MDD. Most panic disorder patients do better if started at an initial dose of 10 mg per day, with gradual titration to a target dose of 40 mg per day. Dose increases can be made at the rate of 10 mg per week. The maximal dose studied in premarketing clinical trials of paroxetine was 60 mg per day. The dosing strategy with paroxetine CR is similar, starting at 12.5 mg per week, and the maximal dose studied in clinical trials was 75 mg per day.

Dosing for other disorders is usually done with an initial dose of 10 to 20 mg per day (12.5 to 25.0 mg per day for paroxetine CR) followed by a gradual upward titration.

Among the SSRIs, paroxetine is associated with the most severe withdrawal syndrome and carries the strongest FDA warning about use in pregnancy.

Sertraline

Sertraline is available in scored tablets or capsules of 25-, 50-, and 100-mg strengths. The oral concentrate is formulated at a concentration of 20 mg/mL with 12% alcohol content and must be diluted before use. Owing to the alcohol content in the oral concentrate, it is contraindicated in conjunction with disulfiram (Antabuse). Initial dosing for MDD and OCD is typically at 50 mg per day, with escalation to 100 mg per day no earlier than after 14 days of treatment. Initial treatment of panic disorder, SAD, and PTSD is more typically 25 mg per day. Children in OCD studies were started at 25 mg per day, whereas adolescents in OCD studies were started at 50 mg per day. Treatment of PMDD is usually started at 50 mg per day given continuously daily or during the 2 weeks of the luteal phase. Individual patients may demonstrate improved tolerability starting at lower doses. Not uncommonly, patients require an upward titration of the dose.

The dose range in most patients with anxiety or affective disorders is typically 100 to 200 mg a day, although some patients respond to 50 mg per day. Patients with OCD often require higher doses for full therapeutic effect.

Citalopram and Escitalopram

Citalopram is available in 10-, 20-, and 40-mg-size tablets. The 20- and 40-mg-size tablets are scored. Citalopram is also available in an oral solution at a concentration of 10 mg/5 mL. Escitalopram is available in 10- and 20-mg-size tablets, both of which are scored. Disintegrating tablets are also available and may be useful when patients have difficulties swallowing. An oral solution of 5 mg/5 mL is available as well.

The manufacturer recommends a starting dose for citalopram of 20 mg per day, with the expectation of generally increasing the dose to 40 mg per day, which, in clinical practice, is typically done after at least 1 week on the initial dosing. Highly anxious patients or those with increased sensitivities to side effects of medications may benefit from starting with the 10-mg tablet. The recommended starting dose of escitalopram is 10 mg per day. If the dose is to be increased to 20 mg, this should generally occur no sooner than after one week on the initial dose. Because the 10-mg tablet is scored, 5 mg as a starting dose, if required, is available.

Many patients are observed to do well if citalopram or escitalopram is taken after meals for the first few days. After that period, they can take the medication with or without food.

Fluvoxamine

Fluvoxamine is available in 25-, 50-, and 100-mg scored tablets and 100- and 150-mg controlled-release capsules. Adults with OCD are often started at a dose of 50 mg administered at bedtime. The dose may be increased by 50 mg every 4 to 7 days. The effective dosing range in premarketing trials with OCD was 100 to 300 mg per day. The manufacturer suggests dividing the daily dose if it exceeds 100 mg per day, although many patients tolerate doses larger than 100 mg as a single dose. Initial upward titration is often easier with a split-dose regimen.

Treatment of OCD in adolescents and children should start at 25 mg per day with 25-mg-per-day increases every 4 to 7 days. The effective dosing range in premarketing studies was 50 to 200 mg per day. Adolescents often require a dose close to that used in adults, whereas children, perhaps owing to higher plasma fluvoxamine levels, may respond to the lower portion of the dosing range. Using the controlled-release formulation obviates this need for divided doses.

Dosing for disorders other than those for which fluvoxamine is approved in the United States is usually initiated at 25 to 50 mg per day. Patients with MDD typically show responses over the range of 100 to 300 mg per day, although the response is often seen in the range of 100 to 200 mg per day. Due to possible early activation of anxiety symptoms, treatment of panic disorder is best started at a dose of 25 mg per day for most patients, owing to increased sensitivity of side effects in this population. The typical effective dose is usually 100 to 200 mg per day.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND SUICIDALITY

In the early 1990s, a debate arose as to whether fluoxetine treatment was associated with an increase in suicidal ideation and suicide attempts in some patients. A comparison of the emergence of suicidal ideation in patients receiving fluoxetine, tricyclic derivatives, or placebo suggested that fluoxetine-treated patients had less emergent suicidal ideation than those treated with the older drugs. Both groups on medication showed less emergent suicidal ideation than the group treated with a placebo. At times, fluoxetine produces symptoms, often described as restlessness, that are similar to akathisia in some patients. In the spring of 2004, the FDA asked manufacturers of the SSRIs, along with those of the other newer-generation medications for depression, to include a black box warning in their labeling recommending close observation of both adult and pediatric patients for signs or symptoms of worsening depression, including suicidal ideation, early on in therapy with these medications or on titration of dosing. This followed earlier recommendations concerning the potential of SSRIs to be associated with a higher rate of agitation, suicidal thoughts, or both in clinical trials when these rates were compared to treatment with placebo in studies of children and adolescents with MDD. Many clinicians believe that the recommendations to observe patients for worsening symptoms during the initiation of therapy represent a recommendation for sound clinical care. The issue regarding the treatment of children and adolescents remains somewhat unclear. One distinct possibility is that the 2% rate of agitation that was generally observed in studies that have been made public may represent pediatric patients who would ultimately go on to develop bipolar disorder.

A problem with the FDA advisory is that it was based on short-term trials and did not include suicidal patients. A study—the Adolescent Depression and Psychotherapy Trial (ADAPT)—actively included suicidal patients and found that the propensity for depressive relapse and self-reported suicidality in adolescents was reduced with SSRI administration. Furthermore, this study found that the reduction in clinical symptoms with SSRIs appeared to be a long-term effect. The authors of that study concluded that SSRIs are not detrimental to adolescent brain development and that therapeutic benefits outweigh the potential developmental risks.

A meta-analysis assessed the efficacy and suicidality risk of SSRIs, nefazodone, venlafaxine, and mirtazapine in a pediatric population. The authors found that these medications were effective for MDD, OCD, and anxiety disorders, as showed by an NNT of 10 (95% CI = 7–15), 6 (95% CI = 4–8), and 3 (95% CI = 2–5), respectively. Regarding the risk of reported suicidal ideation or attempt, the overall NNH was 143 (95% CI = 77–1,000). No completed suicide was identified.

Since the first press reports appeared, and especially since the new warning about suicidality in children and adolescents, there has been a drop in both SSRI prescriptions for that group and a decrease in the diagnosis of depression. Unfortunately, studies in the United States, Canada, and The Netherlands have shown a significant increase starting from 2003 to 2004 in suicide attempts and completed suicides. Analysis involving older adults shows that medications for depression reduce the risk of suicidal thoughts for 25- to 64-year-olds and may reduce the risk of both suicidal thoughts and behavior for people older than 65 years. The obvious conclusion is that although SSRIs might increase suicidality (suicidal ideation and behavior, but not death) in a small percentage of patients, the use of these drugs is associated with significant decreases in suicide attempts at the population level. Health advisories and warnings issued by the FDA may, in fact, have produced an unintended withholding of appropriate care and caused unexpected harm.

PREGNANCY

SSRIs are the most frequently used class of medications to treat depression among women of childbearing age. It is therefore not surprising that they are the most commonly used psychotropic drugs during pregnancy. Except for paroxetine, the SSRIs are considered relatively safe to take during pregnancy when deemed necessary for the treatment of the mother.

Women who are pregnant or planning a pregnancy and are taking SSRIs should consult with their physician about whether to continue taking their medication. As with all medications that treat serious disorders, such as those treated by SSRIs, the potential benefits and risks of SSRI treatment need to be weighed against the potential risks of not treating, given that pregnancy does not protect against the serious disorders these drugs treat.

A prospective study giving a choice to continue or stop medication for depression during pregnancy showed a higher rate of relapse following medication discontinuation, and women resuming their antidepressant regimen did not do as well as those who did not interrupt treatment.

Although studies have shown conflicting results, depression during pregnancy has been associated with a greater risk of obstetrical complications, premature delivery, pre-eclampsia, and a lower likelihood of breastfeeding initiation. Newborns of these women may be at an increased risk of low birth weight, and irritability, and may exhibit lower activity and interactive behaviors. Peripartum depression may also impact the maternal-fetal attachment process. A recent meta-analysis found a small-to-moderate association between antenatal anxiety and/or depression in mothers and performing worse offspring in social-emotional, cognitive, language, and adaptive behavior development. Interestingly, these findings were not limited to infancy but extended to childhood and adolescence.

Studies that assessed the risks associated with taking SSRIs during pregnancy have yielded conflicting results. This reflects the difficulty of studying this topic, as conducting randomized controlled trials on this matter poses ethical problems. Hence, the evidence is mostly derived from observational studies, and residual confounding is very likely. Among the possible risks identified, meta-analyses found an increased risk of preterm birth associated with the use of medications for depression (not limited to SSRIs) during pregnancy. The possibility of an association between SSRI use during pregnancy and autism has also been suggested but remains controversial.

A Centers for Disease Control and Prevention epidemiologic study on the causes of major birth defects among 9,622 case infants and 4,092 controls looked at the use of fluoxetine, sertraline, paroxetine, and citalopram during early pregnancy. It found that these drugs as a group did not significantly increase the risk for most birth defects, including congenital heart defects. The study did find an association between SSRI use and a slightly increased risk for three specific birth defects: anencephaly (adjusted odds ratio [OR] = 2.4; 95% CI 1.1–5.1), craniosynostosis (adjusted OR 2.5; 95% CI 1.5–4.0), and omphalocele (adjusted OR = 2.8; 95% CI, 1.3–5.7). Nevertheless, the authors emphasized that the absolute risks for these birth defects were small.

Concerns have been raised about the use of paroxetine during pregnancy and cardiovascular malformations in the newborn. In a study using Swedish national registry data, the risk of a cardiac defect was about 2% in infants exposed to paroxetine during pregnancy versus 1% among all registry infants. Another study using a U.S. insurance claims database compared the risk of congenital cardiac malformations in infants of women who received paroxetine versus other medications for depression in the first trimester. The results showed a trend toward increased risk with paroxetine (OR = 1.5; 95% CI 0.8–2.9). Most of the cardiac defects observed in these studies were atrial or ventricular septal defects, conditions in which the wall between the right and left sides of the heart is not completely developed. In general, septal defects are among the most common types of congenital malformations. They range from those that are symptomatic and may require surgery to those that are asymptomatic and may resolve on their own. It is generally recommended to avoid paroxetine during the first trimester of pregnancy or in women who plan to become pregnant in the near future.

Neonates exposed to SSRIs in the third trimester may develop poor neonatal adaptation syndrome (PNAS). This refers to short-term neurobehavioral effects in newborns. Symptoms such as poor muscle tone, trouble sleeping, shaking, weak or excessive crying, irritability, hypoglycemia, or seizures can be seen. It has been reported to affect up to 30% of exposed neonates and may represent discontinuation syndrome. The symptoms appear shortly after birth and may last up to two weeks. A meta-analysis found an increased risk of PNAS among neonates exposed to a medication for depression in utero (OR = 5.07; 95% CI, 3.25–7.90; P <.0001).

Another possible pregnancy-related side effect in offspring of SSRI-treated mothers is persistent pulmonary hypertension of the newborn (PPHN), a condition associated with substantial infant mortality and morbidity. A large cohort study examined the risk of PPHN associated with exposure to an SSRI in the 90 days before delivery versus no exposure. A total of 102,179 women had been exposed to SSRIs late in pregnancy. The authors found that 322 SSRI-exposed newborns (31.5; 95% CI, 28.3–35.2 per 10,000 births) were diagnosed with PPHN, compared to 7,630 newborns not exposed to medication for depression (20.8; 95% CI, 20.4–21.3 per 10,000 births). The unadjusted OR was 1.51 (95% CI, 1.35–1.69), and the OR became statistically nonsignificant when restricting to women diagnosed with depression and adjusting for confounders (OR = 1.10; 95% CI, 0.94–1.29). This data suggests that the risk of PPHN in newborns exposed to SSRIs late in pregnancy is low and may even be lower than previously thought.

Clinicians should not hesitate to offer a pharmacologic treatment for depression when meeting with pregnant women who struggle with moderate to severe depression, as the benefits most likely outweigh the potential risks in most cases.

Excretion of SSRIs in Breast Milk

SSRIs appear in breast milk to varying extents, and data from the literature differ in their findings regarding the relative dose being transmitted to the infant. Various reports about drug levels in milk are unreliable because of variations in milk collection procedures and because such medications tend to be lipophilic. Breast milk concentrations for some drugs may vary more than twofold between the watery fore milk and the fattier hind milk, whereas others may show little variation. Accordingly, clinical monitoring of maternal plasma or breast milk is not routinely indicated.

In some studies, concentrations are lowest for fluvoxamine and sertraline. Low levels of both sertraline and its metabolite are found in the sera of infants. The concentration of sertraline and desmethylsertraline in breast milk is highly variable and, on average, is of the same order of magnitude as their concentration in the blood plasma of the mother. As a result, more than half of breastfed babies receive less than 2 mg/day of sertraline and desmethylsertraline combined, and in most cases, these substances are undetectable in their blood. No changes occur in 5-HT uptake by the platelets of breastfed infants as measured by blood 5-HT levels before and after beginning sertraline treatment. Sertraline is more likely to be detected in an infant if the maternal daily dose is 100 mg or higher. Data on paroxetine are mixed, with some studies showing somewhat higher breast milk concentrations and others reporting paroxetine to have the lowest transfer into breast milk. According to a pooled analysis of available data, breastfed infants exposed to paroxetine or sertraline are least likely to demonstrate detectable or elevated plasma drug levels, whereas infants exposed to fluoxetine appear to be at higher risk of developing elevated levels. Most data show that the relative infant dose of citalopram is intermediate between those of paroxetine and fluoxetine. High doses of citalopram should also be used with caution. Escitalopram and its demethyl metabolite are present in breast milk, and unwanted effects in breastfed infant should be assessed.

If treatment with an SSRI is started during the postpartum period, fluoxetine should not be the first choice. Fluoxetine transfers to a greater extent, and its active metabolite, norfluoxetine, has a long half-life of 1 to 2 weeks and may accumulate in a breastfed infant.

Adverse effects are rarely reported in breastfed infants. Some short-term adverse effects that have been reported in association with fluoxetine include colic, seizures, irritability, withdrawal symptoms, and cyanosis. Caretakers should report irritability, poor feeding, poor sleep, or any other worrisome signs or symptoms in the infant. Premature breastfed infants, or those with impaired hepatic or other metabolite disturbances, need to be monitored more closely if the mother is taking an SSRI and breast-feeding.

When the use of an SSRI is clearly indicated in a breastfeeding woman, the data generally indicate that the positive effects of breastfeeding outweigh the risks for pharmacologic effects on the infant.

USE IN CHILDREN

The use of SSRIs in children and adolescents has been controversial. Few studies have shown clear-cut benefits from the use of these drugs. However, some children and adolescents do exhibit a beneficial response to these drugs in terms of depression and anxiety. Fluoxetine has most consistently demonstrated effectiveness in reducing symptoms of depression in both children and adolescents. This may be a function of the quality of the clinical trials involved. Given the potential negative effect of untreated depression and anxiety in a young population as well as the uncertainty about many aspects of how children and adolescents might react to medication, any use of SSRIs should be undertaken only within the context of a comprehensive management of the patient.

ACKNOWLEDGMENTS

This is a revised and updated version of the Selective Serotonin Reuptake Inhibitors chapter from Edition 10 of Kaplan & Sadock’s Comprehensive Textbook of Psychiatry by Dr. Norman Sussman (deceased).

33.5a.2 Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)

PIERRE BLIER, M.D., PH.D., AND MICHAEL E. THASE, M.D.

Neuroscience-Based Nomenclature (NbN)

Desvenlafaxine, venlafaxine, duloxetine, milnacipran, levomilnacipran

Pharmacologic domain	Serotonin, norepinephrine
Mechanism of action	Reuptake inhibitor (SERT and NET)

The term *serotonin-norepinephrine reuptake inhibitor* (SNRI) describes a group of medications that have therapeutic effects that are presumably mediated by concomitant blockade of neuronal serotonin (5-HT) and norepinephrine (NE) uptake transporters. The SNRIs are also sometimes referred to as *dual reuptake inhibitors*, a broader functional class of medications that includes drugs sharing a tricyclic moiety such as clomipramine and, arguably, imipramine and amitriptyline. What distinguishes the newer SNRIs from the tricyclic derivatives is selectivity, which in this context refers to a relative lack of affinity for receptors, especially muscarinic, histaminergic, and the families of α- and β-adrenergic receptors. This distinction is an important one because the SNRIs have a more favorable tolerability profile than the older dual reuptake inhibitors.

Clinical interest in the SNRIs has largely stemmed from the hypothesis that direct modulation of these two monoamine systems conveys greater antidepressant effects than exerted by medications that selectively enhance only 5-HT or NE neurotransmission. Greater therapeutic benefits could result from: (1) an acceleration of postsynaptic adaptation to increased neuronal signaling, (2) simultaneous activation of two pathways for intracellular signal transduction, (3) additive effects on the activity of relevant neuronal factors such as brain-derived neurotrophic factor, (4) or, quite simply, broader coverage of depressive symptoms. Clinical evidence supporting this hypothesis first emerged in a pair of studies conducted by the Danish University Antidepressant Group, which found an advantage for the dual reuptake inhibitor clomipramine in comparison to the selective serotonin reuptake inhibitors (SSRIs) citalopram and paroxetine. A third report that compared the results of a group of patients prospectively treated with the combination of the tricyclic NE reuptake inhibitor desipramine and the SSRI fluoxetine, with a historical comparison group treated with desipramine alone, provided additional support. A meta-analysis of 25 inpatient studies comparing the efficacy of the tricyclic derivatives and SSRIs yielded the strongest evidence. Specifically, although the tricyclic medications were found to have a modest overall advantage, the superiority over SSRIs was almost entirely explained by the studies that used the drugs that are considered to be dual reuptake inhibitors—clomipramine, amitriptyline, and imipramine.

There are currently five SNRIs approved for use in the United States: Venlafaxine (Effexor and Effexor XR), desvenlafaxine succinate (Pristiq), duloxetine (Cymbalta), milnacipran (Savella), and levomilnacipran (Fetzima). The racemic agent milnacipran is indicated for major depressive disorder in a number of countries, including France and Japan, but in the United States, only for fibromyalgia.

VENLAFAXINE AND DESVENLAFAXINE

Venlafaxine (Fig. 33.5a.2–1) and desvenlafaxine are bicyclic phenylethylamine compounds that are structurally unrelated to other medications used to treat depression or anxiety. First synthesized in the late 1970s, venlafaxine was found to block uptake of 5-HT and NE in vitro, with a greater affinity for the 5-HT transporter. Importantly, venlafaxine was found to have virtually no affinity for muscarinic, histaminergic, or α- or β-adrenergic receptors. Venlafaxine thus was predicted to exert antidepressant activity comparable to the prototypic dual reuptake inhibitors (i.e., amitriptyline and clomipramine), yet affording a safety and tolerability profile that was more similar to the SSRIs.

After efficacy was established compared to placebo in the requisite phase II and phase III randomized controlled trials (RCTs), the original immediate-release (IR) formulation of venlafaxine hydrochloride was approved by the U.S. Food and Drug Administration (FDA) in 1994 for the treatment of major depressive disorder. A microencapsulated extended-release (XR) formulation was introduced in 1997, which permitted once-daily dosing. Generic formulations of venlafaxine are now available. An extended-release formulation of the succinate salt of O-desmethylvenlafaxine (ODV), the principal active metabolite of venlafaxine (DVS; Pristiq), was developed as a novel salt to improve its physicochemical and biologic characteristics. It was approved by the FDA for the treatment of major depressive disorder in early 2008. Generic formulations of desvenlafaxine are now available, but one of them is a free base.

Pharmacology

Venlafaxine and ODV inhibit neuronal uptake of 5-HT and, with significantly lower in vitro affinity, NE. In addition to an essential lack of affinity for muscarinic, histamine 1 (H_1), and adrenergic receptors, neither the parent drug nor the metabolite affects sodium fast channel activity. Venlafaxine and ODV do not inhibit the activity of monoamine oxidases.

FIGURE 33.5a.2–1. Chemical structures of the serotonin-norepinephrine reuptake inhibitors (SNRIs) venlafaxine, desvenlafaxine, duloxetine, levomilnacipran, and milnacipran.

It is widely believed that the relative affinities of venlafaxine for inhibition of 5-HT and NE uptake underpin an ascending dose-response relationship. Specifically, venlafaxine is an SSRI at the lowest therapeutic doses (i.e., 75 mg per day), and NE transporters are consistently engaged at a dose of 225 mg/day. This hypothesis cannot be tested definitively until a specific ^{11}C-ligand for NE transporters is developed so that in vivo studies correlating clinical response with NE transporter occupancy can be undertaken. Venlafaxine at higher doses has also been proposed to be a triple reuptake inhibitor on the basis of in vitro work documenting weak inhibition of dopamine reuptake. Such a direct effect is probably not significant at usual therapeutic doses; however, considering that dopamine is taken back up by NE transporters in the frontal cortex and hippocampus, NE reuptake inhibitors can enhance synaptic levels of dopamine in some brain structures.

Orally administered venlafaxine and DVS are well absorbed from the gastrointestinal (GI) tract and undergo extensive first-pass metabolism in the liver. During venlafaxine therapy, ODV accumulates in higher concentrations (typically about twofold higher) than the parent drug. It thus can be said that ODV accounts for a majority of the therapeutic activity of venlafaxine. Coadministration with food decreases the rate, but not the extent, of absorption of the IR formulation and does not appreciably alter the absorption of venlafaxine XR or ODV. Peak plasma concentrations are achieved within 2 to 3 hours after ingestion of the IR formulation of venlafaxine. During therapy with the XR formulation, peak plasma concentrations are achieved within 5.5 hours for venlafaxine and 9 hours for ODV. When compared to the initial formulation, administration of venlafaxine XR results in lower peak plasma concentrations and a flatter plasma drug concentration curve when compared to venlafaxine IR and essentially the identical bioavailability. During the administration of DVS, peak plasma concentrations of ODV are achieved within about 7 to 9 hours. Formulation of ODV as a succinate salt significantly increases the bioavailability of DVS compared to venlafaxine ER.

Venlafaxine and ODV have linear kinetics over a dose range of 75 to 300 mg per day. Venlafaxine and ODV are primarily eliminated by the kidneys. The elimination half-lives of venlafaxine and its metabolite are short (i.e., 4 and 10 hours, respectively). Neither venlafaxine nor ODV is highly bound to plasma albumin (i.e., 25% to 30% protein binding at therapeutic concentrations).

Clearance of venlafaxine and ODV is reduced among patients with cirrhosis and severe renal disease, necessitating the use of lower doses for such patients. Without data from formal studies on the treatment of patients with severe hepatic or renal disease, a “half-dose–half-speed” approach is clinically reasonable. Adjustments in dosing on the basis of age alone typically are not necessary. However, a low starting dose and slow titration are recommended for the treatment of frail or medically compromised older patients.

Therapeutic Indications

Venlafaxine is approved by the FDA for the treatment of four disorders: major depressive disorder, generalized anxiety disorder, social anxiety disorder, and panic disorder. Major depressive disorder is currently the only FDA-approved indication for DVS.

Depression. The recommended starting dose of both formulations of venlafaxine, 75 mg per day, is the minimum effective dose for treatment of depression. It should be administered with meals on a two- or three-times-a-day basis for the IR. The XR formulation is available in 37.5-, 75-, and 150-mg capsules. The minimum therapeutic dose of DVS is 50 mg per day, and it is available in 50- and 100-mg tablets. Venlafaxine XR and DVS may be taken in the morning or evening, with or without food, as clinically indicated. In ambulatory clinical trials of venlafaxine using flexible doses, a modal daily dose of 150 mg per day was typically observed, regardless of the formulation used. When therapy at modest doses is ineffective, further increases up to 375 mg per day can be considered as tolerated. However, the maximum recommended daily dose of the XR formulation is 225 mg because of a lack of data on once-daily ingestion of higher dosages. However, higher mean doses are observed in studies of treatment-resistant depression. Despite some concerns that noradrenergic activity may exacerbate anxiety, efficacy has been established in studies of depressed people with significant concomitant symptoms of anxiety.

In placebo-controlled RCTs of DVS, doses ranging from 50 mg per day to 400 mg per day have shown efficacy, with no evidence of greater efficacy at higher doses, although higher regimens were introduced abruptly.

Venlafaxine is one of the most extensively studied newer medications for MDD. In published studies using active comparators, venlafaxine therapy has been shown to be at least as effective as treatment with the tricyclic derivatives imipramine, clomipramine, dothiepin, and amitriptyline (seven studies total). Research also suggests comparable overall efficacy with two other multi-action medications, mirtazapine (Remeron) and bupropion (Wellbutrin), although the former drug was found to have a better effect on sleep and the latter drug was found to have fewer sexual side effects. As described later in the chapter, a pair of RCTs has contrasted venlafaxine XR and duloxetine.

For both conceptual and commercial reasons, comparisons of venlafaxine and various SSRIs have garnered considerable attention. Looking at published fluoxetine (Prozac)-controlled studies, the differences in remission rates have ranged from nil to as much as 30% favoring venlafaxine; in aggregate, the difference in effect sizes was statistically significant. Although there are fewer published studies using other SSRIs, venlafaxine therapy similarly has ranged from comparable to more effective than citalopram, fluvoxamine, paroxetine, and sertraline. Only two studies have directly compared escitalopram and venlafaxine; the SNRI showed no efficacy advantage in these trials, and tolerability indices favored the SSRI.

A few comparative clinical trials have sufficient statistical power to distinguish between two effective medications for MDD, meta-analyses are increasingly used to examine relative efficacy. One such meta-analysis used the entire set of double-blind RCTs comparing venlafaxine IR and XR versus SSRIs conducted by the manufacturer of venlafaxine through 2005, focusing primarily on remission rates after 8 weeks of therapy. In this analysis of more than 7,000 depressed patients, those treated with venlafaxine were about one-third more likely to achieve remission than patients treated with SSRIs (odds ratio = 1.31), with an absolute advantage in remission rates of about 6%. Inspection of the results of all studies comparing venlafaxine and SSRIs, including those conducted by other sponsors, largely confirm this finding, although again, the average difference is small (odds ratio = 1.26), and the numeric difference favored the SSRI in approximately 20% of the studies (Fig. 33.5a.2–2).

Despite a noteworthy amount of comparative data, venlafaxine has not been studied extensively in MDD with psychotic features or bipolar depression. There are only three randomized studies of bipolar depression, including one comparison versus the SSRI paroxetine (bipolar I only), one versus the SSRI sertraline and bupropion (bipolar I and bipolar II), and one versus lithium (bipolar II only). In the first two studies, which required that patients take concomitant lithium or valproic acid, there were no significant differences in efficacy, although venlafaxine therapy was associated with a higher rate of treatment-emergent affective switches (TEAS) than the comparators. In the third study, which compared monotherapies, venlafaxine was significantly more effective than lithium and was not associated with an increased risk of TEAS.

Two long-term studies using more methodologically rigorous placebo-controlled discontinuation designs have confirmed efficacy for the prevention of relapse (i.e., 6 months after acute-phase treatment) and recurrence (12 and 24 months thereafter).

Generalized Anxiety Disorder. Venlafaxine XR received FDA approval for the treatment of generalized anxiety disorder in 1999. Efficacy and tolerability data for this indication are documented in four published randomized, controlled trials. In the one published study that used an active comparator, venlafaxine was found to be significantly more effective than the 5-HT$_{1A}$ agonist (BuSpar), which was not significantly more effective than placebo.

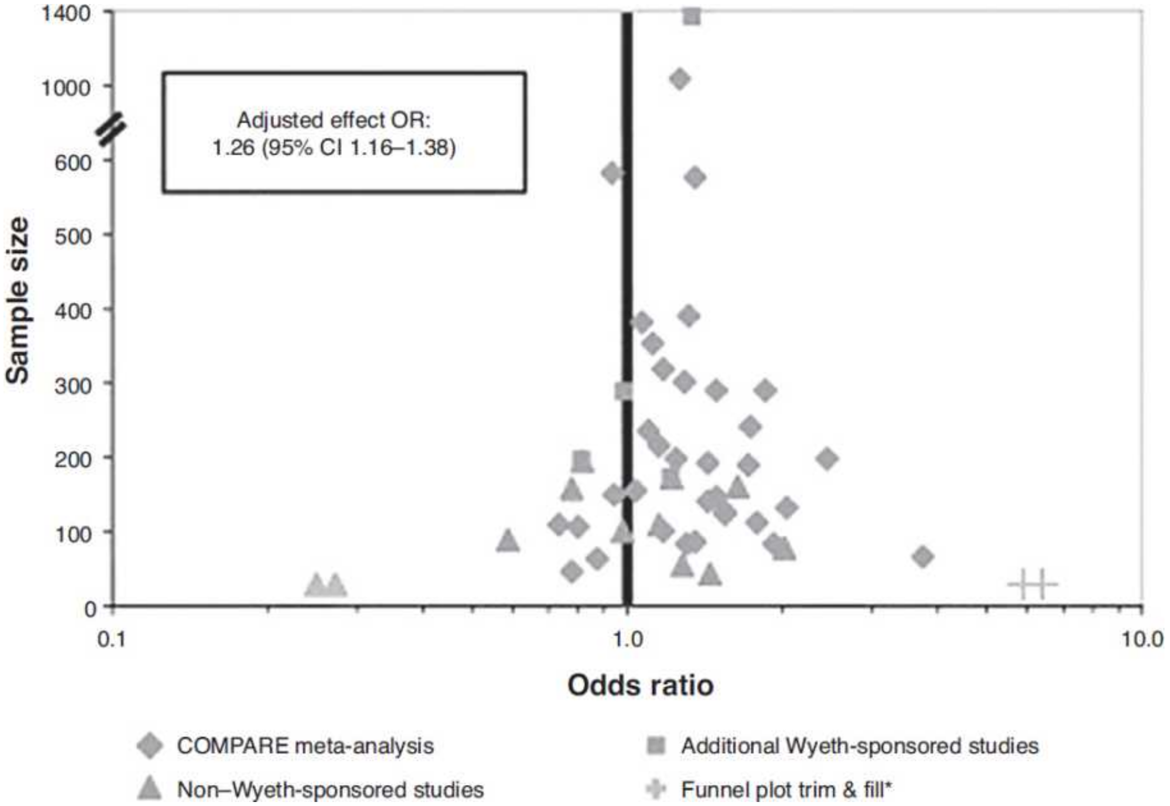

FIGURE 33.5a.2–2. Funnel plot of randomized controlled trials comparing venlafaxine and selective serotonin reuptake inhibitors. CI, confidence interval. (Reprinted from Nemeroff CB, Entsuah R, Benattia I, Demitrack M, Sloan DM, Thase ME. Comprehensive analysis of remission (COMPARE) with venlafaxine versus SSRIs. *Biol Psychiatry.* 2008;63(4):424–434. doi: 10.1016/j.biopsych.2007.06.027.)

To date, higher-dose venlafaxine therapy for generalized anxiety disorder has not been studied systematically, nor have there been any studies using another medication indicated for depression as the active comparator. The regulatory requirements of the first wave of double-blind studies also necessitated the exclusion of patients meeting criteria for MDD. Nevertheless, efficacy has been established in studies of anxious patients with a primary diagnosis of MDD.

Social Anxiety Disorder. The FDA approved venlafaxine for the treatment of social anxiety disorder in early 2003. To date, the results of three double-blind, placebo-controlled studies have been presented at scientific meetings. These trials demonstrated the efficacy and tolerability of venlafaxine at doses of 75 to 225 mg per day; both therapeutic effects and tolerability appear to be comparable to those of paroxetine.

Other Psychiatric Disorders. With respect to panic disorder, efficacy has been established in two RCTs, one including a 40 mg/day regimen of the SSRI paroxetine. In this specific study, 225 mg/day of venlafaxine outperformed 75 mg/day and the paroxetine treatment. Despite the obvious parallels with clomipramine, the antiobsessional effects of venlafaxine have not been as extensively studied. Two large RCTs have shown the efficacy of venlafaxine XR in post-traumatic stress disorder (PTSD), but it is an off-label use.

There are studies pertaining to the treatment of various other mood and anxiety disorders, attention-deficit/hyperactivity disorder (ADHD), and other psychiatric disorders. Premenstrual dysphoric disorder may be thought of as a sex-specific form of brief recurrent depression, and it is known to be responsive to SSRIs. A randomized, double-blind, placebo-controlled study evaluated flexible doses of venlafaxine therapy (ranging from 50 to 200 mg per day) across four menstrual cycles among 157 women with premenstrual dysphoric disorder. There was significantly greater improvement in the venlafaxine group compared to the placebo group across measures of mood, function, physical symptoms, and pain.

Tolerability

Venlafaxine has a safety and tolerability profile that approaches that of the more widely prescribed SSRI class. For example, in the pooled data set of Michael Thase and colleagues, 9% of venlafaxine-treated patients withdrew because of adverse events, as compared to 7% of SSRI-treated patients.

Nausea is the most frequently reported treatment-emergent adverse effect associated with venlafaxine therapy. The mechanism mediating this side effect is thought to be the stimulation of 5-HT type 3 (5-HT_3) receptors. With an incidence of upto 35% in short-term placebo-controlled trials, nausea is approximately one-third more likely than seen with SSRIs. This is presumed to be because low protein binding results in relatively high concentrations of free (biologically active) venlafaxine in the central nervous system (CNS) shortly after dosing. Nausea reliably diminishes in prevalence and severity during the first few weeks of therapy, presumably because of the desensitization of 5-HT_3 receptors. Use of the XR formulation somewhat reduces the incidence and intensity of nausea, as does taking the medication with meals. Initiating therapy at lower dosages (37.5 mg per day) also may help attenuate nausea. When extremely problematic, treatment-induced nausea can be controlled by prescribing a selective 5-HT_3 antagonist or mirtazapine.

As with other 5-HT reuptake inhibitors, venlafaxine therapy is associated with sexual side effects, predominantly decreased libido and a delay to orgasm or ejaculation. The incidence of these side effects is underreported in clinical trials and may exceed 30% to 40% when there is a direct, detailed assessment of sexual function. Although the exact mechanisms of the sexual side effects are not known, it is thought that 5-HT–mediated inhibition of NE and dopamine effects are implicated.

Other common side effects include headache, insomnia, somnolence, dry mouth, dizziness, constipation, asthenia, sweating, and nervousness. Although several side effects are suggestive of anticholinergic effects, the drug has no affinity for muscarinic or nicotinic receptors. Thus, noradrenergic agonism is likely to be the culprit.

Hypertension

Higher-dose venlafaxine therapy is associated with an increased risk of sustained elevations of blood pressure. Experience with the IR formulation in studies of depressed patients indicated that sustained hypertension was dose-related, increasing from 3% to 7% at doses of 100 to 300 mg per day and to 13% at doses greater than 300 mg per day. In this data set, venlafaxine therapy did not adversely affect blood pressure control of patients taking antihypertensives and even lowered the mean values of patients with elevated blood pressure readings before therapy. In controlled studies of the XR formulation, venlafaxine therapy resulted in only approximately a 1% greater risk of high blood pressure when compared to placebo. Arbitrarily capping the upper dose of venlafaxine used in these studies thus greatly attenuated concerns about elevated blood pressure. When higher doses of the XR formulation are used, however, monitoring of blood pressure is recommended.

Discontinuation Syndrome

Venlafaxine is one of the medications most commonly associated with discontinuation syndrome. This syndrome is characterized by the appearance of a constellation of adverse effects during a rapid taper or abrupt cessation, including dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances. As the XR formulation does *not* affect the elimination half-life of the compound, it does not decrease the potential for discontinuation symptoms. Patients need to be informed that venlafaxine therapy should not be stopped abruptly and that even missing a few days of therapy may provoke discontinuation symptoms. It is recommended that, whenever possible, a slow taper schedule should be used when longer-term treatment must be stopped (e.g., reducing the daily dose by no more than 75 mg each week). On occasion, substituting a few doses of fluoxetine may help to bridge this transition, especially at the last step of discontinuation.

Overdose

There were no overdose fatalities in premarketing trials, although electrocardiogram (ECG) changes (e.g., prolongation of QT interval, bundle branch block, QRS interval prolongation), tachycardia, bradycardia, hypotension, hypertension, coma, 5-HT syndrome, and seizures were reported. Fatal overdoses have been documented subsequently, typically involving venlafaxine ingestion in combination with other drugs or alcohol, or both. In an analysis of fatal medication overdoses in the United Kingdom from 1993 to 1999, Nicholas A. Buckley and Peter R. McManus found that venlafaxine had a significantly greater fatal toxicity index (a measure of overdose deaths per million prescriptions) than the SSRIs (13.2 vs. 0.7 to 3.0). These data could raise some concerns about the first-line use of venlafaxine for the treatment of suicidal patients. However, it should be noted that the authors did not take into account that psychiatrists wrote most of the venlafaxine prescriptions in the United Kingdom during the time in which these data were collected, whereas the SSRIs were widely prescribed by primary care providers. Thus, the higher fatality index may be describing the patient profile treated with venlafaxine (i.e., inpatients or those with more chronic, severe, or treatment-resistant mood disorders) rather than the toxicity of the drug.

Drug–Drug Interactions

Venlafaxine is metabolized in the liver primarily by the cytochrome P450 (CYP) 2D6 isoenzyme. Because the parent drug and principal metabolite are essentially equipotent, medications that inhibit this isoenzyme usually do not adversely affect therapy. In vitro and in vivo studies have shown venlafaxine to cause little or no inhibition of other P450 isoenzymes.

Venlafaxine is contraindicated in patients taking monoamine oxidase inhibitors (MAOIs) because of a potentially lethal pharmacodynamic interaction (i.e., serotonin syndrome). An MAOI must not be started for at least 7 days after stopping venlafaxine. There are now considerable data from trials examining the addition of partial dopamine agonists such as aripiprazole and brexpiprazole in inadequate response to SNRIs showing no complications. Regarding the combination of venlafaxine with lithium (Eskalith) and other medications for the treatment of bipolar disorder, clinical judgment should be exercised when combining medications, given the paucity of data.

DULOXETINE

Duloxetine hydrochloride is a propanamine compound that was synthesized in the 1980s by the same drug discovery team that identified the SSRI fluoxetine (Fig. 33.5a.2–1). Like fluoxetine, duloxetine is a potent 5-HT uptake inhibitor and lacks affinity for muscarinic, histaminic, and α- and β-adrenergic receptors. Unlike fluoxetine, duloxetine is also a relatively potent inhibitor of NE reuptake, and in in vitro studies, duloxetine was found to be a substantially more potent NE reuptake inhibitor than venlafaxine. If these studies predict effects in the brain, duloxetine should be expected to produce dual reuptake inhibition at lower absolute doses than observed with venlafaxine. Duloxetine was approved by the FDA for the treatment of major depressive disorder in 2004; other indications include generalized anxiety disorder, fibromyalgia, diabetic peripheral neuropathy, and chronic musculoskeletal pain.

Pharmacology

Orally administered duloxetine is well absorbed, and peak plasma levels are achieved approximately 3 hours after ingestion. Duloxetine has no active metabolites and exhibits linear pharmacokinetics within a dose range of 20 to 120 mg. Steady-state concentrations are achieved within 3 days of oral dosing, and the drug has an elimination half-life of approximately 12 hours (Fig. 33.5a.2–3).

In the plasma, approximately 90% of the drug is protein bound. After hepatic oxidation, metabolites of duloxetine are primarily eliminated by the kidneys. Duloxetine is metabolized by CYP 1A2 and is a moderately potent inhibitor of the CYP 2D6 isoenzyme.

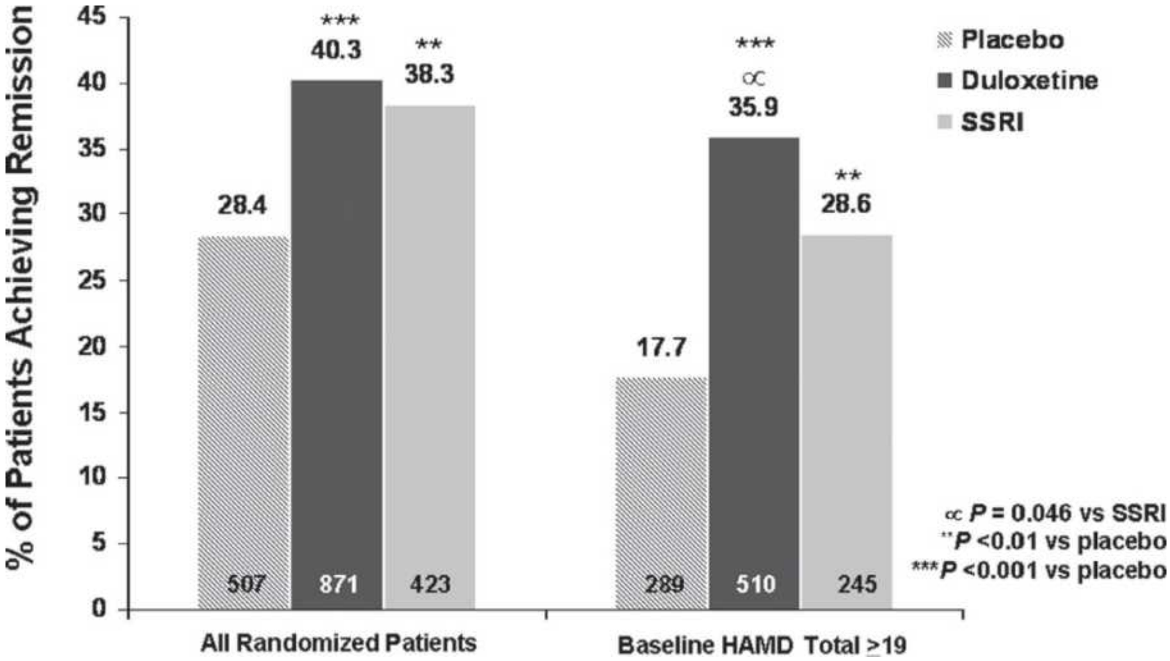

FIGURE 33.5a.2–3. Meta-analytic comparison of duloxetine (40 to 120 mg per day) and two selective serotonin reuptake inhibitors (SSRIs; fluoxetine and paroxetine; 20 mg per day) in six placebo-controlled studies of major depressive disorder. Remission is defined as Hamilton Depression (HAMD) Rating Scale Score <7 at the endpoint. Both antidepressants were more effective than placebo overall, with a significant advantage for duloxetine over the SSRIs among the subset of patients scoring 19 or higher on the 17-item HAMD. (Reprinted from Thase ME, Pritchett YL, Ossanna MJ, Swindle RW, Xu J, Detke MJ. Efficacy of duloxetine and selective serotonin reuptake inhibitors: comparisons as assessed by remission rates in patients with major depressive disorder. *J Clin Psychopharmacol*. 2007;27(6):672–676. doi: 10.1097/jcp.0b013e31815a4412.)

Antidepressant Efficacy

Eight phase II and phase III placebo-controlled, randomized, controlled trials were completed to establish efficacy and safety; these studies formed the basis for the FDA's approval of duloxetine therapy for major depressive disorder. No evidence of a dose-response relationship was observed between 60 mg per day and 120 mg per day; somewhat weaker antidepressant effects were observed at 40 mg per day. These clinical results are fully consistent with the observations that 40 mg of duloxetine reached the 80% occupancy level of the 5-HT transporter in the brain achieved with the minimal effective doses of SSRIs and venlafaxine, but that 60 mg once daily was necessary to maintain it. Consequently, given the lower affinity of duloxetine for the NE than the 5-HT transporter, higher doses than 60 mg/day are needed to reliably obtain a noradrenergic effect in the brain.

Six of the initial registration studies of duloxetine (40 to 120 mg per day) included an SSRI as an active comparator. A meta-analysis confirmed that both duloxetine and the comparators were effective and, among the subset of patients with moderate to severe depressive symptoms, there was a significant advantage favoring the SNRI in remission rates (Fig. 33.5a.2–3). However, none of these studies utilized the 60 mg per day dose of duloxetine and all of these studies used low (20 mg per day) doses of the comparators (fluoxetine or paroxetine). Three studies subsequently compared duloxetine (60 mg per day) versus escitalopram (10 to 20 mg per day). No advantage in efficacy was observed for the SNRI, and tolerability indices favored escitalopram. A pooled analysis of a pair of 6-week double-blind studies contrasting duloxetine (60 mg per day) and venlafaxine XR (150 mg per day) likewise found significant differences in efficacy. Duloxetine therapy was associated with a significantly higher incidence of nausea; venlafaxine therapy was associated with a higher incidence of treatment-emergent high blood pressure and, following the withdrawal of study medication, discontinuation-emergent symptoms.

Tolerability

The discontinuation rate due to adverse events in the studies summarized by Charles Nemeroff and colleagues was 15% in duloxetine-treated patients and 5% in placebo-treated patients. Side effect attrition was slightly higher in the duloxetine groups in the studies that used fluoxetine (10% vs. 6%) and paroxetine (14% vs. 10%) comparison groups, although these differences were not statistically significant in individual studies. The most commonly reported side effects during duloxetine therapy were nausea (22%), dry mouth (16%), fatigue (11%), dizziness (11%), and somnolence (8%). Incidence of sexual dysfunction appears to be comparable to that of the SSRIs. Of note, the incidence of nausea was similar for duloxetine (dosed twice daily) to fluoxetine and paroxetine (dosed once daily) in head-to-head double-blind trials. Despite the potential usefulness of the drug for the treatment of urinary incontinence, urinary hesitancy and urinary retention were not common occurrences in studies of depressed patients.

Like other 5-HT uptake inhibitors, duloxetine therapy has been associated with sexual dysfunction and, after abrupt cessation, a characteristic discontinuation syndrome. It is not yet possible to determine the relative risks of these phenomena during duloxetine therapy on a continuum with the other newer medications for MDD.

Duloxetine therapy resulted in a small increase in resting pulse rate (approximately two beats per minute) and an average increase in blood pressure of approximately 2 mm Hg in the studies reviewed by Nemeroff and colleagues. Of note, the risk of sustained high blood pressure during duloxetine therapy was approximately 1% greater than observed in placebo-treated patients. Curiously, the risk of increased blood pressure does not appear to be dose-dependent.

Although the CYP enzyme inhibition profile of the drug looks generally favorable, duloxetine levels are about 30% lower in smokers, likely as a result of CYP 1A2 induction, and increased four-fold by potent CYP 1A2 inhibitors, like fluvoxamine and some fluoroquinolone antibiotics. A lethal interaction with MAOIs is expected with duloxetine, and the guidelines suggested previously for venlafaxine therapy must be followed.

MILNACIPRAN AND LEVOMILNACIPRAN

The SNRI milnacipran is distinguished as a dual reuptake inhibitor that on the basis of in vitro and in vivo studies (Fig. 33.5a.2–1). Specifically, milnacipran is twice more potent for inhibition of NE uptake than for 5-HT reuptake inhibition. Milnacipran thus can be thought of as a preferential NE uptake inhibitor at the minimum therapeutic dosage (50 mg twice a day) that exerts progressively greater inhibitory effects on 5-HT reuptake at higher doses (i.e., 200 mg/day, its maximal recommended dose for fibromyalgia). Like the other SNRIs, milnacipran has almost no affinity for muscarinic, histaminic, or α- and β-noradrenergic receptors.

Pharmacology

Milnacipran has a half-life of approximately 8 hours and shows linear pharmacokinetics between doses of 50 and 250 mg per day. It is minimally metabolized in the liver and has no active metabolites. Milnacipran is primarily excreted by the kidneys. Most orally administered milnacipran is bioavailable, and only 13% of milnacipran is bound to plasma protein. Milnacipran is not an inhibitor of any of the CYP isoenzymes.

Antidepressant Efficacy

The countries that have approved milnacipran for general use in the treatment of depression have not required completion of a large number of placebo-controlled studies, therefore, efficacy is not as well established as in the case for venlafaxine or duloxetine. A meta-analysis of 16 RCTs (including all published and unpublished studies) encompassing 2,277 patients concluded that milnacipran did not have significantly different efficacy, acceptability, and tolerability when compared to other medications for MDD. However, when compared to TCAs, fewer patients dropped out due to the side effects of milnacipran.

Tolerability

In comparative clinical trials, milnacipran therapy was associated with significantly fewer anticholinergic and antihistaminic side effects than the tertiary amine tricyclic derivatives and fewer GI side effects than the SSRIs. Noteworthy side effects (i.e., incidence greater than an SSRI) included dizziness, sweating, and urinary hesitancy. Neither prospective data nor any expert opinion on the incidence of sexual dysfunction, especially when contrasted to the SSRIs, could be located. Likewise, the potential for lethality in overdose has not been systematically examined. Like 5-HT reuptake inhibitors, milnacipran should not be prescribed in proximity to an MAOI.

Characteristics of Levomilnacipran

Levomilnacipran is the active enantiomer of the racemic mixture of milnacipran. It is available in an extended-release formulation and has a higher maximal plasma concentration (peaks in 6 to 8 hours), a greater area under the curve, and a longer half-life (12 hours) than its much less active dextrorotary enantiomer. It is only 22% bound to plasma proteins and excreted by the kidneys 58% unchanged. It is recommended to initiate it at 20 mg/day for 2 days and gradually increase the dose to 40, 80, and 120 mg/day according to tolerability and response. It is effective in 40 to 120 mg/day doses based on a data set of five placebo-controlled studies on 2,598 patients aged 18 to 80. Interestingly, it was effective in patients aged 60 and older, a population that is generally resistant to other medications. Currently, there are no active comparator studies, but there is a positive double-blind maintenance trial that has not revealed evidence of discontinuation symptoms. In both acute and long-term studies, there was no evidence of weight gain. On average, there was approximately a 7 beat per minute increase in heart rate, a thumbprint of NE reuptake inhibition. Only prospective studies using specific sexual function scales, and not merely TEAEs, could determine whether it is less problematic than other more potent 5-HT reuptake inhibiting medications. As for other SNRIs, it is recommended to utilize a gradual taper to discontinue the medication.

SUMMARY

The SNRIs venlafaxine, desvenlafaxine, duloxetine, milnacipran, and levomilnacipran are effective medications for the treatment of MDD. There is evidence of an ascending dose-response relationship for venlafaxine and, possibly, milnacipran and duloxetine. A substantial body of research documents that venlafaxine therapy (at higher doses) has stronger antidepressant effects than the SSRIs; some data suggest a similar advantage for duloxetine and, for patients with severe depression, milnacipran. The efficacy of venlafaxine also has clearly been established in controlled studies of generalized anxiety, social anxiety, and panic disorders. Treatment with SNRIs is generally well tolerated. Tolerability and safety profiles are superior to the tricyclic derivatives and approach those of the SSRIs. A higher initial incidence of nausea and, at higher doses, elevated blood pressure may be distinguishing characteristics of venlafaxine therapy. Apart from duloxetine, the four other medications have a low potential for CYP-mediated drug–drug interactions.

33.5a.3 Tricyclics and Tetracyclics

J. CRAIG NELSON, M.D.

Neuroscience-Based Nomenclature (NbN)	
Desipramine, Protriptyline, Nortriptyline	
Pharmacologic domain	Norepinephrine
Mechanism of action	Reuptake inhibitors (NET)
Lofepramine, Amoxapine	
Pharmacologic domain	Norepinephrine, Serotonin
Mechanism of action	Reuptake inhibitors (NET and SERT)
Imipramine, Dosulepin, Clomipramine	
Pharmacologic domain	Serotonin, Norepinephrine
Mechanism of action	Reuptake inhibitors (SERT and NET)
Amitriptyline	
Pharmacologic domain	Serotonin, Norepinephrine
Mechanism of action	Reuptake inhibitors (SERT and NET) and receptor antagonist (5-HT_2)
Doxepin	
Pharmacologic domain	Norepinephrine, Serotonin
Mechanism of action	Reuptake inhibitors (NET and SERT) and receptor antagonist (5-HT_2)
Trimipramine	
Pharmacologic domain	Serotonin, Dopamine
Mechanism of action	Receptor antagonist (5-HT_2 and D_2)

HISTORY

In 1957, Roland Kuhn, a Swiss psychiatrist, observed that imipramine (Tofranil) had antidepressant effects in a small sample of 40 patients. This serendipitous observation, like those before for lithium (Eskalith) and chlorpromazine (Thorazine), had far-reaching import. It demonstrated that medications could be used to treat depression. It led to the development of a new class of antidepressant compounds. This clinical observation, coupled with Julius Axelrod's report of imipramine's role in blocking the reuptake of norepinephrine, laid the foundation for the norepinephrine hypothesis of depression.

The study of the treatment of depression with imipramine and related compounds would drive the development of a new methodology. For example, objective measures were required to assess change during treatment. Max Hamilton developed the Hamilton Depression Rating Scale to monitor change during the administration of these new compounds. Other scales followed. Better methods of defining depression were needed, and the Washington University group proposed criteria for primary affective disorder, criteria that became the basis for the category of major depression in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). Observation of substantial placebo effects in depression during clinical trials led to the appreciation of the need for placebo controls.

The field also learned the basics of pharmacologic management of depression with imipramine and other tricyclics. The necessity for administering an adequate dose for an adequate duration was described. The need to continue treatment to prevent relapse and recurrence was identified. The observation of the substantial variability of the tricyclic concentrations in plasma stimulated a whole area of study of the pharmacology of these compounds. This research introduced psychiatry to the concept of *genetic polymorphisms* and the possible consequences of drug interactions.

After the introduction of imipramine, several other antidepressant compounds were developed that shared a basic tricyclic structure and relatively similar secondary or side effects. Later, other heterocyclic compounds were also marketed that were somewhat similar in structure and that had relatively comparable secondary properties.

FIGURE 33.5a.3–1. Molecular structure of tricyclics and tetracyclics.

CHEMISTRY

Tricyclic and tetracyclic compounds are categorized primarily on the basis of their chemical structure (Fig. 33.5a.3–1). The *tricyclics* have a three-ring structure, hence, their name. The tertiary amine tricyclics, such as amitriptyline (Elavil) and imipramine, have two methyl groups at the end of the side chain. These compounds can be demethylated into secondary amines, such as desipramine (Norpramin, Pertofrane) and nortriptyline (Aventyl, Pamelor). The tetracyclic compounds maprotiline (Ludiomil) and amoxapine (Asendin) have a four-ring central structure. Five tertiary amines have been marketed in the United States—amitriptyline, clomipramine (Anafranil), doxepin (Sinequan), imipramine, and trimipramine (Surmontil). The three secondary amine compounds are desipramine, nortriptyline, and protriptyline (Vivactil).

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Absorption. Absorption of the tricyclic and tetracyclic drugs occurs in the small intestine and is reasonably complete and rapid. Peak levels after ingestion occur within 2 to 8 hours. Exceptions are protriptyline, which is absorbed more slowly, with peak levels obtained between 6 and 12 hours, and maprotiline, which has peak levels occurring in 8 hours or more. Because the antidepressant action of these drugs occurs over several weeks, the timing of peak levels is relatively unimportant for efficacy but does have implications for side effects, especially during initial dosing.

Distribution. The tricyclic and tetracyclic compounds are basic lipophilic amines. As a result, they are concentrated in a variety of tissues throughout the body and have a high volume of distribution. In some organs, the heart, for example, the drug is concentrated at levels exceeding those in plasma. Because of their lipid solubility, these compounds are extensively bound to plasma proteins. Binding of the tricyclic and tetracyclic drugs is generally 90% or greater. Exceptions are the hydroxymetabolites of the tricyclics, which have lower plasma protein binding.

The lipophilic properties of the tricyclic and tetracyclic compounds also contribute to their ability to cross the blood–brain barrier and reach their targets in the CNS. Previously it was thought that brain concentrations of antidepressants were dependent primarily on the free or unbound plasma concentrations. Recent work suggests that p-glycoproteins (P-GP) actively transport some antidepressant compounds out of the brain, thus lowering drug concentrations. P-GP is encoded by the ABCB1 gene and is expressed on capillary endothelial cells of the blood–brain barrier. The clinical relevance of P-GP is supported by studies finding single nucleotide polymorphisms of the ABCB1 gene associated with response to paroxetine, a P-GP substrate, but not all studies agree. Not all antidepressants are substrates of P-GP, but several of the tricyclics—amitriptyline, nortriptyline, imipramine, desipramine, doxepin, and trimipramine—are substrates.

Tricyclic compounds cross the placenta. Transfer of the tertiary compound amitriptyline is slightly higher than that for the secondary compound nortriptyline. Neonatal drug withdrawal can occur. The tricyclics are excreted in breast milk at concentrations similar to plasma. The actual quantity delivered, however, is small so drug levels in the infant are usually undetectable or very low.

Metabolism and Elimination. After absorption, the tricyclics are taken up in the circulation, pass first through the liver, and metabolism of the drug begins. As a result of this *first-pass effect,* the amount of the compound that enters the systemic circulation is reduced.

Clearance of the tricyclic and tetracyclic compounds is principally the result of hepatic metabolism. Renal clearance accounts for only a small portion of drug elimination. Rates of hepatic metabolism vary widely from person to person. Elimination half-lives for most of the tricyclic and tetracyclic compounds are approximately 24 hours or longer. Thus the drugs can be given once a day (Table 33.5a.3–1). Amoxapine, which has a shorter half-life, is an exception.

Note: Affinity and potency = $10^{-7} \times 1/K_d$. K_d= equilibrium dissociation constant in molarity. Larger numbers indicate greater activity or potency.

Uptake potency data adapted from Tatsumi M, Groshan K, Blakely RD, Richelson E. Pharmacological profile of antidepressants and related compounds at human monoamine transporters. *Eur J Pharmacol*. 1997;340:249–258. Receptor affinity data adapted from Richelson E, Nelson A. Antagonism by antidepressants of neurotransmitter receptors of normal human brain in vitro. *J Pharmacol Exp Ther*. 1984;230:94–102.

There are two principal metabolic pathways: demethylation of the side chain and hydroxylation of the ring structure. Demethylation converts tertiary amines to secondary amines. Examples are the conversion of amitriptyline to nortriptyline and imipramine to desipramine. This process alters the activity of the compound. The tertiary amines are relatively more serotonergic, whereas the demethylated amines are relatively more noradrenergic. Hydroxylation of the compounds also occurs and results in hydroxymetabolites. The concentration of 10-hydroxynortriptyline usually exceeds that of the parent. For desipramine, 2-hydroxydesipramine is present at levels of approximately 45% of the parent, but these ratios are quite variable. Hydroxyimipramine and hydroxyamitriptyline are present at low concentrations and are clinically unimportant. The hydroxymetabolites are then conjugated and excreted. The conjugated metabolites are not active.

Hydroxynortriptyline and hydroxydesipramine have antidepressant activity. Hydroxy-desipramine is comparable to the parent in terms of norepinephrine reuptake blockade. There are two isomers of hydroxynortriptyline: E- and Z-10-hydroxynortriptyline. E-10-hydroxynortriptyline is present at levels greater than the Z-isomer and the parent compound but is approximately 50% as potent as nortriptyline. The clinical significance of high levels of less potent hydroxynortriptyline is not entirely clear but may contribute to the therapeutic window described for this drug. The hydroxymetabolites of nortriptyline and desipramine are less anticholinergic than their parent compounds but may contribute disproportionately to the cardiac conduction abnormalities associated with tricyclic antidepressants.

The principal metabolic pathway for amoxapine is hydroxylation. 7-Hydroxyamoxapine and 8-hydroxyamoxapine are produced. These compounds differ in their clinical activity. 7-Hydroxyamoxapine has high-potency neuroleptic properties but has a short half-life. 8-Hydroxyamoxapine is metabolized more slowly and appears to contribute to the drug's antidepressant action.

The tricyclics are metabolized by the cytochrome 450 (CYP) system. The CYP 2D6 pathway is responsible for the hydroxylation of desipramine and nortriptyline. Demethylation of the tertiary amine compounds appears to involve several CYP isoenzymes, including CYP 1A2, CYP 3A4, and CYP 2C19. Approximately 5% to 10% of Caucasians are homozygous for the recessive autosomal CYP 2D6 trait, resulting in deficient hydroxylation of desipramine and nortriptyline. Approximately 50% of those of Asian descent carry the 2D6*10 allele, which results in reduced clearance by the 2D6 enzyme and is intermediate metabolizers. In addition, about 20% of Asians have a genetic polymorphism resulting in deficient CYP 2C19 metabolism of the tertiary tricyclic compounds.

The variability in plasma concentrations that results from these metabolic differences is substantial, often described as a 40-fold variation among individuals (Fig. 33.5a.3–2). Even among the extensive metabolizers, there can be moderate interindividual variability in the rates of metabolism.

The concept of *steady-state* is important for clinicians to understand if plasma concentration monitoring is used. A Steady-state is that point, on a fixed dose, at which plasma concentrations of the drug plateau. The steady-state is achieved after five times the half-life.

If blood level monitoring is used, a trough sample (before the next dose) is drawn when the patient has reached a steady-state. At steady-state, drug concentrations are relatively stable if the dose is constant, the patient is adherent, and no drugs with interactive effects are added.

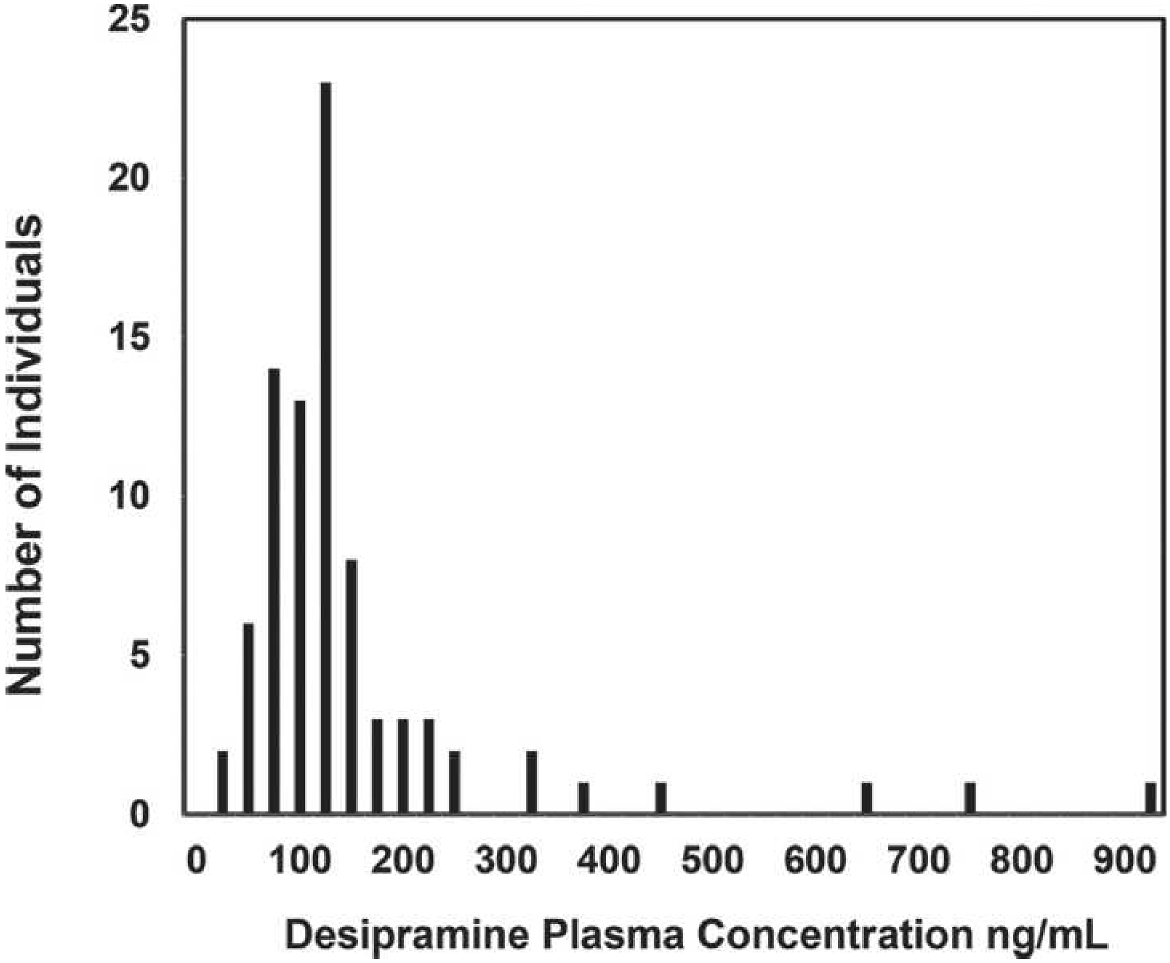

FIGURE 33.5a.3–2. Distribution of steady-state desipramine (Norpramin, Pertofrane) concentrations in 83 in-patients receiving desipramine (2.5 mg/kg/day). (Adapted from Nelson JC. Use of desipramine in depressed inpatients. *J Clin Psychiatry.* 1984;45(10 Pt 2):10–16.)

When the drug concentration is measured, the total of the free and bound tricyclic fractions are reported; yet it is the free levels that are directly related to the concentration of the drug in the cerebrospinal fluid (CSF). The free concentration is dependent on dose and hepatic clearance but not plasma protein binding. The latter is often misunderstood. If the binding protein concentration falls, the total (free and bound) concentration declines, but the absolute free concentration is unaffected.

The day-to-day biologic variability of drug concentrations is not frequently described. In outpatients, the day-to-day variability of nortriptyline levels (the coefficient of variation equals the standard deviation divided by the mean plasma concentration) has been reported to be 25%. In inpatients at steady-state, the coefficient of variation of desipramine is approximately 10% to 15%. (If the average plasma concentration is 150 ng/mL, two-thirds of samples obtained will be between 128 and 172 ng/mL.) For clinical purposes, usually, one sample is drawn, and the clinician needs to remember that, even if the laboratory error is low, the biologic variability is sufficiently great that blood levels are better viewed as estimates than precise measures.

Recently assays have become available that can genotype-specific isoenzyme pathways such as 2D6. Genotyping might be useful for predicting how an individual would metabolize a group of drugs that are cleared by a common pathway. Alternatively, a plasma drug concentration is more informative about the actual concentration of a specific drug present and accounts for variations in absorption, distribution, and adherence in addition to differences in metabolic rate.

For most tricyclics, kinetics are relatively linear, although there are some exceptions. Desipramine, for example, appears to have nonlinear kinetics in the usual dose range. The patients most vulnerable to nonlinear changes are the rapid metabolizers—patients who, at usual doses, have low blood levels. In cases of overdose, nonlinear changes are more likely to occur, and the clinician cannot assume that usual rates of drug elimination are maintained.

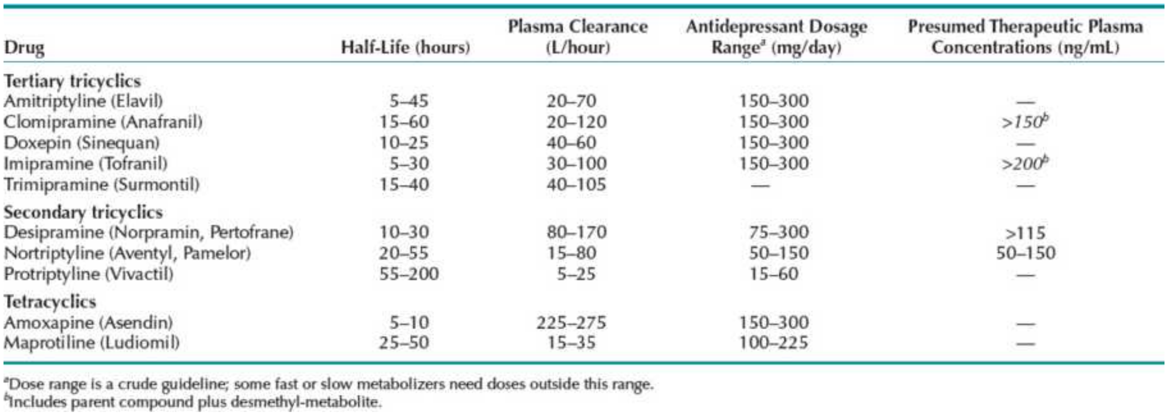
The pharmacokinetics of drug treatment in the older adults is complicated. A number of changes occur. For example, the ratio of fat to lean body mass increases, and cardiac output and hepatic blood flow decrease. There may be further changes associated with medical illness. Yet, the magnitude of these changes is usually relatively small in relation to the dramatic variability of hepatic metabolism. Metabolic changes with age appear to vary with the isoenzymes involved. Clearance by the CYP 3A4 pathway slows with age. Most studies of tertiary amines, such as imipramine, suggest that concentrations of these drugs are increased somewhat in the older adults. Concentrations of nortriptyline and desipramine, compounds metabolized primarily by CYP 2D6, are relatively unaffected by aging. Similarly, the relationship of drug concentrations to therapeutic effects appears to be relatively similar in younger and older adults for these agents. Renal clearance of the hydroxymetabolites does decrease with age. Concentrations of hydroxynortriptyline may be substantially elevated in older patients.

In children, the clearance of tricyclic compounds is increased. Half-lives of imipramine are shorter, and ratios of desmethylimipramine to imipramine are higher, consistent with more rapid metabolism.

Pharmacodynamics

Mechanisms of Action. The tricyclic and tetracyclic antidepressants block the transporter sites for serotonin and norepinephrine and thus reduce uptake of these amines into the presynaptic neuron (Table 33.5a.3–2). The tertiary amines have a greater affinity for the serotonin transporter. The secondary amines primarily block the uptake of norepinephrine. Because the tertiary amines are demethylated to secondary amines, during the administration of amitriptyline, imipramine, or clomipramine, secondary amines are also present; thus, serotonergic and noradrenergic effects occur. Because dopamine is inactivated by norepinephrine transporters in the frontal cortex, the tricyclics would be expected to increase dopamine concentrations in that region.

Table 33.5a.3–2.
Pharmacokinetic Parameters and Clinical Information for Tricyclic and Tetracyclic Drugs



Drug	Half-Life (hours)	Plasma Clearance (L/hour)	Antidepressant Dosage Range[a] (mg/day)	Presumed Therapeutic Plasma Concentrations (ng/mL)
Tertiary tricyclics				
Amitriptyline (Elavil)	5–45	20–70	150–300	—
Clomipramine (Anafranil)	15–60	20–120	150–300	*>150*[b]
Doxepin (Sinequan)	10–25	40–60	150–300	—
Imipramine (Tofranil)	5–30	30–100	150–300	*>200*[b]
Trimipramine (Surmontil)	15–40	40–105	—	—
Secondary tricyclics				
Desipramine (Norpramin, Pertofrane)	10–30	80–170	75–300	>115
Nortriptyline (Aventyl, Pamelor)	20–55	15–80	50–150	50–150
Protriptyline (Vivactil)	55–200	5–25	15–60	—
Tetracyclics				
Amoxapine (Asendin)	5–10	225–275	150–300	—
Maprotiline (Ludiomil)	25–50	15–35	100–225	—

[a] Dose range is a crude guideline; some fast or slow metabolizers need doses outside this range.
[b] Includes parent compound plus desmethyl-metabolite.

After the initial reuptake blockade, a sequence of events occurs. The tertiary tricyclic compounds, particularly clomipramine, inhibit the uptake of serotonin and concentrations of serotonin rise. In response, the presynaptic somatodendritic serotonin autoreceptors reduce the firing rate of the presynaptic serotonin neuron, and concentrations of serotonin metabolites fall. Over a 2-week period, the presynaptic autoreceptor is desensitized, resulting in a normalization of the firing rate. At this point, serotonin transmission is enhanced.

The tricyclic agents also sensitize or upregulate *postsynaptic* 5-HT_{1A} receptors and downregulate the 5-HT_2 receptors. In addition, doxepin, clomipramine, amitriptyline, trimipramine, and nortriptyline act as antagonists at the 5-HT2 receptor. The 5-HT_2 receptors principally mediate excitatory effects, whereas the 5-HT_{1A} receptors have an inhibitory effect in the brain. Thus these two systems act in opposition. Thus, downregulation of 5-HT_2 receptors appears to facilitate the effects of serotonin at postsynaptic 5-HT_{1A} receptors. Changes in the sensitivity of postsynaptic receptors occur over a period of weeks and are more consistent with the timing of antidepressant response than the initial uptake blockade.

The sequence of events in the noradrenergic system is more complicated and less well-understood. Following reuptake inhibition, concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, tall rapidly within 24 hours. Presumably, this is mediated by the presynaptic somatodendritic α_2-autoreceptor, which lowers the firing rate of the presynaptic neuron. Different from the 5-HT system, the firing rate of the presynaptic noradrenergic neuron remains inhibited with chronic treatment. Norepinephrine concentrations, however, do increase at postsynaptic sites in the hippocampus and frontal cortex, and norepinephrine transmission is increased. This may be mediated by desensitization of the *terminal* α_2-autoreceptor.

During chronic treatment, the postsynaptic β-adrenergic receptor is downregulated or decreased in density. This appears to be a compensatory change. In fact, during continued administration of a noradrenergic reuptake inhibitor, the system is upregulated. This is reflected in the enhanced formation of the second messenger cyclic adenosine monophosphate (cAMP). Clinically, this is reflected as a persistent increase in heart rate.

Early theories of depression posited depletion of serotonin, norepinephrine, or both, and the tricyclics were thought to “correct” this imbalance through reuptake blockade. Subsequent theories suggested that the changes in presynaptic and postsynaptic receptors were a likely explanation for the delayed effects of these drugs in depression. Monoamine depletion studies indicated that the effects of antidepressant agents are, in part, mediated by serotonin and norepinephrine; however, they do not necessarily imply that tricyclics are correcting *deficits* in these neurotransmitter systems associated with depression.

Early theories of antidepressant action suggested that it might be possible to identify serotonergic and noradrenergic depressions based on the relative deficiencies of metabolites associated with each of these neurotransmitters and thus predict which type of antidepressant would be most effective. Several studies investigated the predictive value of MHPG levels pretreatment, but a clear predictive link with a type of antidepressant was not established. These studies were, in part, hampered by the use of agents such as amitriptyline and imipramine, which are not selective.

The possible role of the anticholinergic effects of tricyclics in the mechanism of antidepressant action has not received much attention. These effects usually have been associated with unwanted adverse effects. Yet, as early as 1972, theories about the role of the cholinergic system in depression were advanced. Scopolamine, an anticholinergic agent, has rapid antidepressant effects given intravenously. Physostigmine and donepezil, which have cholinergic effects, have been noted to exacerbate depression or increase the risk of relapse in patients with recurrent depression. Amitriptyline has anticholinergic effects at therapeutic doses, and it is likely these actions would contribute to antidepressant activity; however, it would be difficult to disentangle the contribution of these effects relative to the effects of monoamine reuptake inhibition.

Other possible mechanisms of action in depression have been explored, including the effects of tricyclics on postsynaptic signal transduction, glucocorticoid receptors, neurotrophic factors, and gene expression. The antidepressants, including tricyclics, appear to have neuroprotective effects. They raise levels of BDNF and promote neurogenesis in the hippocampus. A particularly intriguing finding is the observation of an association of decreased hippocampal volume with lifetime duration of *untreated* depression, implying that antidepressant treatment might protect against this outcome. A 2017 repositioning study screened 249 generic compounds that cross the blood–brain barrier for a variety of neurotrophic effects. Of these compounds, clomipramine appeared most promising. It inhibited iron-mediated neurotoxicity, had antioxidative properties, and reduced T-lymphocyte proliferation, among its effects. The use of clomipramine in multiple sclerosis or to reduce the “cytochrome storm” associated with COVID-19 has been suggested. Yet, at the present time, the role of these neuroprotective effects in mediating the actual antidepressant effects of tricyclics remains unclear.

The reuptake inhibition of the tricyclics and tetracyclic compounds also occurs in descending pathways of the spinal cord and contributes to analgesic effects. Animal studies suggest that serotonin and norepinephrine have independent synergistic effects on pain. In addition, the effects of tricyclics on sodium channels also contribute to their analgesic effects, although these same effects appear to be responsible for the dose-dependent delay in cardiac conduction.

The tricyclic and tetracyclic compounds have *secondary* effects on a variety of other receptors (Table 33.5a.3–2). These compounds block muscarinic receptors, producing anticholinergic effects. They block histamine-1 (H_1) receptors, and they block α_1- and α_2-adrenergic receptors. They affect fast sodium channels, and this explains their adverse cardiac effects. The potency of these various secondary effects varies considerably. Amitriptyline is the most anticholinergic. Doxepin is the most potent H_1 antagonist among the tricyclics, although it is less potent at this receptor than mirtazapine (Remeron).

Plasma Concentrations and Relation to Response. The wide interindividual variability of tricyclic plasma concentrations suggested that plasma level drug monitoring might ensure that therapeutic blood levels were achieved and might help to avoid toxic levels. In carefully selected endogenous or melancholic inpatients with major depression, treatment with adequate levels of imipramine or desipramine did result in response rates of approximately 85%. Alternatively, the careful selection of patients in these studies may result in samples not representative of typical clinical practice.

An American Psychiatric Association (APA) task force reviewing the evidence concluded that a relationship between blood levels and response had been demonstrated for imipramine, desipramine, and nortriptyline (Table 33.5a.3–1). For imipramine, drug levels greater than 200 ng/mL were more effective than lower levels. For desipramine, levels greater than 115 ng/mL were more effective. For desipramine and imipramine, blood levels of more than 300 ng/mL were more likely to be associated with serious side effects. Effective plasma concentrations were also established for nortriptyline, but the relationship appeared to be curvilinear: Plasma levels between 50 ng/mL and 150 ng/mL were more effective than levels outside this window.

For amitriptyline, it was difficult to establish a therapeutic relationship between levels and response. In part, this was related to the fact that during amitriptyline administration, amitriptyline, nortriptyline, and hydroxynortriptyline are all present and active. Amitriptyline responders usually have total amitriptyline and nortriptyline levels between 150 and 250 ng/mL, but there is no good agreement between studies. For clomipramine, blood levels of 150 to 300 ng/mL (total of clomipramine and desmethylclomipramine) have been suggested for antidepressant effectiveness. Higher doses and levels are usually used in the treatment of OCD. The data relating to blood levels and response are limited for the other tricyclic and tetracyclic compounds.

The clinical value of blood level monitoring has been the subject of much debate. Although relationships between blood levels and response have been best demonstrated in melancholic inpatients, it has proven difficult to demonstrate a relationship between blood levels and response in depressed outpatients. In this group, placebo rates are high, the difference between drug and placebo is modest, and the effect of drug treatment is harder to detect. Moderately depressed outpatients are a heterogeneous group and include patients who are not responsive to drug treatment. Finally, many studies are not designed to detect blood level–response relationships. It is logical to conclude that blood level relationships determined in severely depressed inpatients might be used as a guide for treating outpatients, but that has not been empirically confirmed.

The case study provided here gives an example of blood level monitoring.

A 74-year-old man was admitted to the hospital with severe depression. Irritability was prominent. Desipramine was started, but on 150 mg/day, he had no response whatsoever. He was adherent to treatment. Some of his symptoms seemed atypical, and the diagnosis was questioned. A blood sample revealed a very low drug concentration. In fact, the level suggested that if kinetics were linear, he would need a dose of 900 mg/day to achieve a therapeutic level. On 400 mg/day, the approved maximum dose, his plasma level was still subtherapeutic. On 600 mg, his level rose disproportionately. He achieved an adequate level and responded.

The case illustrates several issues. Blood levels can be useful for guiding dose adjustment in nonresponding patients. The extremely low plasma concentration on a conventional dose suggested he might be an ultrafast metabolizer. Nonlinear kinetics are most likely to occur in fast metabolizers. Ironically, this 74-year-old man had the lowest concentration-to-dose ratio encountered among over 400 patients treated with desipramine.

The alternative question is whether blood level monitoring might help avoid toxicity. A variety of data support this view. The risk of delirium is increased at amitriptyline plasma concentrations greater than 300 ng/mL. However, amitriptyline is the most anticholinergic tricyclic and is most likely to produce delirium. The risk of cardiac arrhythmia also is substantially increased at higher blood levels. First-degree atrioventricular block is increased with plasma concentrations of imipramine greater than 350 ng/mL. The risk of seizures also increases in patients at higher doses and, presumably, at higher blood levels, although a clear plasma level threshold has not been demonstrated for seizures. The risk of seizures for clomipramine is 1.66% with doses greater than 250 mg/day but is approximately 0.50% for doses less than 250 mg/day. In one large sample of patients with OCD at steady-state on 250 mg/day of clomipramine, the average blood level was 155 ng/mL for clomipramine and 335 ng/mL for desmethylclomipramine, or a total of 490 ng/mL. For the older drugs, amitriptyline and imipramine, the risk of seizures also appears to be increased at doses greater than 250 mg/day. For patients who are especially vulnerable to delirium, delayed cardiac conduction, or seizures, adverse events can occur at levels below those cited above. After an overdose, tricyclic blood levels greater than 1,000 ng/mL can be achieved, and the risks of delirium, stupor, cardiac abnormalities, and seizures are all substantially increased.

One of the problems in exploring the relationship of toxicity to increased blood levels is that, although the risk may increase, actual rates are still low, and large samples are required to demonstrate any difference in risk. For certain types of toxicity, there may be no early signs of impending seizures or cardiac arrhythmia to alert the clinician. Blood level monitoring might be most useful to reduce the risk of these side effects.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Design

Early in the history of tricyclics, there was interest in which patients or which conditions would respond to these medications. Yet, defining an adequate trial proved challenging. In early trials, high rates of response to placebo were noted; thus, open-label studies proved to be of limited value. Because of side effects, the tricyclics were started at a low dose and increased slowly, often resulting in subtherapeutic dosing. Subsequently, blood levels were employed to achieve adequate doses; however, the determination of effective blood levels itself proved challenging. Some early studies were quite brief (e.g., 3 to 4 weeks) and may have underestimated drug effects. As experience grew, randomized, double-blind, placebo-controlled, or comparison trials of adequate dose and duration became the yardstick by which efficacy was determined and “tricyclic responders” defined.

Interpretation

The clinical efficacy of the tricyclic and tetracyclic compounds in major depression is well-established and has been extensively reviewed by John Davis and Alexander Glassman in the fifth edition of this text and in the Agency for Health Care Policy and Research (AHCPR) Clinical Practice Guideline. Imipramine is the best-studied compound. In 44 placebo-controlled studies, imipramine was more effective than placebo in

30 studies. Overall, in studies reporting response rates ($N = 1{,}334$), 65% of the patients *completing* treatment with imipramine were substantially improved, whereas 30% of those on placebo were similarly improved. In a meta-analysis of *intent-to-treat* response rates for placebo-controlled studies of tricyclics in outpatients reported in the AHCPR guideline, response rates were 51% for imipramine and 30% for placebo. In most comparison studies, the other tricyclic and tetracyclic antidepressants have been found to be comparable to imipramine in efficacy.

In addition to efficacy in acute phase treatment of major depression, the tricyclic compounds are also effective for maintenance treatment. Several early studies demonstrated that maintenance treatment with a tricyclic would reduce the relapse rate associated with a placebo by approximately 50%. These studies, however, often used low doses. Subsequently, an important study by the Pittsburgh group found that if the full dose of imipramine used for acute treatment was continued, nearly 80% of the depressed patients maintained their improvement, whereas only 10% of those on placebo remained well at the end of a 3-year period. In this study, maintenance psychotherapy had an intermediate effect, with approximately 30% of the patients remaining well. This study again confirmed the value of maintenance treatment and underscored the importance of continuing the full dose of imipramine. The magnitude of the findings may, in part, relate to the sample selected, namely, patients with recurrent depression who had been symptom-free between prior episodes. In clinical practice, if patients with chronic depression, prior residual symptoms, or comorbid psychiatric disorders are included, the number of patients who remain in remission may be lower.

Efficacy in Subtypes

The efficacy of the tricyclic compounds varies in different subtypes of depression. Kuhn thought it was essential to establish the efficacy of imipramine in *endogenous* inpatients. The tricyclic compounds have been frequently studied in severely depressed inpatients and were found to be effective. It has been suggested that tricyclics may be more effective than SSRIs in severe major depressive disorders with melancholic features. The issue remains unsettled, in part, because of the paucity of studies on the SSRIs in severe melancholic depression. In addition, it was unclear if the suggested advantage of some tricyclics in severe depression was unique to tricyclics as a class or applied to those tricyclics, particularly clomipramine, that had potent effects on both serotonin and norepinephrine.

The tricyclic and tetracyclic compounds have often been studied in *anxious depression*. Three of the compounds—doxepin, amoxapine, and maprotiline—have FDA approval for use in patients with depression and symptoms of anxiety. For many years, clinical lore suggested that amitriptyline was most effective for anxious depression. Direct comparison studies, however, found little evidence that these compounds differ in their efficacy for the treatment of anxiety associated with depression. Alternatively, three studies found that, among depressed patients, those with high levels of anxiety responded less well to amitriptyline, imipramine, or desipramine than those with lower levels of anxiety. Yet, these drugs are still more effective than placebo in anxious-depressed patients, and it is not established that other classes of antidepressants are more effective in anxious-depressed patients.

In patients with *atypical features* (defined by DSM-IV criteria), imipramine is more effective than placebo but significantly less effective than the MAOI phenelzine. Little information is available regarding comparisons of the tricyclics and the SSRIs in atypical depression.

Major depression with *psychotic features* is less responsive than nonpsychotic depression to tricyclic antidepressants used alone. Several open studies and one prospective study found that the tricyclics, when combined with an antipsychotic, were effective in psychotic depression. Yet other trials did not find an antidepressant/antipsychotic combination more effective than nortriptyline, imipramine, or trimipramine monotherapy. One double-blind study compared the efficacy of amoxapine with the combination of perphenazine (Trilafon) and amitriptyline, finding amoxapine to have comparable efficacy in psychotic depression. It was suggested that the antipsychotic action of 7-hydroxyamoxapine might explain the efficacy of this compound in psychotic depression.

In controlled studies of patients with *bipolar depression*, imipramine was found to be less effective than tranylcypromine (Parnate) or fluoxetine (Prozac). These studies and others suggest that tricyclics appear to be more likely to induce mania than serotonergic agents or bupropion (Wellbutrin).

In the AHCPR review of drug trials in *late-life depression*, tricyclic antidepressants appear to be effective, but, overall, drug and placebo response rates appear to be lower than in non-older adult patients. Efficacy in the older adults may have, in part, reflected cautious dosing because of safety and tolerance concerns. In children and adolescents, tricyclic antidepressants have not demonstrated superiority over placebo. An FDA review of clinical trials of second-generation antidepressants revealed an increased risk of suicidal thinking and suicide-related behaviors in children, adolescents, and young adults under the age of 25. Although this risk has not been established for tricyclics, the warning has been extended to all antidepressants.

Tricyclic antidepressants are effective in *dysthymia*. Controlled trials suggest both imipramine and desipramine are effective for acute treatment of dysthymia and for maintenance treatment.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Somatic symptoms that occur during treatment are the result of the interaction of direct effects of the medication on specific organs and indirect effects of the medication on depression and its associated somatic symptoms. Depression is accompanied by a variety of somatic symptoms. Headache, constipation, poor memory, drowsiness, and difficulty sitting still have been observed in more than 50% of untreated inpatients with major depression. Other symptoms, such as palpitations, dry mouth, tremors, light-headedness, and poor coordination, are reported by more than 40% of depressed patients before treatment. The determination of whether a somatic symptom is an adverse drug effect or a symptom of depression involves a judgment about whether the symptom is new or has worsened during drug treatment. Severely depressed patients may not remember the severity of a symptom prior to treatment accurately. During treatment, the strongest predictor of overall somatic symptom severity is the level of depression at the time of assessment.

Antidepressant drugs do have adverse effects. The in vitro potency or affinity of antidepressant compounds for various receptor sites (Table 33.5a.3–1) is one method for comparing the likelihood that various agents will produce side effects. The other pharmacologic factor that needs to be considered is the bioavailability of the drug.

Central Nervous System

In the CNS, the principal action of the tricyclic and tetracyclic agents is to alleviate depression. These agents do not have a direct mood-elevating effect. They do not produce euphoria. Rather, they reduce the symptoms of depression. Apparently related to their effects on brain amines, these compounds can cause or aggravate psychotic symptoms and can induce mania.

The central anticholinergic and antihistaminic effects of tricyclics and tetracyclics can produce confusion or delirium. The incidence of delirium is dose-dependent and increases at blood levels greater than 300 ng/mL and may rise to 67% in patients with blood levels greater than 450 ng/mL and in patients receiving tertiary amines, particularly amitriptyline. Patients with dementia or early Alzheimer disease are more vulnerable to the anticholinergic effects of the tricyclics, and delirium can occur in these patients at lower drug concentrations.

Seizures can occur with all the tricyclic and tetracyclic agents. Seizures are dose- and blood-level related. For clomipramine, the risk for seizures is reported to be 0.5% in doses up to 250 mg/day. At doses greater than 250 mg/day, the seizure risk increases to 1.67%. For maprotiline, the overall risk of seizures is reported to be 0.4%, but, again, the risk of seizures increases at doses greater than the maximum recommended dose of 225 mg/day. Determination of seizure risk for some of the older compounds was hampered by less rigorous data collection during drug development. In one meta-analysis of data for imipramine, patients receiving less than 200 mg had a seizure rate of 0.1%. In patients receiving more than 200 mg/day, the rate was 0.6%. In patients receiving 250 to 450 mg/day, reported rates varied from 1% to 4%, but these samples were often small. Thus, these rates had wide confidence intervals. Seizure rates for the secondary amines have not been well-described. The mechanism by which tricyclics produce seizures is not well-understood, although it is proposed that antidepressant drugs may act at the GABA receptor chloride–ionophore complex, inhibiting chloride conductance and consequently inducing convulsions. The risk of convulsions is clearly increased in patients with predisposing factors, including a prior history of seizures, brain injury, and concurrent use of neuroleptics. The risk of seizures is substantially increased after overdose.

A fine rapid tremor can occur with the tricyclic agents, tends to be dose-dependent, and may be a clinical indication of an elevated blood level.

Because the 7-hydroxymetabolite of amoxapine has neuroleptic properties, administration of amoxapine carries the potential risk of a neuroleptic malignant syndrome, which has been reported, and tardive dyskinesia.

A 73-year-old male was referred for evaluation of his antidepressant. He had had a good response to desipramine, but it had taken some time to achieve it. He now had a fine rapid tremor that was quite bothersome. Both the patient and his physician were concerned that reducing the dose would compromise antidepressant efficacy. A blood sample revealed a desipramine concentration of over 300 ng/mL. His dose was adjusted to achieve a level of about 150 ng/mL. His tremor resolved, but the antidepressant effect was maintained.

Several of the tricyclic compounds and maprotiline have clinically significant antihistaminic effects. Doxepin is the most potent H_1-receptor blocker of the tricyclics, although mirtazapine and olanzapine are more potent. Central H_1-receptor blockade can contribute to sedation and delirium. Antihistaminic effects also appear to be related to increased appetite and associated weight gain.

Autonomic Nervous System

The tricyclics block muscarinic receptors and can cause a variety of anticholinergic side effects. These include dry mouth, constipation, blurred vision, urinary hesitancy, and an ocular crisis in patients with narrow-angle glaucoma. The tricyclic and tetracyclic compounds vary substantially in their muscarinic potency (Table 33.5a.3–2). Amitriptyline is the most potent, followed by clomipramine. Desipramine is the least anticholinergic. Amoxapine and maprotiline also have minimal anticholinergic effects. Anticholinergic effects can contribute to tachycardia, but tachycardia commonly occurs in patients receiving desipramine, which has minimal anticholinergic effects. It seems likely that noradrenergic effects also contribute to increased pulse. Increased sweating is another secondary effect of the tricyclic compounds that can occur. The mechanism for this symptom is unclear but may be associated with noradrenergic effects.

Cardiovascular Effects

Orthostatic hypotension is one of the most common reasons for discontinuation of tricyclic antidepressant treatment. Orthostatic hypotension can occur with all the tricyclics but is less pronounced with nortriptyline. It has been suggested that orthostatic hypotension is caused by α_1-adrenergic blockade; however, it is the postural reflex that is primarily affected. Resting supine blood pressure may be unaffected or may be elevated. Orthostatic hypotension is most likely to occur or is most severe in patients who have pre-existing orthostatic hypotension.

Desipramine has been reported to raise supine blood pressure in younger patients, although it is not clear that this effect is limited to that age group. This effect may be like that reported for venlafaxine (Effexor).

Tachycardia occurs with all tricyclics, not just the more anticholinergic agents. Supine and postural pulse changes can occur. Patients do not accommodate the pulse rise, which can persist for months. Tachycardia is more prominent in younger patients, who appear to be more sensitive to sympathomimetic effects, and is one of the most common reasons for drug discontinuation in this age group.

The exploration of the effect of tricyclic antidepressants on cardiac conduction has received much attention. *Cardiac arrhythmia* is the principal cause of death after overdose. As a result, for many years, there was great concern about the use of tricyclic antidepressants in patients with heart disease. The effect of these agents has now been well-described. These agents have type I antiarrhythmic qualities or quinidine (Cardioquin)-like effects. Apparently, through inhibition of Na^+:K^+ adenosine triphosphatase (ATPase), the tricyclics stabilize electrically excitable membranes and delay conduction, particularly His-ventricular conduction.

At therapeutic blood levels, tricyclics can have beneficial effects on ventricular excitability. Alternatively, in patients with pre-existing conduction delay, tricyclic antidepressants can further delay conduction and cause heart block. High-drug plasma levels further increase the risk of cardiac toxicity. For example, first-degree atrioventricular heart block is increased with imipramine plasma concentrations greater than 350 ng/mL and is increased more than 30-fold in patients with plasma concentrations greater than 450 ng/mL.

The tricyclic antidepressants do not appear to adversely affect cardiac contractility or cardiac output. Studies using radionuclide angiography indicate no adverse effect of imipramine or doxepin on cardiac output, even in patients with diminished left ventricular ejection fractions. However, it is noted that severe orthostatic hypotension was common in these patients.

Another potential hazard of tricyclic treatment was suggested by the Cardiac Arrhythmia Suppression Trial (CAST) studies, which found that type I antiarrhythmic drugs are given after myocardial infarction increased the risk of sudden death. Alexander Glassman and associates suggested that tricyclics may pose similar risks. Thus, the clinician considering the long-term use of tricyclics in patients with ischemic heart disease needs to weigh this possible risk against possible benefits.

Hepatic Effects

Drug-induced hepatitis can occur with these agents. Mild increases in liver enzymes are not uncommon and usually can be monitored safely over a period of days or weeks without apparent harmful consequences. However, acute hepatitis can occur quickly and is associated with high enzyme levels; for example, serum aspartate aminotransferase (AST) levels may be elevated 20-fold. The rise in enzymes can be hepatocellular or cholestatic in form and may precede clinical symptoms, especially in the hepatocellular form. This is a dangerous and potentially fatal condition. The antidepressant must be discontinued. The etiology is not well-established but, in some cases, appears to be a hypersensitivity reaction. The risk of severe drug-induced hepatitis is not well-established but appears to be between 1 in 1,000 and 1 in 100.

THERAPEUTIC INDICATIONS

Indications

The tricyclic and tetracyclic compounds have a variety of clinical uses. In fact, it is interesting to consider what these agents might have been called had their effectiveness in panic disorder, OCD, or pain been described before their antidepressant action was observed.

The FDA approved all tricyclic and tetracyclic compounds discussed in this section for use in the United States for the treatment of depression, with the exception of clomipramine. In Europe, clomipramine is also used for depression and, in fact, is regarded by many as the most potent antidepressant. Clomipramine acts on serotonin and norepinephrine, and the empirical data suggest that it is more effective than selective serotonin agents in severely depressed inpatients.

Although a variety of antidepressants appear to be effective in depressive disorders, this is not the case for OCD. In this instance, serotonergic antidepressants, such as clomipramine, appear to be substantially more effective than noradrenergic tricyclics, such as desipramine. Among the tricyclic drugs, clomipramine is the only agent approved by the FDA for use in OCD.

Other Indications

Tricyclic agents have been used for a variety of other clinical indications without FDA approval. Tricyclic antidepressants are effective in panic disorder; in fact, imipramine was the first drug found to be effective in these patients.

Amitriptyline has been a popular drug for the treatment of chronic pain syndromes and migraine headache prophylaxis. Over 60 placebo-controlled clinical trials of tricyclics or tetracyclics have been conducted in various chronic pain syndromes, including headache, back pain, fibromyalgia, gastrointestinal discomfort, idiopathic pain, and tinnitus. In fact, the magnitude of their effects on chronic pain appears greater than that in depression. For example, in meta-analyses of placebo-controlled pain trials, one patient out of three treated would benefit versus one out of six patients treated in depression trials. The analgesic effects appeared, at least in part, to be independent of antidepressant effects. In humans, comparison studies suggested tricyclics with effects on both serotonin and norepinephrine were more effective than agents selective for one neurotransmitter. During treatment of pain, the dose of amitriptyline ranged from 25 mg/day to 150 mg/day, with 75 mg/day being an approximate median dose. This dose is lower than that in depression, and effects occur more quickly, usually within the first 2 weeks. These differences suggest a different mode of action of amitriptyline in pain syndromes. The tricyclics appear to be of some benefit in chronic fatigue syndrome.

For many years, desipramine was commonly prescribed for ADHD in children. Reports of cases of sudden death, apparently of cardiac origin, in children younger than 12 years of age substantially reduced the use of this drug in younger patients. Imipramine has been used with FDA approval for the treatment of nocturnal enuresis in children. Usual doses are 25 to 50 mg at bedtime. It is doubtful, however, that the risk of cardiac problems would be substantially less with imipramine than with desipramine in young children.

Nortriptyline has been shown to be helpful for smoking cessation in controlled studies, but it is not approved for use in this syndrome.

Taking advantage of its antihistaminic effects, topical doxepin (Zonalon) is FDA-approved for use in pruritus associated with atopic dermatitis and lichen simplex chronicus. Doxepin (Silenor) is approved for use in insomnia at doses of 3 or 6 mg/day.

Tricyclic antidepressant drugs have been extensively studied in schizophrenic patients. However, in the absence of a major depressive syndrome, they appear to be of limited value, and their use for the treatment of negative symptoms has been eclipsed by the introduction of atypical neuroleptics.

PRECAUTIONS AND ADVERSE REACTIONS

Central Nervous System Effects

The central effects of tricyclics can produce delirium and seizures. These adverse effects are more frequent at blood levels greater than 300 ng/mL and are more common with amitriptyline. Recognition of delirium is important because the signs of delirium may be mistaken for worsening depression. Patients with concurrent dementia are particularly vulnerable to the development of delirium. Intramuscular (IM) or intravenous (IV) physostigmine (Eserine Salicylate) can reverse or reduce the symptoms of delirium. However, the short duration of action of this agent makes its continued use difficult. Because the risk of delirium and seizures increases at higher tricyclic plasma concentrations, some experts advocate routine blood level monitoring, especially in patients at increased risk, for example, older adults, patients with dementia, or patients with a history of seizures.

Tricyclic antidepressants can cause a fine rapid tremor. This adverse event is often associated with elevated plasma concentrations and may improve with dose reduction.

Because the 7-hydroxymetabolite of amoxapine has neuroleptic effects, this agent can potentially cause tardive dyskinesia and neuroleptic malignant syndrome. Although the occurrence of these adverse events is rare, the seriousness of the risk serves as a relative contraindication to this product unless the clinical condition warrants the use of an agent with antipsychotic properties.

Autonomic Effects

Tricyclics can cause a variety of anticholinergic side effects, including dry mouth, constipation, visual changes, urinary hesitancy, delirium, and an ocular crisis in patients with narrow-angle glaucoma. The use of nortriptyline or desipramine, which are less anticholinergic, can help reduce the likelihood of these problems.

Usually, anticholinergic effects are annoying but not serious. In some circumstances, however, these effects can be severe. An ocular crisis in patients with narrow-angle glaucoma is an acute condition associated with severe pain. Urinary retention can be associated with stretch injuries to the bladder. Constipation can progress to severe obstipation. (Paralytic ileus has been described but is rare.) Medication must be discontinued, and appropriate supportive measures must be instituted. Older adult patients appear most vulnerable to this adverse consequence. The frequency of severe anticholinergic adverse reactions is increased by concomitant neuroleptic administration.

Some anticholinergic effects may benefit from other interventions. Patients with urinary hesitancy may benefit from the use of bethanechol (Urecholine) at a dose of 25 mg three or four times daily. Patients with constipation often benefit from regular use of stool softeners. Patients with narrow-angle glaucoma who are receiving pilocarpine (Pilocar) eye drops regularly can be treated with a tricyclic, as can those who have had an iridectomy. Tricyclic agents do not affect patients with chronic open-angle glaucoma.

Cardiovascular Effects

Orthostatic hypotension is the most common reason for discontinuation of tricyclic antidepressant treatment. It is most likely to be problematic in patients with pre-existing orthostatic hypotension. Older adults are more likely to have pre-existing hypotension and are also more vulnerable to the consequences of orthostatic hypotension—falls and hip fractures. Orthostatic hypotension can occur at blood levels that are relatively low. Although the subjective experience of light-headedness usually improves with time, the actual orthostatic blood pressure change does not accommodate within a reasonable period (e.g., 4 weeks). Consequently, unless the plasma level is elevated and the dose can be reduced, patients who experience serious symptomatic orthostatic hypotension may not be treatable with a tricyclic antidepressant. Fludrocortisone (Florinef) has been used to raise blood pressure, but it is not very effective. If patients are taking an antihypertensive, it may be possible and helpful to reduce these agents. Orthostatic hypotension is less common with nortriptyline.

Tachycardia occurs with all tricyclics, not just the more anticholinergic agents. The supine pulse rate commonly increases by 8 to 10 beats/min. The standing pulse can be markedly elevated. Patients do not accommodate the pulse rise, which can persist for months. Although an 8 to 10 beat/min increase in heart rate may be subjectively tolerated by the patient, in the older adults, a sustained increase in cardiac work can be detrimental. Tachycardia is more prominent in younger patients, who appear to be more sensitive to the sympathomimetic effects of these agents, and is one of the most common reasons for drug discontinuation in this age group. Propranolol (Inderal) at low doses may help to reduce tachycardia unless it is associated with significant hypotension.

Cardiac Conduction Effects

Tricyclic antidepressants have type I antiarrhythmic effects. In patients without conduction delay, tricyclics are well-tolerated. They may be helpful in patients with premature ventricular beats. However, in patients with pre-existing conduction delay, tricyclic antidepressants can further delay conduction and can cause heart block. Patients with a QTc interval of 450 msec or greater are at increased risk and are not candidates for tricyclic antidepressant treatment. The risk of cardiac toxicity is increased in patients with high plasma levels and greatly increased with overdose.

Hepatic Effects

Mild increases in liver enzymes usually can be monitored safely over a period of days or weeks without apparent harmful consequences. However, acute hepatitis develops quickly, over 3 to 4 days, and is associated with high enzyme levels, for example, a 20-fold increase in AST levels. This can be life-threatening, and the antidepressant must be discontinued. If it is clear which drug caused hepatitis, that drug should not be introduced again because the next reaction may be more severe. However, it is not uncommon for the patients to be receiving several medications so the offending agent is hard to identify. If a random blood test indicates mildly elevated liver enzymes, enzyme levels can be followed for a few days to distinguish the more severe form of hepatitis from mild enzyme elevations.

Other Adverse Effects

Sexual dysfunction is a potential problem with a variety of antidepressant drugs but appears to be more frequent with clomipramine. Unlike many of the side effects that are more likely to be reported early in treatment, this side effect may be more bothersome to the patient in the second or third month of treatment after the depression has improved. Numerous pharmacologic antidotes have been described but without much success.

Tricyclic antidepressants can cause allergic skin rashes. They are sometimes associated with photosensitivity reactions. Various blood dyscrasias also have been reported, but fortunately, these are very rare.

Overdose

Because the risk of overdose is increased in depressed patients, the target population for which antidepressants are used, the lethality of antidepressant drugs in overdose is of great concern. A tricyclic overdose of 10 times the daily dose can be fatal. Death most commonly occurs because of cardiac toxicity. However, seizures and respiratory depression can occur. Amitriptyline is one of the leading causes of death by overdose for any single drug in the United States because of its high mortality risk and common use. A 15-year study (2000 to 2014) of single drug ingestions found more deaths from amitriptyline than all other TCAs combined and all second-generation antidepressants combined. The mortality risk with the TCAs was 25-fold higher than with SSRIs. The other tricyclic and tetracyclic compounds are also dangerous in overdose, although their use has diminished. Desipramine has the highest fatality rate (deaths per ingestion) among the tricyclics. Amoxapine has been reported to produce high rates of seizure in overdose. The morbidity and mortality risks for clomipramine were lower than for other TCAs. Because the second-generation antidepressants are safer in overdose, subtle differences in lethality between the tricyclic and heterocyclic compounds have become relatively unimportant.

Teratogenicity and Pregnancy-Related Risks

A definitive link between the tricyclic compounds and tetracyclic compounds and teratogenic effects has not been established, although isolated reports of morphogenesis have been reported. Tricyclics cross the placenta, and neonatal drug withdrawal can occur. This syndrome includes tachypnea, cyanosis, irritability, and poor sucking reflex. If possible, tricyclic and tetracyclic medications should be discontinued 1 week before delivery. Recently, norepinephrine and serotonin transporters have been identified in the placenta and appear to play an important role in the clearance of these amines in the fetus. The understanding of the effects of reuptake inhibitors on these transporters during pregnancy is limited, but one study compared intelligence and language development in 80 children exposed to tricyclics during pregnancy with 84 children exposed to other nonteratogenic agents and found no deleterious effects of the tricyclics. The tricyclics are excreted in breast milk at concentrations similar to plasma. The actual quantity delivered, however, is small so that drug levels in the infant are usually undetectable or very low. Because the risk of relapse is a serious concern in patients with recurrent depression, and these risks may be increased during pregnancy or the postpartum period, the risks and benefits of continuing or withdrawing treatment need to be discussed with the patient and weighed carefully.

DRUG INTERACTIONS

There are two principal types of drug interactions: pharmacodynamic and pharmacokinetic. Pharmacodynamic interactions are those in which the actions of two drugs interact. The effects may be deleterious. Because the tricyclics have acute effects on amine uptake, they are potentially dangerous when given with the MAOIs. The most dangerous sequence is to give a large dose of a tricyclic to a patient already on an MAOI. This can result in a sudden increase in catecholamines and a potentially fatal hypertensive reaction. If used cautiously, these two compounds can be used together to treat patients with refractory depression. Treatment is begun with lower doses, and the two compounds are started together, or the tricyclic is started first. Once begun, coadministration may reduce the risk of tyramine reactions; however, because the protective effect is variable and unpredictable, the usual MAOI diet is maintained.

Other pharmacodynamic interactions can occur. By blocking the transporters, the tricyclics block the uptake and thus interfere with the action of guanethidine (Ismelin). Quinidine poses two problems. First, the tricyclics have quinidine-like effects. Thus, their effects on cardiac conduction are potentially additive with those of quinidine. In addition, quinidine is a potent enzyme inhibitor that can raise tricyclic levels, further adding to the problem.

Pharmacokinetic Interactions

Several drugs can block the metabolic pathways of the tricyclics, resulting in higher and potentially toxic levels. Desipramine has been of particular interest because it is metabolized via the CYP 2D6 isoenzyme, and there are no major alternative pathways. Inhibition of CYP 2D6 can result in high desipramine plasma levels. Quinidine, mentioned previously, is a potent CYP 2D6 inhibitor. Several psychotropic drugs are 2D6 inhibitors, including fluoxetine, paroxetine (Paxil), duloxetine (Cymbalta), and bupropion. For example, fluoxetine 20 mg/day, on average, raises desipramine levels three- to fourfold in extensive metabolizers. In slow metabolizers, enzyme inhibitors have less of an effect because the patient is already deficient in this enzyme. At moderate doses, sertraline (Zoloft), citalopram (Celexa), and escitalopram (Lexapro) have less potent effects on CYP 2D6, but at high doses may have appreciable effects in some patients. Venlafaxine, nefazodone (Serzone), and mirtazapine appear to have minimal effects on CYP 2D6. It would be expected that CYP 2D6 inhibitors would also block nortriptyline metabolism, but the magnitude of this interaction has not been well-studied.

The other group of drugs commonly used in psychiatry, which interact with the tricyclics, is the antipsychotic drugs. Chlorpromazine and perphenazine, at antipsychotic doses, inhibit CYP 2D6. The magnitude of the effect appears to be somewhat less than that of fluoxetine. For example, perphenazine, on average, raises desipramine levels twofold, but this effect varies with dose and varies with the neuroleptic used.

Because the tertiary tricyclics are metabolized by several pathways (CYP 1A2, CYP 3A4, and CYP 2C19), inhibition of one of these pathways has less of an effect on these compounds. Drug interactions with the tertiary amines do occur but appear to be less robust than that for desipramine.

Enzyme induction also occurs. Unlike enzyme inhibition, which occurs quickly, enzyme induction requires the synthesis of a new enzyme. As a result, the full effect of an enzyme inducer may take 2 to 3 weeks to develop and, similarly, if the inducer is discontinued, it takes 2 to 3 weeks to dissipate. Barbiturates and carbamazepine (Tegretol) are two potent inducers commonly encountered in psychiatry. Although CYP 2D6 is a noninducible isoenzyme, phenobarbital (Luminal) reduces the availability of desipramine by approximately 40%. Apparently, CYP 3A4 is induced, becomes a more important pathway, and the metabolism of desipramine is increased. It can be difficult to attain an effective blood level with a tricyclic in the presence of barbiturates or carbamazepine. Phenytoin (Dilantin) is also an enzyme inducer, but the magnitude of its effects on the tricyclics appears to be less dramatic. Nicotine induces the CYP 1A2 pathway and may affect the tertiary tricyclics, but the secondary tricyclics, such as desipramine, are less affected.

Alcohol has a complicated interaction with tricyclics. Acute ingestion of alcohol can reduce first-pass metabolism, resulting in higher tricyclic levels. Because of the association of alcohol use with overdose, this can be an important factor resulting in higher tricyclic levels after overdose. Alternatively, chronic use of alcohol induces hepatic isoenzymes and may lower tricyclic levels.

Although most of the known drug-drug interactions have focused on interactions involving the CYP450 system, there is a growing body of literature examining the role of P-GP in drug interactions. P-GP plays an active role in the blood–brain barrier resulting in the efflux of some drugs from the CNS. Several of the tricyclics—amitriptyline, desipramine, doxepin, imipramine, nortriptyline, and trimipramine—are P-GP substrates. Drugs such as verapamil and quinidine inhibit P-GP, potentially leading to increased CNS concentrations of P-GP substrates. Some antidepressants, such as sertraline and paroxetine, are also P-GP inhibitors with effects equivalent to quinidine. The clinical consequences of these potential interactions in humans are not well established, but inhibition of P-GP may increase efficacy but also increase adverse effects.

LABORATORY INTERFERENCES

The tricyclic compounds are present at low concentrations (ng/mL) and are not likely to interfere with other laboratory assays. It is possible that they may interfere with the determination of conventional neuroleptic blood concentrations because of their structural similarity and the low concentrations of some neuroleptics.

Two types of assays are performed for the tricyclic and tetracyclic antidepressants. After an overdose, an immunoassay is commonly performed to determine if a tricyclic is present and to estimate the level. This assay is sensitive, simple to perform, and can be done quickly. The immune assays, however, are not specific, can cross-react with metabolites and other drugs, and thus are not precise quantitative measures. For therapeutic drug monitoring, a quantitative measure is needed, and a slower turnaround time for the laboratory is usually acceptable. For this purpose, high-performance liquid chromatography (HPLC) is sufficiently precise and is usually employed. In a competent laboratory, the coefficient of variation is less than 10%. This assay is relatively specific; however, other drugs can interfere. Because there are many modifications of the HPLC technique, and because the drugs that interfere depend on these modifications (the extraction method, the column used), the interfering drugs vary among labs. A clinician who frequently obtains tricyclic plasma levels is best advised to use one laboratory and to find out from that laboratory what agents interfere with their assay.

DOSAGE AND ADMINISTRATION

At one time, amitriptyline and imipramine were the two most commonly prescribed antidepressants in the United States, but because of their anticholinergic and antihistaminic side effects, their use declined, and nortriptyline and desipramine became more popular. Nortriptyline has the least effect on orthostatic hypotension, and desipramine is the least anticholinergic. Because therapeutic plasma concentrations have been established for nortriptyline and desipramine, blood level monitoring can be used to ensure that a therapeutic level is achieved.

Most studies of nortriptyline find that the average dose needed to reach a blood level of 100 ng/mL is approximately 75 mg/day; however, there is considerable variability. For desipramine, the average dose required to reach a target level of 150 ng/mL is 3.0 mg/kg or 180 mg/day for a 60-kg patient. Nortriptyline and desipramine can be adjusted to a full dose quickly, but the clinician needs to assess factors such as medical health, age, other medications present, and the severity of the depression when deciding how quickly to adjust the dose. The dose can be given once a day at bedtime and, if tolerated, can be increased every 3 days. The target dose can then be determined in one of two ways. An average dose can be targeted (e.g., nortriptyline 75 mg/day), and blood levels employed only if the patient fails to respond. Alternatively, a blood level can be drawn after 5 to 7 days on a moderate dose, 50 to 75 mg/day, and used to guide further dose adjustment for the trial. Because the kinetics of nortriptyline are linear, a proportional adjustment in dose can be made to reach a target level of 100 ng/mL. The advantage of the latter method is that one drug trial at an adequate blood level should establish if the drug is effective. Because nortriptyline has a therapeutic window, if the plasma level is near the upper limit of 150 ng/mL, a reduction in dose could be considered. Desipramine dose can also be adjusted relatively proportionately, with the exception that patients with low initial plasma levels (rapid metabolizers) are likely to have nonlinear changes. Plasma concentration–guided dose adjustment should reduce the time to achieve an effective dose (as opposed to a series of trials at gradually increasing doses) and should be of benefit in severe depression. Once the patient is at an adequate dose, treatment should then be continued for an adequate duration. At the time of the initial clinical trials of the tricyclics, trial duration was often short, 4 to 6 weeks. Recently, trials of up to 12 weeks have been advocated to achieve remission. Although it was suggested that tricyclics were more rapid-acting than the SSRIs, a 12-week comparison trial of nortriptyline and sertraline in late-life depression found no difference in the timing of the response. A retrospective analysis of that data concluded that for both drug classes, a 12-week trial was useful to achieve remission, but that patients showing minimal improvement after 4 to 6 weeks were not likely to remit, and other treatments should be considered. Doses and therapeutic plasma concentrations for other tricyclic and tetracyclic compounds are shown in Table 33.5a.3–1.

If patients experience side effects, this approach may be altered. If patients on desipramine report insomnia, the dose can be given early in the day. Sedation and anticholinergic effects may diminish with time, and gradual dose adjustment may help manage these effects. Although subjective light-headedness may improve with time, blood pressure and pulse changes do not usually accommodate during the first 4 weeks, and gradual dosing does not help avoid these effects. In patients at high risk for side effects, the dose can be increased gradually to assess tolerance. If anticholinergic side effects occur, allowing more time between dose increases allows the patient to accommodate these side effects.

Prospective Dosing Techniques

Conventional dosing requires the administration of a given dose for a long enough period to determine if that dose is effective. Sometimes two or even three trials are needed to determine the effective dose. Once therapeutic blood levels were established for the tricyclics, it was possible to adjust dosage quickly to achieve an effective plasma concentration and determine efficacy after one trial. In clinical practice, plasma level monitoring was most commonly employed in patients whose depression was not responding to a reasonable dose.

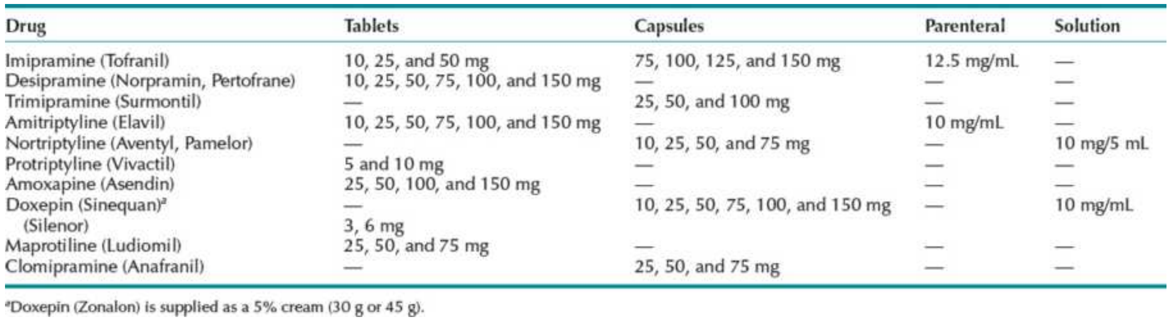
Exceptions

In older adult depressed patients, gradual dosing may be required to assess tolerance, but studies of desipramine and nortriptyline indicate that the final doses and blood levels required for response are similar to those needed in younger patients.

In panic patients, lower starting doses are used, and the dose is increased slowly to avoid exacerbation of panic attacks. In OCD, higher doses of clomipramine are used than those used in depression. In part, this is because OCD responds more slowly and less completely than depression, and, thus, the dose is raised to ensure that the most effective treatment has been given.

If amitriptyline is used for pain, lower doses (e.g., 75 mg/day) are used. When effective, the action of the drug is observed within the first 2 weeks.

Table 33.5a.3–3.
Tricyclic and Tetracyclic Drug Preparations



Drug	Tablets	Capsules	Parenteral	Solution
Imipramine (Tofranil)	10, 25, and 50 mg	75, 100, 125, and 150 mg	12.5 mg/mL	—
Desipramine (Norpramin, Pertofrane)	10, 25, 50, 75, 100, and 150 mg	—	—	—
Trimipramine (Surmontil)	—	25, 50, and 100 mg	—	—
Amitriptyline (Elavil)	10, 25, 50, 75, 100, and 150 mg	—	10 mg/mL	—
Nortriptyline (Aventyl, Pamelor)	—	10, 25, 50, and 75 mg	—	10 mg/5 mL
Protriptyline (Vivactil)	5 and 10 mg	—	—	—
Amoxapine (Asendin)	25, 50, 100, and 150 mg	—	—	—
Doxepin (Sinequan)[a]	—	10, 25, 50, 75, 100, and 150 mg	—	10 mg/mL
(Silenor)	3, 6 mg			
Maprotiline (Ludiomil)	25, 50, and 75 mg	—	—	—
Clomipramine (Anafranil)	—	25, 50, and 75 mg	—	—

[a] Doxepin (Zonalon) is supplied as a 5% cream (30 g or 45 g).

If doxepin is used for sleep, doses lower than those in depression are used, for example, 3 to 6 mg/day.

At this time, it is not clear when tricyclic antidepressants should be used in children. It is recommended that desipramine should not be used in children younger than 12 years of age because of possible adverse cardiac effects, but the same logic also applies to other tricyclics. Tricyclic antidepressants have not been shown to be more effective than placebo in adolescents with depression, although this probably relates, in part, to diagnostic problems. The lethality of tricyclics in overdose should be kept in mind. Higher doses, on a milligram-per-kilogram basis, are likely to be required in younger patients than in adults to reach the same plasma level, but effective plasma level ranges have not been established in children.

Tricyclic and heterocyclic preparations are shown in Table 33.5a.3–3.

33.5a.4 Dopamine-Noradrenaline Reuptake Inhibitors (Bupropion)

Charles DeBattista, D.M.H., M.D., and Alan F. Schatzberg, M.D.

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic domain	Norepinephrine, dopamine
Mechanism of action	Reuptake inhibitor (NET, DAT) and releaser (NE, DA)

Originally introduced in the 1980s, bupropion (Wellbutrin) is one of the more commonly prescribed antidepressants in the United States. As a result of unique pharmacology, bupropion is often used as an alternative to SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs). In addition to its FDA approval in the treatment of depression, bupropion is also approved for smoking cessation and is the only antidepressant to receive FDA approval for the preventive treatment of seasonal affective disorder (SAD). Additionally, bupropion is used for numerous off-label indications, including the treatment of ADHD, sexual dysfunction, obesity, and fatigue related to a nonpsychiatric medical condition. Currently, all formulations of bupropion are generically available, and the major metabolite of bupropion, hydroxybupropion, is being investigated as a potential antidepressant.

PHARMACOLOGY

Pharmacodynamics

The pharmacodynamics of bupropion remains in debate. Although frequently described as a noradrenergic agonist/dopamine reuptake inhibitor, the human in vivo effects of bupropion on dopamine appear rather modest. Animal studies have indicated that bupropion is associated with an increase in nucleus accumbens dopamine concentrations, and it appears to inhibit the reuptake of dopamine more potently than tricyclics. However, human studies have not consistently shown a dopamine effect.

For example, some PET studies have shown that bupropion increases occupancy of the dopamine transporter as a dopamine reuptake inhibitor should, but others have shown no effect. Likewise, concentrations of homovanillic acid (HVA), a major metabolite of dopamine, do not appear to rise in clinical responders, although they may rise in nonresponders.

The effects of bupropion on noradrenergic activity appear more consistent than its dopamine effects. Bupropion reduces the 24-hour excretion of norepinephrine and its metabolites. Bupropion and its active metabolites, hydroxybupropion, erythro-hydrobupropion, and threo-hydrobupropion, inhibit the reuptake of norepinephrine in rat cortex, although much less potently than does imipramine. Downregulation of beta-adrenergic receptors and decreased firing of norepinephrine cells in the locus ceruleus have been reported in animal studies. In addition, chronic administration of bupropion appears to modestly inhibit tyrosine hydroxylase activity. In addition to its noradrenergic and dopaminergic effects, bupropion is also known to interact with nicotinic receptors. Bupropion is a noncompetitive inhibitor of the nicotine $\alpha_3\beta_4$ receptor, while one of its metabolites, *S,S*-hydroxybupropion, is a noncompetitive inhibitor of the nicotine $\alpha_4\beta_2$ receptor in the rat brain. Along with the effects of bupropion on the reward circuits of the locus ceruleus, the inhibition of nicotinic receptors by bupropion and its metabolites provide a rationale for its use in smoking cessation.

Bupropion became the focus of investigation by medicinal chemists in the 1960s when it appeared to be effective in standard screening models of antidepressants but lacked many of the properties of the TCAs and MAOIs that make both classes problematic to use. These include muscarinic side effects, tyramine pressor effects, hypotension, and so forth. Bupropion is not a significant inhibitor of serotonin reuptake, an agonist of 5-HT$_{1A}$ receptors, or an antagonist of 5-HT$_2$ receptors. The lack of significant serotonergic effects is thought to be the major factor in bupropion’s lack of sexual side effects and its general lack of efficacy in anxiety disorders.

Pharmacokinetics

Bupropion is a racemic mixture of enantiomers and is rapidly absorbed. This absorption is not substantially affected by concurrent food of anticholinergic administration. The peak blood level occurs within 2 hours of administration, and bupropion is tightly bound to protein (80% to 90%). Protein binding for hydroxybupropion is similar to bupropion, while the other metabolites are about half as tightly bound as bupropion.

Elimination of bupropion is biphasic, consistent with what has been referred to as a “two-compartment model,” that is, after distribution, serum levels are in equilibrium between the intravascular and extravascular compartments. The terminal mean half-life is about 21 hours, while the distribution phase half-life is about 4 hours. Hydroxybupropion may have a half-life of as long as 45 hours.

Bupropion undergoes extensive first-pass metabolism, with only 1% of the drug excreted unchanged in the urine. Most elimination is fecal. Bupropion is a substrate for the CYP450 2B6 isoenzyme, which is not commonly inhibited or induced by other drugs. Oncology agents such as thiotepa (Thioplex) for meningeal neoplasms are among the rare, potent inhibitors of CYP 2B6, while barbiturates, such as phenobarbital (Bellatal), may induce the enzyme. There have been conflicting in vitro and in vivo studies of bupropion’s CYP 2D6 inhibition. While bupropion is a weak inhibitor of CYP2D6, a number of its metabolites are more potent inhibitors. Thus, there is a potential for bupropion to inhibit the metabolism of some CYP 2D6 substrates, including many antidepressants, some antipsychotics, lipophilic beta-blockers, tamoxifen, and some opiates.

CLINICAL USES

Depressive Disorders

Bupropion has long been known to be an effective antidepressant. It appears to be comparable in efficacy to both TCAs and SSRIs. Most studies with bupropion have involved outpatients with mild to moderate depression. However, inpatient studies with more severely depressed patients have also indicated benefits. Small open-label studies in children and adolescents suggest a benefit of bupropion in pediatric depression, but no controlled studies are available. Geriatric depression studies indicate that bupropion in lower doses may be effective and well-tolerated. Case reports suggest an occasional worsening of psychotic features in patients with delusional depression.

Unlike most antidepressants, the efficacy of bupropion in treating MDD with concomitant anxiety or anxiety disorders is not well-established. Some studies in depressed patients have reported comparable anxiolytic effects of bupropion to SSRIs. However, most studies of bupropion in the treatment of panic disorder have failed to show benefits. Likewise, no controlled trials have been completed that demonstrate the clear benefit of bupropion monotherapy for GAD, Social anxiety, or other anxiety disorders. On the other hand, anxiety may be a consequence of bupropion treatment on occasion.

Among the most common applications of bupropion is in the augmentation of response to other antidepressants. Thus, it is frequently combined with SSRIs, SNRIs, or mirtazapine in patients who have shown inadequate responses to monotherapy. It makes intuitive sense that the combination of a noradrenergic and perhaps dopaminergic molecule such as bupropion might.

Among the largest trials to evaluate the efficacy of bupropion augmentation to date is the Sequenced Treatment Alternatives in Resistant Depression (STAR*D) trial. In that study, patients who had failed citalopram (Celexa) treatment could opt to be randomized to either buspirone (BuSpar) or bupropion augmentation. Both treatments were equally effective, with about 30% of patients achieving remission after failing citalopram monotherapy. Bupropion was somewhat more effective than buspirone in an overall reduction of depressive symptoms. However, the lack of a placebo arm makes it difficult to determine whether either augmenting strategy was more effective than would be longer treatment with citalopram alone.

The other major study to evaluate the efficacy of bupropion augmentation was the VA Augmentation and Switching Treatments for Improving Depression Outcomes (VAST-D) study. In the 1,522-subject trial, patients with MDD who had not responded to an antidepressant were randomized to bupropion alone, bupropion augmentation, or augmentation with aripiprazole. The response rate appeared to be higher in the aripiprazole group than in either the switch or bupropion augmentation groups. Likewise, the remission rate in the aripiprazole group was higher than in the group switched to bupropion but not statistically different than bupropion augmentation. Thus, bupropion augmentation seemed slightly less effective than augmentation with aripiprazole overall.

Given the low remission rates of monotherapy of major depression with antidepressants, attempts have also been made to initiate combined treatment with bupropion and an SSRI as a way of enhancing the speed of onset and remission rates. A randomized controlled study of 245 MDD patients compared the combination treatment with escitalopram and bupropion to monotherapy with either escitalopram or bupropion (The Co-Med trial). No advantage was found for the combination treatment with bupropion to either monotherapy in the speed of response or overall remission rates.

Bupropion is commonly used adjunctively with antidepressants to treat SSRI-induced sexual side effects. Again, the rationale for using a dopaminergic agent, even a modest one, to impact sexual side effects appears sound. Stimulants and other dopamine-enhancing agents enhance libido. Although case reports and open studies supported the use of bupropion, several placebo-controlled trials have not demonstrated substantial benefit in depressed patients. Two studies at 150 mg per day of bupropion sustained-release (SR) added to an SSRI did not report significant benefit over placebo in treating sexual side effects; one study at 300 mg per day did demonstrate mild efficacy. The benefit of adding bupropion to a serotonergic antidepressant may be more evident in women than men. A randomized controlled study of 218 women with antidepressant-induced sexual side effects found that 300 mg per day of bupropion added to an existing antidepressant was significantly more effective than placebo in increasing libido and, to a lesser extent, arousal. Similarly, male patients with methadone-induced sexual dysfunction appeared to have a significant improvement in sexual function with the addition of bupropion in a placebo-controlled, randomized trial. Switching from a serotonergic antidepressant to bupropion also appears to be an effective strategy to reduce sexual side effects in both men and women. In 2022, the combination of bupropion with dextromethorphan was approved for the treatment of major depression. The combination of a relatively low dose of bupropion SR 105 mg and 45 mg of dextromethorphan 45 m, given twice daily, appears to increase the speed of on onset of the antidepressant response and may improve the overall efficacy relative to similar doses of bupropion alone.

Bupropion was approved for the preventive treatment of SAD in 2006. In a series of three trials, 1,042 patients who met the criteria for SAD were treated in the autumn while they were still well. Patients were randomized to receive either 150 to 300 mg per day of bupropion extended-release (XL) or placebo and then followed through the spring. On average, patients had 13 previous seasonal depressive episodes. Patients on placebo were significantly more likely to experience fall/winter depressive episodes than were bupropion-treated patients. Placebo-treated patients were also more likely to have a recurrence of depression sooner than were those on bupropion. To date, no other antidepressants have received an indication in the treatment of SAD.

Bupropion has been favored as an adjunctive treatment for bipolar depression secondary to the perception that it might be less likely to induce switches into mania or more rapid cycling. This perception, however, is based on very little data. Few large prospective studies have evaluated the utility and safety of bupropion in bipolar depression. The largest study to date to evaluate bupropion in bipolar disorder was a part of the NIMH-funded Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) study. In that study, patients with bipolar depression on a mood stabilizer were randomized to the addition of bupropion or paroxetine (Paxil) versus the addition of a placebo. Patients were treated for 26 weeks and evaluated to determine if they had at least 8 weeks of recovery. Neither bupropion nor paroxetine was significantly better than placebo in achieving a durable recovery from the bipolar depressive episodes. In fact, on some measures, placebo-treated patients fared somewhat better. The rate of switches into mania also did not differ between bupropion, paroxetine, and placebo in patients on therapeutic doses of standard mood stabilizers. A study supported by the Stanley Foundation likewise showed relatively low-switch rates of bupropion in an acute bipolar trial. The response rate in this study was about 50%, with about a 10% switch rate. Thus, the utility of bupropion in bipolar depression is still uncertain, but switch rates of bupropion, when combined with standard mood stabilizers, appear low.

Smoking Cessation

Another FDA indication for bupropion (SR) is for the promotion of smoking cessation. Early conceptualization about the mechanism for its efficacy in nicotine withdrawal and cravings included bupropion’s effects on dopamine reuptake and an influence on reward mechanisms in addictive states. Indeed, there is evidence that dopamine polymorphisms have some predictive value in determining the efficacy of bupropion in smoking cessation. However, more current thinking is that bupropion may have significant, although indirect, effects on nicotine receptors. For example, bupropion may mimic nicotinic effects on dopamine and norepinephrine, which may attenuate withdrawal symptoms. In addition, there is some evidence of direct antagonism of nicotine receptors, which might prevent relapse by diminishing the reinforcing properties of nicotine. In addition, bupropion appears to act as a noncompetitive α3β4 nicotinic antagonist. Despite additional understanding, the mechanism of bupropion for smoking cessation remains unclear, but bupropion appears unlike nicotine-specific therapies such as nicotine substitutes (nicotine patch/gum) or the partial nicotine receptor agonist varenicline (Chantix). There is evidence that the major metabolite of bupropion, hydroxybupropion, may mediate the smoking cessation effects of the drug. Since there are polymorphisms for the CYP2B6 isoenzyme that is responsible for the metabolism of bupropion to hydroxybupropion, slow metabolizers of CYP2B6 may require higher doses to achieve a serum level of 0.7 mcg/mL as these doses may predict better response to bupropion therapy for smoking cessation.

Overall, bupropion appears to be about twice as effective as placebo in reducing acute nicotine withdrawal symptoms, nicotine cravings, and maintaining abstinence. For example, bupropion has been associated with less mood instability and weight gain after acute withdrawal from tobacco. In one pivotal trial, only 27% of patients experienced nicotine cravings 1 month after smoking cessation on bupropion 300 mg per day versus 56% of those on placebo. About 30% of patients on bupropion are able to quit after 1 to 3 months versus about 15% of placebo-treated patients. After 1 year of treatment, patients who remain on bupropion are about 1.5 times as likely to remain abstinent as placebo-treated patients. Bupropion also appears effective in specific populations with nicotine addictions, including those with chronic obstructive pulmonary disease (COPD), cardiovascular illness, concurrent alcoholism, schizophrenia, and comorbid depression.

Direct comparisons with nicotine-specific therapies are few. Bupropion appears to be at least as effective as nicotine replacement with a nicotine patch, but the combination of bupropion and the nicotine patch may not offer benefit over either therapy alone. For example, the addition of bupropion to a nicotine patch did not offer benefit over the addition of placebo in a 26-week study of smoking cessation in adolescents. At least two head-to-head comparisons with varenicline tartrate 1 mg twice daily indicated that varenicline may be somewhat more effective in the acute and long-term management of smoking cessation. The combination of varenicline and bupropion may be more effective than either treatment alone.

The usual starting dose of bupropion SR for smoking cession is 150 mg per day, with a target dose of 300 mg per day within 7 days. An acute course of bupropion tends to last 8 to 12 weeks, with tobacco stopped within the first 2 to 3 weeks of treatment. Responders may continue bupropion treatment chronically to prevent relapse.

Obesity and Eating Disorders

The FDA approved the combination of bupropion and naltrexone for the treatment of obesity in 2014. Four large registration trials involving over 4,500 patients were completed in overweight BMI >27 to obese BMI >30 patients (mean BMI = 36). The general design of these studies was 3 weeks of dose titration followed by approximately 1 year of treatment. Subjects were randomized to the combination of naltrexone (15 to 60 mg) and bupropion (300 to 400 mg) along with dietary modifications (e.g., reducing daily calories by 500 kcal/day), behavioral counseling, and an increase in exercise or physical activity versus the control group included with these interventions with a placebo instead of the active drug. In all four trials, subjects randomized to the active group were more likely to lose a clinically meaningful amount of weight, defined as >5% or >10% of total body weight. In addition, subjects on the combination of bupropion (mean dose 360 mg per day) and naltrexone (mean dose 32 mg per day) lost about 5% more of total body weight versus subjects in the control group.

A large percentage of patients in both the active and control groups of the naltrexone/bupropion obesity studies dropped out before completing the 1-year endpoint. In fact, approximately 45% of both groups dropped out early, with subjects in the active group twice as likely to drop out as subjects in the control group (24% versus 12%). The most common side effects leading to discontinuation of the combination treatment were nausea, headache, and vomiting. Other common side effects of the combination of naltrexone/bupropion are constipation,

Bupropion alone also has mild anorexiant effects that have been evaluated in nondepressed obese patients. Approximately 25% of patients in acute depression trials lost 5 lb or more while taking bupropion. Several controlled studies have evaluated 300 to 400 mg per day of bupropion in the treatment of obesity. These studies have indicated that bupropion-treated patients tend to lose 1.1 to 4.5 kg at 6 to 12 months, and this is significantly greater than placebo-treated patients. Bupropion has also been investigated in the treatment of binge eating disorder. The largest randomized, placebo-controlled trial to date (*n* = 61) did not find the bupropion to reduce binging or to improve weight loss in women with the disorder.

Other Clinical Uses

In addition to the FDA-approved indications in the treatment of major depression and for smoking cessation, bupropion has been clinically tested for a number of other conditions. For example, as with other noradrenergic antidepressants such as nortriptyline (Aventyl), bupropion may be useful in the treatment of adult ADHD. In pediatric populations, the only large controlled trial did not show significant benefit of bupropion on the primary outcome measures. However, in this trial, teachers rated the bupropion-treated children as less aggressive and hyperactive relative to placebo-treated children. Clinicians and parents did not observe a significant difference. There are a few direct comparisons of bupropion with stimulants; however, these studies revealed that bupropion is either about as effective or somewhat less effective. A small randomized trial (*n* = 44) comparison of bupropion and methylphenidate found that both drugs were equally effective and well-tolerated. Studies of bupropion in adults with ADHD have been more consistently positive. For example, in a study of 162 adults with ADHD, 53% of patients responded to bupropion XL versus 31% of placebo-treated patients. Benefits over placebo were noted as early as week 2, and bupropion, with an average dose of 450 mg per day, was well-tolerated.

Finally, bupropion has been suggested to be of benefit in a number of small studies and case series for a broad spectrum of conditions. These have included sexual dysfunction in nondepressed patients, fatigue in cancer patients, the treatment of amphetamine addiction, lowering tumor necrosis factor-α, and improving concentration in patients without ADHD.

SIDE EFFECTS

The pharmacodynamic effects of bupropion result in a side-effect profile different from most antidepressants. Many of the adverse events reported with bupropion are associated with its noradrenergic and, to a lesser extent, dopaminergic effects. For example, CNS activation is associated with bupropion treatment. Insomnia is one of the common side effects of bupropion, affecting at least 11% of patients in clinical trials. Anxiety and agitation may occur as treatment-emergent effects. At least 6% of patients in clinical trials also experienced a mild-to-moderate tremor. Treatment-emergent psychotic symptoms have rarely been reported in depressed patients.

The risk of seizure with the immediate-release (IR) formulation of bupropion became evident in studies of eating disorder patients initially and led to the withdrawal of the drug in 1986. Patients in the eating disorder trials were treated with up to 600 mg per day of bupropion. Analysis of data sets revealed an enhanced risk of seizure in patients with a history of eating disorders, head trauma, or previous seizure disorder. Also, doses above 450 mg per day or 200 mg at one time (for the IR formulation) enhanced the risk of seizure. For XL formulations at doses of 450 mg per day or less, the seizure risk is estimated at 0.1% to 0.2%, which is comparable to the rates reported with SSRIs and may be less than the rates reported with some TCAs and maprotiline (Novo-Maprotiline).

Other common side effects reported in trials included nausea, dry mouth, excessive sweating, tinnitus, and rash. The most common reasons patients discontinued bupropion in acute clinical trials of depression were nausea and rash.

Bupropion has a favorable cardiovascular profile with few cardiac effects. Bupropion is not known to have clinically significant effects on blood pressure, heart rate, or cardiac conduction. Thus, bupropion is commonly used in patients with known cardiac pathology. However, there have been rare reports of significant hypertension associated with bupropion in patients with and without a preexisting history of high blood pressure.

Side effects common to many antidepressants (including sexual side effects and weight gain) appear uncommon with bupropion. As noted earlier, bupropion has been associated with weight loss, and there are many reports of improved sexual functioning, including increased libido and arousal, with the drug.

Other side effects such as hepatoxicity, hematopoietic changes, and severe headaches can rarely occur in bupropion-treated patients. Thus, the side-effect profile makes bupropion an important alternative for many patients who cannot tolerate other antidepressants.

DRUG INTERACTIONS

The limited cytochrome P450 interactions of bupropion contribute to its few drug interactions. Since bupropion and hydroxybupropion are metabolized via the cytochrome P2B6, there is a theoretical risk of an interaction between oncology agents such as IV thiotepa and the muscle relaxant orphenadrine (Norflex). Hydroxybupropion is a weak-to-moderate inhibitor of cytochrome P450 2D6 and has been associated with increased serum levels of some 2D6-dependent drugs such as venlafaxine (Effexor) and desipramine (Norpramin). Rare seizures that have occurred in the combination of fluoxetine (Prozac) and bupropion have sometimes been attributed to inhibition of the metabolism of hydroxybupropion by 2D6 inhibitors, but seizures can occur independent of these potential interactions, so it is unclear whether this mechanism was at play.

Since bupropion may lower the seizure threshold, particularly when the IR form is used in higher doses or in combination with other drugs that lower the seizure threshold, such as some tricyclics, amoxapine (Asendin), clozapine (Clozaril), and theophylline (Elixophyllin), it is sometimes associated with seizures.

As with other antidepressants, the concurrent administration with MAOIs is contraindicated. However, there have been few reports in the literature of serious interactions with MAOIs. Oral selegiline (Carbex) at doses of 10 mg per day or less and transdermal selegiline (Emsam) have sometimes been combined with bupropion without incident.

OVERDOSE

Bupropion has rarely been associated with fatalities in monotherapy overdoses. Overdoses of bupropion as low as 10 g have sometimes been associated with deaths. Causes of death in these overdoses have included complications of status epilepticus and arrhythmias. Although therapeutic doses of bupropion are rarely associated with cardiovascular effects, overdoses have sometimes been associated with tachycardia, intraventricular conduction delays, and QRS complex widening. Treatment for overdoses includes lavage, seizure treatment or prophylaxis, cardiac monitoring, and vital sign support. Most patients who overdose on bupropion recover.

DOSING AND FORMULATIONS

Bupropion hydrochloride is available in IR, SR, and XL forms. As of 2006, all of these formulations had become available as generics in the United States. The usual starting dose in all formulations is 150 mg per day taken in the morning, but the IR form was often started at 100 mg twice a day. The average therapeutic dose of bupropion for the treatment of depression is 300 to 450 mg per day. Doses above 200 mg at once are associated with greater seizure risk in the IR form. Thus, at maximum doses, compliance with bupropion IR prescriptions was somewhat difficult when dosed at 150 mg three times a day. In contrast, the typical therapeutic dose of the SR form was 150 or 200 mg twice a day. The XL form could be taken all in one morning dose, which was said to have more consistent blood levels and perhaps less sleep disruption. A cellulose coating in XL formulation allowed for slow absorption.

In smoking cessation, bupropion SR is typically started at 150 mg per day and then increased to the target dose of 300 mg per day. In the management of obesity (Contrave) comes in a combination tablet of 90 mg of bupropion with 8 mg of naltrexone. The typical therapeutic dose is 1 to 2 tablets, twice daily.

33.5b 5HT$_{1A}$ Receptor Partial Agonists (Buspirone)

PIERRE BLIER, M.D., PH.D., AND CARY KOGAN, PH.D., M.S.C.P.

Neuroscience-Based Nomenclature (NbN)	
Buspirone	
Pharmacologic domain	Serotonin
Mechanism of action	Receptor partial agonist (5-HT_{1A})

Several serotonin (5-hydroxy-tryptamine; 5-HT)$_{1A}$ agonists have been developed and tested in patients diagnosed with various medical conditions and psychiatric disorders. The most extensively studied is buspirone, an azaspirodecanedione derivative approved for use in many countries. Its second-generation compound, gepirone, has also been extensively studied as an extended-release formulation and deemed efficacious by the U.S. Food and Drug Administration (FDA) in the treatment of major depressive disorder (MDD). Two other related azapirones are ipsapirone and tandospirone, with only the latter being on the market (in Japan and China). Since its synthesis in 1968 in the laboratories of Mead Johnson, the azapirones have been studied for their potential antidepressant and anxiolytic effects. Buspirone was, however, initially developed as a drug to treat psychosis because it was thought to act preferentially on dopamine receptors. Indeed, studies conducted in the 1970s revealed that a single dose of buspirone decreased aggressive behavior in rhesus monkeys. In the early 1980s, buspirone showed marked anxiolytic effects in behavioral models of anxiety in rodents. It was then subsequently realized that its therapeutic effects were more likely mediated by the 5-HT system, more specifically the 5-HT_{1A} receptor subtype identified in the early 1980s. Eventually, placebo-controlled studies in patients with anxiety disorders showed improvement in symptoms, with buspirone leading to FDA approval for generalized anxiety disorder (GAD) in 1986. FDA approval for the treatment of GAD with buspirone reflected the new DSM-III classification whereby anxiety neurosis had been replaced by GAD. At that time, buspirone was the only non-benzodiazepines medication approved by the FDA for the treatment of this disorder. Other clinical uses have been investigated, such as treatment for other disorders (e.g., social anxiety disorder, obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), panic disorder), depressive disorders, eating disorders, and attention-deficit/hyperactivity disorder (ADHD). Buspirone has only been indicated for the treatment of GAD and anxiety associated with depressive symptoms. It is, however, listed in treatment guidelines for adjunctive treatment for depression (i.e., CANMAT) and some anxiety disorders.

PHARMACOLOGIC ACTIONS

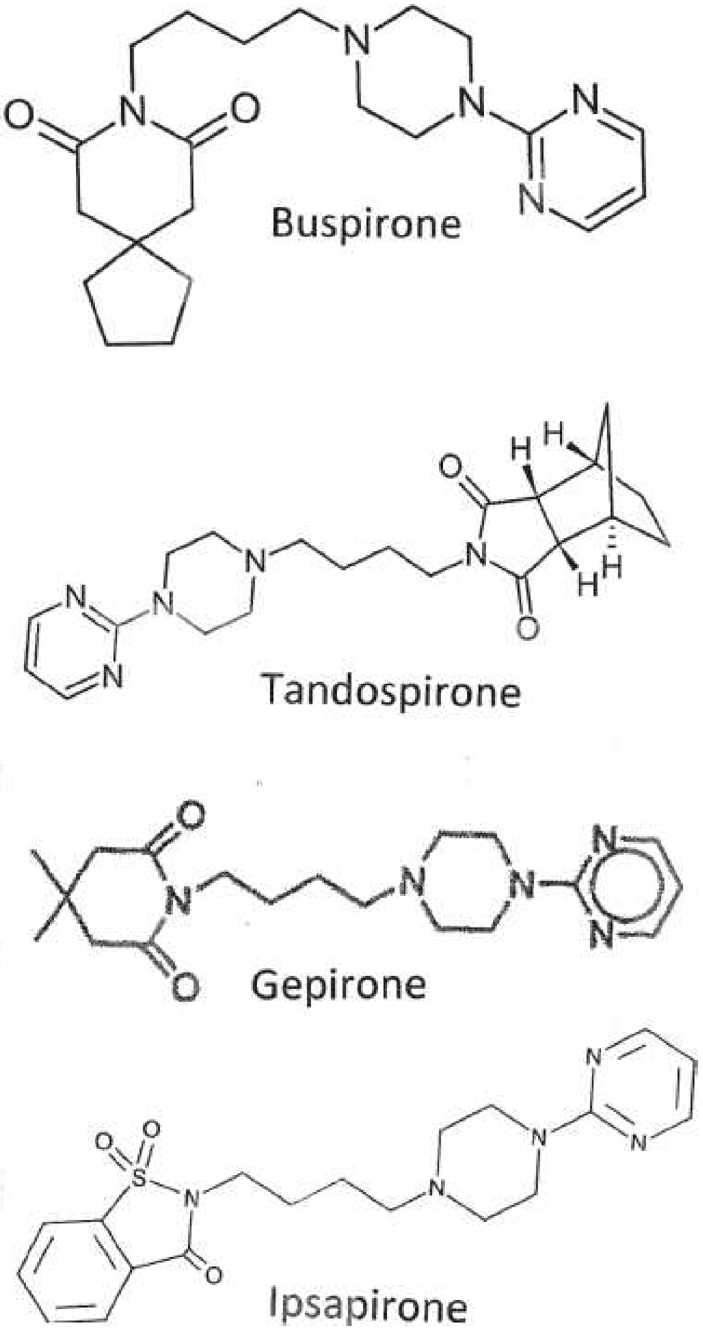
Buspirone hydrochloride (BuSpar) has been shown to act on two types of receptors: 5-HT and, to a much lesser extent, dopamine. It has a high affinity for the 5-HT_{1A} receptor, acting as an agonist or partial agonist, and has a moderate affinity for the D_2-dopamine receptor, acting as both an agonist and antagonist. It was initially believed that the azapirones were a better alternative to the $GABA_A$ positive allosteric modulators (PAMs; formerly referred to as the benzodiazepines) since they are not sedating and do not possess the same potential for dependence. However, clinical experience with these drugs, especially buspirone, revealed that they produce significant undesirable side effects, more delayed onset of therapeutic action, and are not more effective than the $GABA_A$ PAMs.

The chemical structures for the azapirones (buspirone, gepirone, tandospirone, and ipsapirone) are presented in Figure 33.5b–1.

PHARMACOKINETICS

Absorption

Buspirone undergoes extensive first-pass metabolism when ingested orally, with an absolute bioavailability of 4%. A 20-mg dose of buspirone produces peak plasma concentrations of 1 to 6 ng/mL (C_{max}) from 0.7 to 1.5 hours following administration (T_{max}). Buspirone exhibits linear pharmacokinetics only over the 10- to 40-mg oral dose range in humans, which is generally within the usual therapeutic range. It has a plasma elimination half-life of 2.5 hours and thus, should be administered twice to thrice daily. The oral bioavailability of buspirone is increased when taken with food when compared to fasting conditions such that the area under the plasma concentration-time curve (AUC) and the maximal peak concentration (C_{max}) are increased by 84% and 116%, respectively. Patients with cirrhosis can have an AUC increased up to 13-fold, and therefore other anxiolytic alternatives that do not undergo hepatic metabolism should be considered (i.e., oxazepam).



Buspirone
Tandospirone
Gepirone
Ipsapirone

FIGURE 33.5b–1. Chemical structures for the azapirones (buspirone, gepirone, tandospirone, and ipsapirone).

Distribution

Following first-pass liver metabolism, the remaining drug enters the systemic circulation. The volume of distribution is 5.3 L/kg as calculated by intravenous (IV) administration. Buspirone and its major active metabolites, 6-OH-buspirone and 1-pyrimidinylpiperazine (1-PP), both readily cross the blood-brain barrier, as demonstrated using IV administration in electrophysiologic recording experiments in the rat brainstem and forebrain. In vitro studies indicate that 86% to 95% of the drug is bound to plasma protein. In vivo studies in rats demonstrate that both buspirone and its metabolites are found in maternal milk and cross the placenta. It is not known to what extent both these events occur in humans.

METABOLISM AND ELIMINATION

Buspirone is metabolized through oxidation by cytochrome P450 3A4 (CYP3A4). CYP3A4, the most abundant form of cytochrome P450 in the human adult liver, is polymorphic and thus shows wide interindividual variation in its activity. Main metabolic pathways include hydroxylation on the 6′-position on the spiro ring system (6-OH buspirone) and the 5′-position on the pyrimidine ring of the drug complex (5-OH buspirone), as well as an *N*-dealkylation of a butyl side group, forming 1-PP. Approximately 26% of buspirone was found to be converted to 1-PP, and this metabolite had a 49-fold greater AUC than that of buspirone but conversely had 25% of the potency of the parent compound.

Another major active metabolite is 6-OH-hydroxybuspirone. This metabolite was found to have 12 times greater mean AUC in the brain compared to the parent compound. Similar to the parent compound, 6-OH-hydroxybuspirone had four times greater affinity for presynaptic 5-HT_{1A} receptors in the dorsal raphe nucleus compared to postsynaptic 5-HT_{1A} located in the hippocampus. As expected, given that CYP3A4 is polymorphic, the mean half-life ($t_{1/2}$) of buspirone varied greatly between healthy individuals, with a minimum of 2 to 3 hours and a maximum of 11 hours after a single dose of 10 to 40 mg. The mean half-life of 1-PP was 6 hours following a 20-mg dose. In subjects with renal impairment, defined as lower than normal range creatinine clearance, the half-life of buspirone increased on average by only 2 hours and would therefore not necessitate dose adjustment.

PHARMACODYNAMICS

Mechanism of Action

Buspirone has a unique mechanism of action from other medications used to treat anxiety, especially because it does not bind to the $GABA_A$ receptor complex. Although the exact mechanism of action of the azapirones has not been fully elucidated, it mainly relies on the 5-HT system with potential additional interactions with the dopamine and norepinephrine (NE) systems.

Serotonin System

Buspirone and the other azapirones act as full agonists at 5-HT_{1A} autoreceptors on 5-HT neurons and as partial agonists at postsynaptic 5-HT_{1A} receptors. The short-term activation of somatodendritic 5-HT_{1A} autoreceptors in the midbrain raphe nuclei has been demonstrated to decrease the firing rate of 5-HT neurons and the synthesis of 5-HT in rats. Under these conditions, such a decrease in 5-HT release does not result in decreased 5-HT_{1A} transmission in postsynaptic areas because the drug is also present in such regions, thereby counterbalancing the attenuated effect of 5-HT release. After sustained administration, however, firing rates of 5-HT neurons and 5-HT synthesis gradually return to normal as a result of desensitization of the 5-HT_{1A} autoreceptors. Subsequently, there is a net increase in 5-HT_{1A} transmission in the forebrain resulting from (1) normalized 5-HT release and (2) enhanced activation of postsynaptic 5-HT_{1A} receptors by the exogenous azapirone. The postsynaptic 5-HT_{1A} receptors in the forebrain do not desensitize with sustained administration of azapirones, unlike their presynaptic counterparts in the brainstem. Furthermore, the levels of the azapirones under such conditions, whereby the drug is administered systemically, do not attenuate the full agonistic effect of 5-HT. Therefore, such a net but delayed increase in 5-HT_{1A} neurotransmission in the forebrain is believed to underlie the therapeutic effect of buspirone in depression and anxiety beginning to manifest itself after at least 2 weeks.

Dopaminergic System

The dopaminergic system is an entity that can be considered to contribute to the clinical actions of buspirone. Buspirone has been categorized as both an agonist and antagonist to the D_2 subtype of the dopamine receptor. Buspirone acts as an antagonist to presynaptic dopamine autoreceptors, but some evidence has also pointed to the involvement of postsynaptic dopamine receptors. The inhibition of the autoreceptors on dopamine cell bodies and terminals increased dopamine synthesis and metabolism in the striatum and nucleus accumbens. However, given the much higher affinity of buspirone for 5-HT$_{1A}$ than for dopamine receptors, it is less likely that a dopamine action contributes significantly to the therapeutic action of buspirone.

Norepinephrine System

As mentioned above, buspirone and the azapirones generate 1-PP as a metabolite. This compound has been shown in in vivo electrophysiologic recordings in rats to be an effective antagonist of presynaptic α_2-adrenergic receptors on NE neurons. This could explain an increase in plasma levels of noradrenaline after acute administration of buspirone in humans, which are under an inhibitory influence of these receptors. However, 1-PP is also an effective postsynaptic α_2-adrenergic antagonist, which could counterbalance the impact of increased NE on these receptors. The α_1- and β-adrenergic receptors could, nevertheless, theoretically be under increased activation by 1-PP. However, when tandospirone was administered in a long-term fashion in rats as a precursor of 1-PP, there was no modification of the firing of NE neurons in the locus coeruleus, and the effects of the stimulation of NE fibers on the firing of hippocampus neurons mediated by α_1- and β-adrenergic receptors were unaltered. Therefore, it is unlikely that the NE system is involved in the therapeutic benefits of buspirone.

GABA System

As previously mentioned, buspirone has no affinity for the allosteric binding sites on the GABA$_A$ receptor, nor does it affect the binding of the endogenous ligand GABA to its receptor site. Despite this fact, there has been some suggestion that buspirone can indirectly affect the GABA system since buspirone was found to increase the level of binding of flunitrazepam in an in vivo model. Further studies are needed to explore the functional implication of this effect.

Acetylcholine System

Binding experiments have shown that buspirone has no binding affinity for muscarinic cholinergic receptors. However, some evidence indicates the possibility of an indirect relationship with this system. Acute administration of buspirone caused an efflux of acetylcholine in the rat hippocampus, a modest increase in motor activity, and was observed to have a trophic effect on septal cholinergic-containing neurons. Again, in order to link the delayed onset of action of buspirone to these observations in animal experiments with single-dose injections, repeated or sustained administration paradigms have to be carried out, and doses that mimic the plasma levels achieved in patients should be used.

Blood Concentration and Relation to Action

There is no definitive evidence linking plasma concentrations to the therapeutic effects of buspirone, although a study using tandospirone showed a robust anxiolytic effect with higher doses in patients with GAD.

CLINICAL TRIALS

Generalized Anxiety Disorder

Several double-blind, randomized, placebo-controlled trials have established the anxiolytic efficacy of buspirone. Most monotherapy studies have focused on the treatment of GAD, with the majority of trials finding buspirone to be significantly associated with a greater reduction in anxiety symptoms compared to placebo. Standard outcome measures of severity of anxiety symptoms (Hamilton Anxiety [HAM-A] scale) and global improvement (Clinical Global Impressions [CGI] scale) were generally employed. A clinical trial also examined the use of buspirone or placebo in conjunction with anxiety management therapy or nondirective therapy. All four treatment groups exhibited a significant reduction in anxiety symptoms, with no significant difference between any of the groups. Although eligibility for entry into each of these trials required a diagnosis of GAD, it is worth noting that the definition of GAD has changed over time, such that the required duration of anxiety symptoms was increased from 1 month (third edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-III]) to 6 months (DSM-III-R to DSM-5). Initial buspirone clinical trials used DSM-III criteria for GAD, while more recent clinical trials utilized DSM-III-R or DSM-IV criteria. It is possible that those initial studies may have included many subjects with anxiety symptoms that would not have been sufficiently chronic to be currently classified as GAD.

Early studies found buspirone to be statistically inferior or equivalent to the GABA PAMs for the acute reduction of anxiety symptoms in GAD, for instance, an adjustment disorder with anxious mood. One clinical trial found buspirone to have significantly less anxiolytic efficacy than either lorazepam (Ativan) or alprazolam (Xanax), which is not surprising since the azapirones do not produce the sedation or muscle relaxation that is associated with the PAMs. In fact, they often produce unpleasant side effects such as nausea and light-headedness. However, two head-to-head studies did not find any statistical difference between buspirone and alprazolam/diazepam (Valium) with respect to the reduction of anxiety symptoms. Furthermore, it has been demonstrated that recent (<1 month) PAM treatment negatively predicts treatment response to buspirone. Specifically, there was no significant difference in response to buspirone or diazepam in patients with no prior exposure to GABA_A PAMs, but as expected, diazepam was significantly more effective than buspirone at reducing anxiety symptoms in patients with recent exposure to PAMs. It is conceivable that patients allocated to the buspirone arm may have experienced rebound phenomena, whereas those on PAMs did not.

A comparison of buspirone and the 5-HT/NE reuptake inhibitor (SNRI) venlafaxine XR (Effexor XR) in reducing anxiety symptoms in GAD did not reveal a significant difference. SSRIs are the first-line treatment for GAD, and the paucity of studies comparing buspirone and other azapirones to SSRIs remains a large gap in the literature. Further trials are needed to compare the use of other first-line medications that are the standard treatment for GAD (i.e., SSRIs, SNRIs, pregabalin) with buspirone to adequately understand its role in this indication. One study found no statistical difference between buspirone and kava-kava with respect to reducing anxiety symptoms in GAD. Kava-kava is a herbal medication with constituents that putatively act both as a monoamine oxidase B inhibitor and as a NE reuptake inhibitor. However, problems with such natural products include the variability in the dose and quality of the active ingredient(s). Another trial found buspirone to be equivalent to hydroxyzine (Vistaril) in reducing anxiety symptoms in GAD. Hydroxyzine is a first-generation antihistamine of the piperazine class that acts via antagonism of the H_1 receptor and is considered a second-line pharmacotherapy for GAD. Further studies comparing selective 5-HT_{1A}

agonists to other alternative pharmacologic and nonpharmacologic interventions are necessary to position these drugs adequately in our armamentarium.

Panic, Post-Traumatic Stress, and Obsessive-Compulsive Disorder

Double-blind, randomized, placebo-controlled trials found that buspirone was not significantly superior to placebo in treating patients with panic disorder. In addition, one of these trials also found alprazolam to be superior to buspirone and placebo with respect to its panicolytic and anxiolytic effects. With respect to PTSD, smaller, open-label trials found buspirone to be effective in alleviating symptoms such as anxiety, insomnia, flashbacks, and depression. In one of these small studies, seven of eight patients exhibited a significant reduction in symptoms as measured by the Structured Inventory for PTSD and the Beck Depression Inventory with buspirone monotherapy. In another case series trial, 12 combat-related PTSD patients exhibited a 40% reduction in re-experiencing symptoms after usage of buspirone as an adjunct to therapy programs, with or without other pharmacologic agents. The promising results from these smaller, open-label trials highlight the need for larger, placebo-controlled studies for these two disorders.

A few double-blind, randomized, placebo-controlled trials evaluated the addition of buspirone to SSRIs for patients with OCD. Two trials added buspirone to SSRIs (fluoxetine [Prozac] and fluvoxamine [Luvox]), and another used buspirone as an adjunct to an SNRI clomipramine (Anafranil). These trials found no significant improvement in Yale-Brown Obsessive Compulsive Scale scores associated with the addition of buspirone. The use of buspirone as an adjunctive treatment for OCD is therefore not recommended in the guidelines.

Table 33.5b–1 provides a summary of clinical trials of buspirone for psychiatric disorders.

Table 33.5b–1.
Buspirone Clinical Trials

	Number of Subjects	Duration	Dose	Significant Difference vs. Comparator
Generalized Anxiety Disorder (GAD)				
Buspirone vs. Placebo				
Ross and Matas, 1987	21	4 weeks	5–40 mg	NS
Enkelmann, 1991	62	6 weeks	18.7 mg (mean)	+
Gammans et al., 1992	Meta-analysis			+
Chiaie et al., 1995	44	8 weeks	15 mg	+
Sramek et al., 1996	162	6 weeks	5–45 mg	+
Lader and Scotto, 1998	163	4 weeks	20 mg	+
DeMartinis et al., 2000	487	4 weeks	30 mg (up to)	+
Bond et al., 2002	44	8 weeks	30 mg (up to)	+
Majercsik et al., 2003	52	6 weeks	30 mg	+
Buspirone vs. Benzodiazepine				
Cohn et al., 1986 (lorazepam)	40	4 weeks	15–50 mg	—
Cohn et al., 1986 (alprazolam)	40	4 weeks	15–50 mg	—
Ross and Matas, 1987 (diazepam)	19	4 weeks	5–40 mg	NS
Enkelmann, 1991 (alprazolam)	63	6 weeks	18.7 mg	NS
DeMartinis et al., 2000 (diazepam)	483	4 weeks	30 mg (up to)	—
Buspirone vs. Hydroxyzine				
Lader and Scotto, 1998	162	4 weeks	20 mg	NS
Buspirone vs. Venlafaxine XR				
Davidson et al., 1999	267	8 weeks	30 mg	NS
Buspirone vs. Kava-Kava				
Boerner et al., 2003	85	8 weeks	10 mg	NS
Panic Disorder				
Buspirone vs. Placebo				
Pohl et al., 1989 (+ imipramine)	60	8 weeks	29.5 mg (mean)	NS
Sheehan et al., 1990	52	8 weeks	57.2 mg	NS
Sheehan et al., 1993 (+ alprazolam)	92	8 weeks	61 mg (mean)	—
Post-Traumatic Stress Disorder (PTSD)				
Buspirone (open-label trial)				
Wells et al., 1991	3	NK	35–60 mg	+
Duffy and Malloy, 1994	8	NK	5–30 mg	+
Fichtner and Crayton, 1994	12	NK	46 mg (mean)	+
Obsessive-Compulsive Disorder (OCD)				
Buspirone vs. Placebo				
Piggott et al., 1992 (+ clomipramine)	14	10 weeks	57 mg (mean)	—
McDougle et al., 1993 (+ fluvoxamine)	33	6 weeks	60 mg (up to)	—
Grady et al., 1993 (+ fluoxetine)	13	4 weeks	60 mg	—
Major Depressive Disorder (MDD)				
Buspirone vs. Placebo				
Fabre, 1990	140	8 weeks	54 mg (mean)	+
Rickels et al., 1990	155	8 weeks	90 mg (up to)	+
Robinson et al., 1990	382	NK	90 mg (up to)	+
Appelberg et al., 2001 (+ citalopram or fluoxetine)	102	6 weeks	10–30 mg	+
Buspirone vs. Bupropion SR				
Trivedi et al., 2006 (+ citalopram)	565	6 weeks	41 mg (mean)	NS
Alcohol Dependence				
Buspirone vs. Placebo				
Malcolm et al., 1992	67	24 weeks	45–60 mg	NS
Malec et al., 1996	Meta-analysis	—	—	NS
Cannabis Dependence				
Buspirone vs. Placebo				
McRae-Clark et al., 2009	50	12 weeks	60 mg (up to)	NS
McRae-Clark et al., 2015	175	12 weeks	60 mg (up to)	NS
Premenstrual Dysphoric Disorder				
Landén et al., 1999	117	4 weeks	20–60 mg (flexible)	+
Landén et al., 2001	63	4 menstrual cycles	10–40 mg (flexible)	+
Nazari et al., 2013	100	8 weeks	10 mg	+

NS, no significant difference; (+), significantly greater improvement in primary efficacy measure for buspirone arm; (–), significantly greater improvement in primary efficacy measure for comparator arm; NK, not known (unpublished).

Major Depressive Disorder

Several large, double-blind, randomized, placebo-controlled trials have examined the efficacy of buspirone in treating patients with MDD. These clinical trials have generally shown buspirone to be significantly superior to placebo in reducing depressive symptoms. One such study compared buspirone to placebo as an adjunct therapy in patients who were treatment-resistant to citalopram. Buspirone was found to be significantly more effective than placebo at reducing depressive symptoms in these patients. Most of these trials used the HAM-D scale as the standard outcome measure of severity of depressive symptoms, although the Montgomery-Asberg Depression Rating Scale was also employed since the score on this measure is less affected by anxiety symptoms making it a better outcome of response to treatment for depression, specifically. The large NIMH-sponsored Sequenced Treatment Alternatives in Resistant Depression (STAR*D) trial included an arm of the study in which MDD patients who did not remit during a treatment course with citalopram could opt for the addition of buspirone or bupropion sustained release (Wellbutrin SR) in a double-blind manner. Both adjunctive medications resulted in similar remission rates, 39% versus 31%, respectively; however, buspirone was not as well-tolerated as bupropion.

Other Uses

Alcohol and Cannabis Dependence. Buspirone use has been examined in alcohol dependence. One clinical trial found that while buspirone reduced anxiety symptoms in male veterans dependent on alcohol, this change was not significantly different from the reductions associated with placebo. In addition, buspirone was found to be statistically equivalent to placebo with respect to standard measures of alcohol consumption, such as time to first drink and the number of standard drinks per drinking day. Similarly, a meta-analysis of five double-blind RCTs concluded that buspirone was not significantly superior to placebo in reducing alcohol consumption. That report did, however, highlight the positive effects of buspirone on treatment persistence and anxiety. The authors suggested that while buspirone did not affect alcohol consumption, it may have had a positive impact on associated psychiatric symptoms. Therefore, given its lack of interaction with alcohol, buspirone may have a role as an adjunct therapy in the treatment of co-occurring anxiety and alcohol dependence.

Treatment of cannabis dependence with buspirone was first examined in a placebo-controlled study of 50 individuals titrated to a target dose of 60 mg daily and treated for 12 weeks. There were no significant differences between the buspirone-treated individuals and those receiving a placebo on self-reported and urine drug detection measures of cannabis use. Similarly, in another controlled study of 175 participants by the same group, no statistically significant differences were identified in the buspirone arm. However, a greater number of female than male subjects taking buspirone had positive urine drug screens. Therefore, buspirone is not recommended for cannabis dependence.

Smoking Cessation. The efficacy of buspirone to help with smoking cessation has been evaluated in open-label trials and a small number of randomized controlled trials. The evidence of efficacy remains inconclusive. A comparison between buspirone and nicotine transdermal patches found both treatments had similar cessation rates, while another study looking exclusively at buspirone found that the greatest improvement was observed in patients reporting high anxiety. When buspirone was coadministered with sertraline (Zoloft) versus placebo in participants who were all receiving cognitive-behavioral therapy (*n* = 98), the combination of buspirone and sertraline improved abstinence rates by 44% compared to 17% for controls at the 26th week following smoking cessation.

Agitation. The possible role of buspirone in the management of behavioral and psychological symptoms of dementia in the context of Alzheimer disease (AD) has been examined. Buspirone was compared to trazodone (Desyrel) and placebo in AD patients with behavioral symptoms (*n* = 10) in a 12-week study. Only subjects taking trazodone showed improvement compared to placebo. In another study looking at an AD population, buspirone (*n* = 12) was also compared to haloperidol (Haldol) (*n* = 14) for the treatment of agitation. Subjects taking buspirone showed only a trend toward decreased tension when compared to subjects taking haloperidol.

Psychosis. Buspirone has not been shown to have intrinsic therapeutic activity in the treatment of psychosis. In the context of schizophrenia, there is no evidence of significant benefits in terms of alleviation of either positive or negative symptoms. This is supported by a meta-analysis of seven RCTs (six with buspirone and one with tandospirone) in 368 patients with schizophrenia. Such adjunctive buspirone was, however, associated with improvement in extrapyramidal symptoms and cognitive benefits while not affecting adverse drug reactions or discontinuation rates.

Somatic Dysfunction. Premenopausal patients with fibromyalgia (n = 22) and healthy female controls (n = 14) were challenged with a single dose of 60 mg of buspirone. Prolactin and growth hormone levels, as well as core body temperature, were measured. Only an increase in prolactin response was observed. The authors concluded that buspirone must only have altered the dopamine system since growth hormone levels and core body temperature after buspirone administration have been shown to be mediated by 5-HT$_{1A}$ receptors, whereas prolactin is mostly controlled by both systems.

Since 5-HT is an important neurotransmitter in the gastrointestinal tract where it plays a key role in the regulation of sensory and motor functions, buspirone has been investigated for its role in altering gastrointestinal functions. It appeared to be efficacious in functional dyspepsia, as it enhanced gastric relaxation and reduced postprandial symptoms in response to a challenge meal. Large, controlled studies are nevertheless needed to establish a clear benefit for such problem(s).

Sexual Dysfunction. Improvement in sexual function has been previously reported in patients with GAD and decreased sexual function after 4 weeks of buspirone. Sexual iatrogenic dysfunction occurs in at least half of individuals taking SSRIs or SNRIs. Buspirone has thus been investigated for its capacity to reverse this side effect. Patients being treated for a major depressive episode (MDE) with a stable dose of an SSRI for at least 4 weeks were given either buspirone or placebo for the primary purpose of evaluating for an additive antidepressant response and, secondarily, to determine if an improvement in sexual function would occur. An attenuation of sexual dysfunction was reported in 58% of patients and only 30% of those on placebo. The effect was more pronounced in women, and since the benefits in women were prominent in the first week, it was concluded that this was not simply attributable to an antidepressant action of buspirone. These results appear to be consistent with the finding that the SSRI/potent 5-HT$_{1A}$ agonist vilazodone produces low levels of sexual dysfunction. Furthermore, the approved indication of the 5-HT_{1A} agonist/5-HT_{2A} antagonist flibanserin in women with hypoactive sexual desire disorder would also appear to be consistent with buspirone having some beneficial action in sexual dysfunction. However, an 8-week double-blind trial in 61 females who had been treated successfully with fluoxetine for a depressive episode compared buspirone to the antiviral/dopamine enhancer amantadine (Symmetrel) and did not show any significantly improved sexual dysfunction compared to placebo.

Premenstrual Dysphoric Disorder. Buspirone has demonstrated some benefit in the treatment of premenstrual dysphoric disorder syndrome (PMDD) in three RCTs. The first RCT compared buspirone (*n* = 19; mean daily dose: 27 mg) to the 5-HT_2 antagonist/5-HT_{1A} agonist nefazodone (*n* = 22; mean daily dose 304 mg) and placebo (*n* = 22). Participants taking buspirone had greater global improvement and improvement in irritability compared to those taking placebo. The second RCT reported that subjects on buspirone (*n* = 17) had a significant improvement in related symptoms, including aches and pains, cramping, impaired social interaction, and irritability. In a third trial, 100 females were randomized to buspirone (10 mg/day) or fluoxetine (20 mg/day) for 2 months. Both drugs produced the same beneficial action.

Sleep Apnea. Buspirone as a treatment option for sleep apnea has been studied. A placebo crossover study in 16 male patients with heart failure (left ventricular ejection fraction <50% and moderate to severe central apnea >14 events/hour) demonstrated reduced carbon dioxide chemosensitivity and improved oxygen saturation across the 24-hour cycle.

Attention-Deficit/Hyperactivity Disorder. Four RCTs (*n* = 362) examined the therapeutic potential of buspirone in ADHD in children and adolescents. One head-to-head comparison with methylphenidate showed benefits, while the other did not. The design of the largest study (*n* = 241) included placebo, atomoxetine (a selective NE reuptake inhibitor), and atomoxetine + buspirone groups. The effect size of atomoxetine was 0.40, whereas that of the combination group was 0.51. This difference was not significant, but most measures showed a trend favoring the group receiving buspirone addition. An RCT (*n* = 57) administering buspirone via a transdermal patch did not report a significant decrease in ADHD-related symptoms in the buspirone group compared to placebo. In summary, the weight of the evidence is not in favor of using buspirone in ADHD.

Withdrawal from Other Medications/Substances of Abuse. Two placebo RCTs (*n* = 49) assessed the potential of buspirone to limit withdrawal symptoms from opiates after 5 days of stabilization on 30 mg of methadone. Both studies found that buspirone was as effective as a methadone taper in alleviating the withdrawal symptoms of subjects dependent on heroin. Another placebo RCT of 12 weeks in duration (*n* = 36) did not find a decrease in anxiety among individuals dependent on opioids receiving continuous methadone treatments. There was, however, a trend toward reduction of depressive symptoms and a longer period prior to substance use relapse in individuals receiving buspirone. Therefore, there seems to be some benefit to using buspirone in opioid dependence.

An RCT looked at the discontinuation of long-term use of alprazolam, diazepam, or lorazepam in 107 patients with GAD who had, on average, used these medications for 8.5 years. Patients received a placebo, buspirone (mean daily dose 38 mg), or imipramine (Tofranil; mean daily dose 180 mg) over a 5-week period during a gradual 4- to 6-week PAM discontinuation at a rate of 25% per week. The success rate of the taper was significantly higher for patients in the imipramine (83%) but not in the buspirone group (68%) as compared to the placebo group (38%) 3 months after the taper.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Nervous System

The most frequent adverse events affecting the nervous system reported by buspirone users included dizziness, headache, drowsiness, light-headedness, insomnia, fatigue, nervousness, decreased concentration, abnormal thinking, excitement, depression, confusion, vivid dreams, and hostility. Less frequent events included noise intolerance, euphoria, fear, apathy, seizures, and suicidal thoughts.

Gastrointestinal System

Users of buspirone report instances of nausea, GI distress, diarrhea, and vomiting. Less frequent events include anorexia and rectal bleeding.

Cardiovascular System

Tachycardia or palpitations was the most frequently listed cardiovascular effect with the use of buspirone. Less common adverse events included syncope, hypotension, and hypertension. Rare cardiovascular effects include congestive heart failure, cerebrovascular accident, myocardial infarction, cardiomyopathy, bradycardia, and ECG change. The causality of these adverse events is, however, difficult to ascertain.

Dermatologic Effects

The most frequent dermatologic side effect reported with buspirone use was skin rash, while facial edema, easy bruising, blisters, hair loss, and dry skin were reported infrequently. Rare events included acne and thinning of nails.

Endocrine System

Patients taking buspirone reported the following infrequent adverse events: change in libido, change in weight, and menstrual irregularity.

THERAPEUTIC INDICATIONS

The FDA has approved buspirone for the management of anxiety disorders or for short-term treatment of anxiety-related symptoms. It is recommended for use in individuals who present symptoms that correspond with GAD based on the former DSM criteria, that is, for at least 1 month. There are no data available pertaining to the long-term use of buspirone.

PRECAUTIONS AND ADVERSE REACTIONS

Patients with hypersensitivity to buspirone should not take this medication. Pharmacologic studies have indicated that liver and kidney impairment affect drug metabolism and drug clearance, respectively. As such, as indicated above, alternative treatments should be sought for patients with liver impairment, whereas those with kidney impairment should receive less than the recommended dose. Buspirone is not recommended for patients with severe liver or kidney impairment. In vivo animal studies have indicated a lack of teratogenic, carcinogenic, and fetal impairment effects of buspirone administration, but similarly, well-controlled studies in humans have not been performed, resulting in a designation of Pregnancy Category B according to the former U.S. FDA classification. In rats, buspirone and its metabolites are found in maternal milk and cross the placenta, although it is not known to what extent both these events occur in humans.

The most commonly listed adverse reactions to buspirone that were significantly higher when compared to placebo included dizziness, nausea, headache, light-headedness, excitement, and sweating or clamminess. A study in a child and adolescent population found that the most frequently reported side effects were light-headedness, headache, and dyspepsia, while studies in geriatric populations found no difference in adverse events reported in comparison to a younger population. Rare side effects include congestive heart failure, bradycardia, slurred speech, claustrophobia, tingling of limbs, burning tongue, and photophobia.

DRUG INTERACTIONS

Buspirone is a substrate for CYP3A4. Concurrent use of buspirone and MAOIs has been associated with a significant increase in blood pressure. Verapamil (Verelan), an inhibitor of CYP3A4, was found to increase the AUC and C_{max} of buspirone by 4.1- and 5.0-fold, respectively. Erythromycin (ERY-C), an inhibitor of CYP3A4, increased both AUC and C_{max} by 19- and 16-fold, respectively. Rifampin (Rifadin), an inducer of CYP3A4, decreased the C_{max} and AUC by 84% to 90% and the half-life from 2.8 to 1.3 hours. With the coadministration of haloperidol and buspirone in subjects with schizophrenia, buspirone increased the plasma concentration of both haloperidol and its metabolite, although this study did not examine the concentration of buspirone in the presence of haloperidol. Grapefruit juice, an inhibitor of CYP3A4, increased the AUC and C_{max} of buspirone by 9.2- and 4.3-fold, respectively. Other known inducers or inhibitors of CYP3A4 that may affect buspirone plasma concentration include ketoconazole (Nizoral), dexamethasone (Decadron), phenytoin (Dilantin), phenobarbital (Bellatal), and carbamazepine (Tegretol). Concurrent use of certain drugs has been found to alter the percentage of protein-bound buspirone. Acetylsalicylic acid (ASA) increased plasma levels of free buspirone by 23%, while flurazepam (Dalmane) decreased levels by 20%. Other drugs that alter the free plasma level of this drug include desipramine (Norpramin), diazepam, ibuprofen (Advil), propranolol (Inderal), thioridazine (Mellaril), and tolbutamide (Orinase).

DOSAGE AND ADMINISTRATION

Buspirone is available as an oral tablet and is provided in the following strengths: 5, 10, 15, and 30 mg. The recommended initial dose listed by the FDA is 15 mg daily (7.5 mg twice a day). Patients may be titrated to an optimal dose within 2 to 3 days by increasing the dose by 5 mg daily. The maximum daily dose should not surpass 60 mg.

33.5c Vilazodone and Vortioxetine

Pierre Blier, M.D., Ph.D., and Charles Desfossés, M.D.

Vilazodone and vortioxetine are two similar medications categorized as multimodal serotonin agents. They share common properties, namely inhibition of serotonin (5-hydroxy-tryptamine; 5-HT) reuptake transporters and agonism of 5-HT_{1A} receptors. For this reason, they are grouped together in this chapter, but vortioxetine also engages other 5-HT receptor subtypes.

VILAZODONE

Introduction and History

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic domain	Serotonin
Mechanism of action	Reuptake inhibitor (SERT) and partial agonist (5-HT_{1A})

Vilazodone (VIIBRYD) was approved by the FDA for the treatment of adults with major depressive disorder (MDD) on January 21, 2011, after more than a decade of development. It was first produced by Merck and then developed by GlaxoSmithKline in 2001, but after several failed trials in phase II, further clinical development was stopped in 2003. Clinical Data Inc purchased the compound and submitted a new drug application (NDA) in March 2010. The FDA accepted the New Drug Application for vilazodone for the treatment of MDD shortly thereafter. In March 2015, Actavis received approval for Viibryd 20 mg/day as a therapeutic dose. Actavis was purchased by Allergan, which in turn was bought by AbbVie, now marketing the medication in the United States and Canada.

Chemistry

The chemical structure of vilazodone is 2-benzofurancarboxamide, 5-[4-[4-[5-cyano-1H-indol-3-yl]butyl]-1-piperazinyl]-, hydrochloride (1:1) (Fig. 33.5c–1). It has a molecular weight of 441.535 g/mole. Given the therapeutic activity of selective serotonin reuptake inhibitors (SSRIs) and 5-HT_{1A} agonists in mood and anxiety disorders, the molecule was produced by combining the respective structural moieties responsible for such properties, an indole-butyl-amine and chromenonyl-piperazine, respectively, into a single compound.

Pharmacologic Actions

Pharmacokinetics. The pharmacologic activity of vilazodone resides in the parent compound, and its metabolites do not possess significant activity. Its pharmacokinetics are dose-proportional in a dose range of 5 to 80 mg, and peak concentrations occur at 4 to 5 hours after administration. When it is taken with food, vilazodone has an absolute bioavailability of 72%. The drug has a large volume of distribution and is 96% to 99% protein bound. It has a terminal half-life of about 25 hours and generally achieves a steady-state level within 4 days. With daily dosing of 40 mg with food, it reaches a maximum plasma concentration (C_{max}) of 156 ng/mL with an area under the curve (AUC) over 24 hours of 1,646 ng-hours/mL. The C_{max} and AUC of vilazodone are markedly lowered by about 50% when taken while fasting. Therefore, vilazodone should be taken with food to favor its absorption and, as with SSRIs, decrease gastrointestinal side effects. The drug is extensively metabolized, with only 1% and 2% recovered unchanged in urine and feces, respectively. Its metabolism primarily occurs by the cytochrome (CYP) 3A4, with CYP2C19 and CYP2D6 isoenzymes being minor catabolic pathways. Dose adjustments with mild to moderate hepatic and renal impairments are not necessary as its clearance is not affected in such individuals.

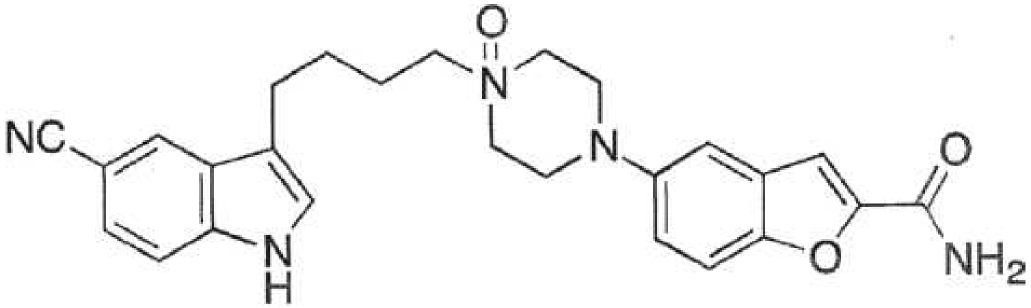

FIGURE 33.5c–1. Chemical structure of vilazodone.

Mechanisms of Action. Vilazodone is an agent that selectively targets the 5-HT system: (1) its affinity for 5-HT reuptake transporters is very high (K_i = 0.1 nM) without significant affinity for the norepinephrine (NE) and dopamine (DA) reuptake transporters (K_i = 56, and 37 nM, respectively), (2) its affinity for 5-HT_{1A} receptors is in the same range as for 5-HT reuptake transporters (K_i = 0.5 nM), and without any relevant affinity for any other 5-HT, NE, DA, and cholinergic receptors. In some secondary messenger systems coupled to 5-HT_{1A} receptors, vilazodone acts as a partial 5-HT_{1A} agonist.

Vilazodone has a delayed onset of therapeutic action similar to other SSRIs and 5-HT_{1A} receptor agonists. The potent 5-HT_{1A} property of the drug was demonstrated in vivo in anesthetized rats depleted of 5-HT:vilazodone injected intravenously was still able to inhibit the firing rate of 5-HT neurons through their 5-HT_{1A} autoreceptors. As expected, when administered in a sustained fashion to rats, the firing rate of 5-HT neurons is initially markedly attenuated, thereby decreasing endogenous 5-HT release. However, since vilazodone is present throughout the brain as an exogenous 5-HT_{1A} agonist, partial compensation of 5-HT transmission at postsynaptic 5-HT_{1A} receptors by the medication is expected. With prolonged administration, the firing rate of 5-HT neurons recovers to normal due to desensitization of their 5-HT_{1A} autoreceptors. Subsequently (i.e., after 14 days of administration through a constant release device), increased tonic activation of postsynaptic 5-HT_{1A} receptors occurs, as has been demonstrated with SSRIs and 5-HT_{1A} agonists separately using the same models. Despite its two combined molecular targets, there is no evidence indicating a more rapid onset of therapeutic action by vilazodone.

Therapeutic Indications

To date, the only FDA-recommended indication for vilazodone is for the treatment of MDD in adults. Its efficacy was initially established in two 8-week, randomized, double-blind, placebo-controlled trials in adult patients with a diagnosis of MDD. However, given that the 5-HT_{1A} agonist buspirone is FDA approved for generalized anxiety disorder (GAD) and that several SSRIs are also approved for the treatment of anxiety disorders such as GAD, social anxiety disorder, panic disorder, and separation anxiety disorder, as well as obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), premenstrual dysphoric disorder, and eating disorders, it is reasonable to assume that vilazodone may also prove useful in treating these conditions. However, only controlled and replicated clinical trials can ascertain the potential benefits of vilazodone for these other disorders.

Clinical Drug Studies

Design. Twenty-four phase I studies were conducted in the clinical development program of vilazodone. For its development in the treatment of MDD, five placebo-controlled phase II trials, three phase III trials (two double-blind, placebo-controlled 8-week trials that led to its FDA approval), and three phase IV trials were conducted, including a relapse prevention study. Although there have been several positive controlled studies of vilazodone, initial trials were failed studies. A main reason for these failed trials relates to the dosing strategies used. Two phase II trials used a fixed low dose of 20 mg/day and only showed a trend toward efficacy. The other three phase II trials were comprised of flexible regimens using flexible dosing strategies. While two of the studies used doses up to 100 mg/day, they consequently did not provide comprehensive information on the dose–response relationship. Three of these phase II trials included an active comparator, which did not separate from the placebo, indicating a lack of sensitivity in the studies.

Interpretation of Drug Studies. There were two phase III 8-week, multicenter, randomized, double-blind, placebo-controlled studies in adults (aged 18 to 65 in one trial and 18 to 70 in the other) with MDD that led to its FDA approval (Table 33.5c–1). These trials encompassed standard inclusion and exclusion criteria and used standard scales to assess clinical responses. The primary outcome measure was the Montgomery–Åsberg Depression Rating Scale (MADRS). Secondary outcomes were the Hamilton Depression-17 item (HAM-D-17), Hamilton Rating Scale for Anxiety (HAM-A), Clinical Global Impressions Severity of Illness scale (CGI-S), and Clinical Global Impressions Severity of Improvement scale (CGI-I). Patients were titrated within 2 weeks to a daily dose of 40 mg/day, but they were allowed to reduce the doses to 20 mg/day if the higher dose was not tolerated. Interestingly, both studies included measures of sexual functioning, whereas most prior studies of medications for depression only relied on spontaneous reporting of sexual side effects. The latter methodology is known to markedly underestimate sexual side effects, especially with SSRIs. The first study used the Changes in Sexual Functioning Questionnaire (CSFQ), whereas the second study used the Arizona Sexual Experiences Scale (ASEX).

Most patients in more recent phase III and IV trials had moderate to severe depression at baseline, with a score of 22 or more on the HAM-D-17 for inclusion but with the MADRS to assess response. Using a scale to assess the antidepressant response that is different from the one used for the study entry likely contributed to signal detection, all the more so that the MADRS is less affected by co-occurring anxiety symptoms and is more sensitive to change. Both trials showed superiority over the placebo on the total MADRS score, with small effect sizes (0.23 and 0.30). Based on the observation that vilazodone separated from placebo at week 1 in the first trial but not until week 6 in the second trial, a claim of rapid onset of action cannot be made. In the absence of an active comparator, such a claim appears even more tenuous.

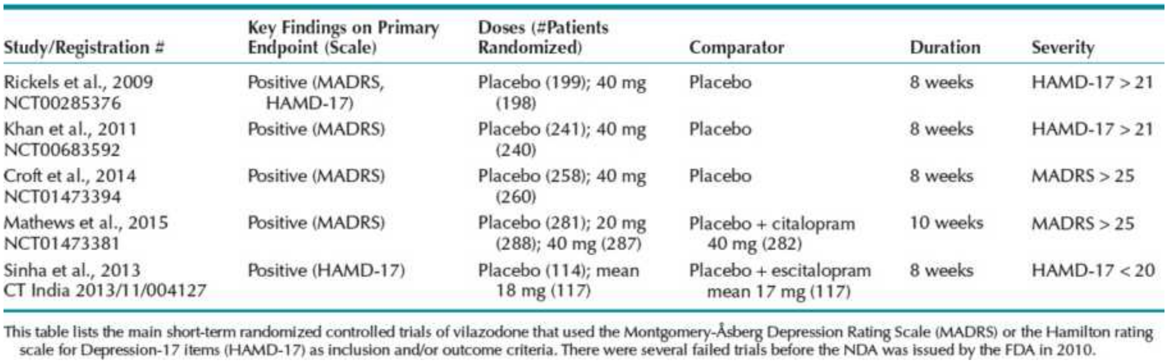
Vilazodone was developed in light of the evidence that the 5-HT$_{1A}$ agonist buspirone is efficacious for GAD. Therefore, secondary measures assessing anxiolysis were examined. By combining the results of the two 8-week phase III trials, a posthoc analysis classifying patients as having anxious depression or nonanxious depression showed significantly greater decreases in both depression and anxiety symptoms versus those taking placebo. Although these results suggest a possible role for vilazodone in the treatment of depression with prominent anxiety symptoms, active comparator studies are needed to determine whether vilazodone has any advantage over other medications. Such a possibility could be supported by the three positive placebo-controlled trials assessing the anxiolytic effect of vilazodone in GAD. All three trials included 200 or more patients in each treatment arm, two were flexible-dose trials (20 to 40 mg/day), whereas a third one had a 20 mg/day and a 40 mg/day group, and only the latter dose separated significantly from the placebo group. GAD is not an official indication in the United States or Canada.

The positive results of the two phase III trials in MDD are now supported by two large phase IV placebo-controlled trials, one of which included an active comparator for assay sensitivity. The first one had a flexible dose (20 to 40 mg/day) design, whereas the second used fixed doses of 20 and 40 mg/day of vilazodone with a 40 mg/day group of the SSRI citalopram, the latter group being titrated over 2 weeks. All three active arms separated significantly from placebo but were not different from each other. A double-blind placebo-controlled maintenance study did not show significantly lower relapse rates in the groups that continued their 20 or 40 mg/day regimen when compared to a switch to placebo after patients had been stabilized on vilazodone. This study may have failed because of the unexpectedly low relapse rates of 11% to 13% in all three groups. Indeed, relapse rates are usually twice as high in such studies in patients who responded to active medication and are then switched to placebo.

Precautions and Adverse Reactions

Vilazodone was not associated with any significant changes in laboratory tests, blood pressure, heart rate, or weight during placebo-controlled trials.

Table 33.5c–1.
Main Short-Term Randomized Controlled Trials of Vilazodone



Study/Registration #	Key Findings on Primary Endpoint (Scale)	Doses (#Patients Randomized)	Comparator	Duration	Severity
Rickels et al., 2009 NCT00285376	Positive (MADRS, HAMD-17)	Placebo (199); 40 mg (198)	Placebo	8 weeks	HAMD-17 > 21
Khan et al., 2011 NCT00683592	Positive (MADRS)	Placebo (241); 40 mg (240)	Placebo	8 weeks	HAMD-17 > 21
Croft et al., 2014 NCT01473394	Positive (MADRS)	Placebo (258); 40 mg (260)	Placebo	8 weeks	MADRS > 25
Mathews et al., 2015 NCT01473381	Positive (MADRS)	Placebo (281); 20 mg (288); 40 mg (287)	Placebo + citalopram 40 mg (282)	10 weeks	MADRS > 25
Sinha et al., 2013 CT India 2013/11/004127	Positive (HAMD-17)	Placebo (114); mean 18 mg (117)	Placebo + escitalopram mean 17 mg (117)	8 weeks	HAMD-17 < 20

This table lists the main short-term randomized controlled trials of vilazodone that used the Montgomery-Åsberg Depression Rating Scale (MADRS) or the Hamilton rating scale for Depression-17 items (HAMD-17) as inclusion and/or outcome criteria. There were several failed trials before the NDA was issued by the FDA in 2010.

Safety and Tolerability. The safety of vilazodone was specifically evaluated using data from 2,177 patients who participated in phase III clinical studies, representing 552 patient years of exposure. The rate of discontinuation due to adverse events in clinical trials is considered a general indicator of tolerability. Vilazodone appears to be well tolerated overall. In pooled phase III data, discontinuation rates due to adverse effects were relatively low (7% vilazodone, 3% placebo). Rates of discontinuation due to lack of efficacy were not significantly different between the vilazodone and placebo groups. While no one single adverse event was responsible for discontinuation in >1% of the patients, the most common adverse event type leading to discontinuation were gastrointestinal complaints (2.3% vilazodone vs. 0.2% placebo). Adverse events significantly more common in vilazodone-treated patients compared with those receiving placebo were diarrhea, nausea, dizziness, insomnia, vomiting, abnormal dreams, gastroenteritis, restlessness or akathisia, palpitations, tremor, feeling jittery, and paresthesia; although in most cases symptoms were considered to be mild to moderate. Only 6.4% and 8.8% of participants in the two phase III trials reported a severe adverse event, compared to 5.6% and 5.4% in the placebo groups, respectively. In the vilazodone-treated group, symptoms in the first trial were diarrhea, fatigue, flatulence, gastroenteritis, palpitations, and paresthesias. In the second trial, symptoms reported were insomnia, nausea, vomiting, headache, and decreased libido.

Serious Adverse Events. There were no deaths in the vilazodone clinical trials in subjects taking vilazodone. Among all of the clinical trials, there were three deaths. These included a homicide in a phase I study and two suicides in a phase II study. Neither of the suicide victims was in the vilazodone arm. A total of 76 patients experienced a nonfatal serious adverse event in phase II and phase III trials, with similar rates for the vilazodone and placebo groups.

Overdose. Limited data exist regarding the effects of a vilazodone overdose. Four patients and the child of a patient experienced an overdose of vilazodone at doses between 200 and 280 mg. Symptoms included 5-HT syndrome, lethargy, restlessness, hallucinations, and disorientation. All patients recovered.

Sexual Dysfunction. Only head-to-head comparator studies using specific questionnaires on sexual function can delineate the impact of different medications. In the case of vilazodone, there is a 5-week study in 199 healthy male and female volunteers using doses of 20 and 40 mg/day in comparison to placebo and a 20 mg/day group on the SSRI paroxetine. Based on plasma level determinations, about 20% of participants did not have any detectable levels of active medication. When excluding these individuals, the CSFQ total score was not significantly different between either dose of vilazodone versus placebo. Nevertheless, the CSFQ total score decreased significantly for those participants on paroxetine versus those on placebo and vilazodone 20 mg/day but not versus vilazodone 40 mg/day. Another study assessed sexual dysfunction during the treatment of 1,147 patients with MDD. Sexual dysfunction, as assessed with the CSFQ, was present in 60% to 70% of women and 50% to 60% of men, with about 55% of the overall sample being female. The CSFQ score changes from baseline were small for all patients with normal baseline sexual function. In contrast, across treatment groups, baseline sexual function improved in men and women at the end of treatment in the MDD responders and in patients with baseline sexual dysfunction. Overall, these results suggest that sexual function improvement appears largely associated with the improvement of depressive symptoms rather than a specific effect of vilazodone.

Weight. Only mild but not clinically relevant changes in body weight were found compared to placebo in the four placebo-controlled 8- to 10-

week studies and in the open-label 52-week study. In the RCTs, vilazodone 20 mg was associated with an increase of +0.59 kg, 40 mg with +0.32 kg and placebo with +0.22 kg. The proportion of patients who had an increase of >7% body weight with 20 mg and 40 mg was 1.7% and 1.3%, respectively, compared to 1.0% for placebo. The proportion of patients who had a decrease of >7% body weight with 20 mg and 40 mg was 1.7% and 0.7%, respectively, compared to 0.7% for placebo.

Cardiac. Vilazodone was not associated with any clinically significant effects on electrocardiograms, arrhythmias, or QTc abnormalities within its recommended dose range (20 to 40 mg/day). Four patients treated with vilazodone in phase III trials discontinued treatment because of palpitations, compared with no patients on placebo. In a study of vilazodone in doses up to 80 mg/day, no QTc abnormalities were observed.

Platelets. Vilazodone may affect platelets, given that SSRI blockade of platelet transport proteins leads to a depletion of more than 90% of 5-HT within platelets and slight inhibition of platelet aggregation. However, in clinical trials, no increased risk of bleeding was observed in patients treated with vilazodone versus placebo, and rates of bleeding events were similar in both groups. As with all SSRIs, the product labeling advises caution when co-administering vilazodone with drugs that potentiate the risk of bleeding.

Hyponatremia. Although no cases of hyponatremia were reported in the clinical trials of vilazodone, hyponatremia has occurred with SSRIs and SNRIs. It is potentially lethal, and risk factors include older age, concomitant use of diuretics or other medications that can cause hyponatremia, volume depletion, and medical conditions causing hyponatremia. The mechanism of action is thought to be due to the development of the syndrome of inappropriate antidiuretic hormone secretion. In patients with symptomatic hyponatremia, vilazodone should be discontinued and appropriate medical intervention implemented.

Gastrointestinal. The most commonly observed adverse events of vilazodone are gastrointestinal in nature. Fortunately, they tend to be mild or moderate in severity and appear to be transient in nature. In the placebo-controlled phase III trials, diarrhea was reported by 28% of vilazodone-treated patients (vs. 9% placebo) and nausea by 23% of vilazodone-treated patients (vs. 5% placebo). Slow dose titration over 2 weeks is recommended to minimize gastrointestinal adverse events.

Suicidality. Vilazodone carries the same black box warning as other SSRIs regarding suicidal thoughts and behaviors in children, adolescents, and young adults. This was based on data showing an increased risk of suicidal thinking and behavior (although no completed suicides were observed) in children, adolescents, and young adults (ages 18 to 24) with MDD and other psychiatric disorders treated with SSRIs or other newer medications for MDD. In pooled phase III placebo-controlled vilazodone trials, suicidal ideation was experienced by one (0.2%) patient receiving vilazodone and three (0.7%) patients on placebo. Seven (1.2%) patients in the 52-week open-label study also experienced suicidal ideation. Suicidal behavior was identified by one (0.2%) vilazodone-treated patient and one (0.2%) patient in the placebo group in the pooled phase III placebo-controlled trials and by two (0.3%) patients in the 52-week open-label trial. In a recent phase IV trial, among patients receiving vilazodone, there was one reported suicidal ideation and one suicide attempt. All patients initiating an efficacious treatment for MDD should be monitored closely for clinical worsening or suicidality, especially upon drug initiation or dose adjustment.

Activation of Mania/Hypomania. As with all medications for the treatment of MDD, cautious monitoring should be exercised when prescribing vilazodone to patients with a history or family history of bipolar disorder, mania, or hypomania because of the risk of a switch. In clinical trials of vilazodone, six patients were identified as having probable treatment-emergent mania or hypomania, five receiving vilazodone and one placebo.

Discontinuation Syndrome. A discontinuation syndrome is a frequent occurrence upon stopping medications that are 5-HT reuptake inhibitors, especially when discontinued abruptly. This is largely linked to those that are rapidly eliminated, that is, within about 1 week, in contrast to fluoxetine, which is eliminated between 4 to 5 weeks and is the least likely to produce discontinuation symptoms. Therefore, abrupt discontinuation of vilazodone is not recommended. Rather, gradual discontinuation should be implemented to avoid a possible discontinuation syndrome.

Serotonin Syndrome. The development of a 5-HT syndrome is always something to consider when using medications that increase 5-HT availability. It is extremely rare when using a single agent within a recommended regimen. However, two subjects in the vilazodone clinical trials were identified as having 5-HT syndrome. The first was a patient in a phase II trial who received vilazodone 80 mg; the other was a patient in the 52-week, open-label, phase III study who took an overdose of approximately 240 mg of vilazodone. These two cases may have resulted from direct overstimulation of 5-HT$_{1A}$ receptors in the presence of optimal 5-HT reuptake inhibition. If a 5-HT syndrome is confirmed, there must be a determination of whether other substances that may stimulate 5-HT transmission, including drugs of abuse like ecstasy, have been ingested. Vilazodone must not be taken within 2, but preferably 3, weeks after stopping an irreversible monoamine oxidase inhibitor (MAOI). If symptoms occur, vilazodone and all other serotonergic agents should be discontinued immediately and supportive management initiated.

Nervous System. Although vilazodone has not been studied in patients with seizure disorders, the product label advises that caution be used when prescribing vilazodone to patients with a seizure disorder. In addition, headache was reported as an adverse event in 20% of patients in the 52-week open-label study.

Sleep. In the two phase III trials, insomnia and abnormal dreams were reported by 6% and 4% of patients on vilazodone, versus 2% and 1%, respectively, of those receiving placebo. Decreased REM and increased slow-wave and delta-wave activity were reported in a single-dose study of 10 healthy men.

Reproductive. There are no published data on vilazodone during pregnancy or during labor and delivery. In animal studies, however, vilazodone was not teratogenic in rats or rabbits at doses of 48 and 17 times, respectively, the maximum recommended human dose (MRHD). Developmental toxicity was observed, but only at doses much higher than the MRHD. The FDA package insert carries the same warning regarding potential neonatal toxicity as is listed with other medications used to treat MDD. Clinicians must consider the well-documented risks of untreated depression in pregnancy, including during the post-partum period, versus the associated risks of taking medications with serotonergic agents (see chapter on SSRI for more considerations).

Lactation. There are no published data regarding the excretion of vilazodone in breast milk. Animal studies have expectedly demonstrated that vilazodone is excreted into the milk of lactating rats. Risks and benefits should be carefully weighed and discussed with patients.

Fertility. There are no data on the effect of vilazodone on fertility in humans. In animal studies with rats, impairment of male fertility was observed with vilazodone at 30 times the MRHD but not at 6 times the MRHD. No effect on fertility was observed in female rats.

Carcinogenicity. In mice studies, the incidence of hepatocellular carcinomas in males was increased at 16 times the MRHD but not at 5 times the MRHD. Similarly, the incidence of malignant mammary gland tumors was significantly increased at 16 times the MRHD but not at 1.8 times the MRHD. Vilazodone was not carcinogenic in rats at doses up to 36 times the MRHD.

Mutagenicity. According to the package insert, vilazodone was not mutagenic in the in vitro bacterial reverse mutation assay and was negative in the in vitro V79/HGRPT mammalian cell forward mutation assay. Vilazodone was clastogenic in two in vitro mammalian cell chromosome aberration assays but was negative for clastogenic activity in an in vivo rat bone marrow chromosome aberration assay and a micronucleus test. Vilazodone was also negative in an in vivo/in vitro unscheduled DNA synthesis assay in rats.

Drug Interactions

Since vilazodone is metabolized primarily by CYP3A4, 3A4 inhibitors or inducers can potentially affect its plasma concentration. If co-administered with a strong inhibitor of CYP3A4 (perhaps the most common being the regular drinking of grapefruit juice), it is recommended that the vilazodone dose be limited to 20 mg daily. If co-administered with 3A4 inducers, like carbamazepine, the package insert states that the dose of vilazodone may be increased based on clinical response (not to exceed 80 mg/day). Co-administration of drugs interfering with other CYP isoenzymes will not affect the plasma levels of vilazodone to a clinically significant extent.

Since vilazodone does not modify the activity of other CYP isoenzymes, it will not alter the activity of other medications metabolized by such catabolic pathways. Given the high metabolic activity of the CYP3A4, co-administration of vilazodone with other substrates will not alter its plasma levels. An interaction of vilazodone with other highly protein-bound drugs has not been evaluated, but given its high protein binding, co-administration with other highly protein-bound drugs may result in increased free concentrations of the other drug. There is a low risk of increased bleeding if vilazodone is used with NSAIDs, aspirin, or oral anticoagulants (see SSRI chapter).

Dosage and Administration

Vilazodone is supplied in 10-, 20-, and 40-mg tablets. A 30-day starter kit is available, which contains (7) 10-mg tablets, (7) 20-mg tablets, and (16) 40-mg tablets. Vilazodone should be taken with food. The recommended dose for vilazodone is 40 mg daily and should be titrated over 2 weeks, starting with 10 mg/day for 7 days, 20 mg/day for the next 7 days, and then depending on the response to 40 mg/day. No dose adjustments are recommended for mild or moderate hepatic or renal impairment.

Geriatric Patients. No dose adjustment is recommended for use in geriatric patients. This is based on results from a study demonstrating similar pharmacokinetics in patients >65 years old and those ages 24 to 55 years. Nonetheless, the product labeling cautions that a greater sensitivity of some older individuals cannot be ruled out and that older adult patient may be at greater risk for hyponatremia.

Pediatric Patients. Vilazodone is not FDA approved for use in pediatric patients, and two studies failed to show an antidepressant effect relative to placebo in adolescents 12 to 17 years of age with MDD.

VORTIOXETINE

Introduction and History

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic domain	Serotonin
Mechanism of action	Reuptake inhibitor (SERT), receptor partial agonist (5-HT_{1A}), receptor antagonist (5-HT_3)

Vortioxetine (TRINTELLIX) was developed by Lundbeck with the aim of adding 5-HT_{1A} and 5-HT_3 receptor affinities to a 5-HT reuptake inhibitor. It is also a partial agonist at 5-HT_{1B} receptors and an antagonist at 5-HT_{1D} and 5-HT_7 receptors. Vortioxetine was initially denoted LU AA 21004, and its first phase II study was published in 2011. The clinical development program, which led to its FDA approval for the treatment of major depressive disorder on September 30, 2013, initially comprised eleven placebo-controlled studies, of which five were active-referenced. Vortioxetine was initially commercialized under the brand name Brintellix but subsequently changed to the brand name Trintellix in May 2016 to avoid confusion with the anticoagulant Brinlinta.

Chemistry

The chemical structure of vortioxetine, which is a piperazine derivative, is 1-[2-(2,4-dimethylphenyl-sulfanyl)-phenyl]-piperazine (Fig. 33.5c–2). It has a molecular weight of 298.4 g/mole.

Pharmacologic Actions

Pharmacokinetics. The pharmacologic activity of vortioxetine comes from the parent compound, its major carboxylic acid metabolite being pharmacologically inactive. At doses studied of 2.5 to 60 mg/day, the pharmacokinetics were linear and time-independent. It is well absorbed from the gastrointestinal tract with an absolute bioavailability of 75%, with no difference in fed or fasting conditions. Peak plasma levels are reached after 7 to 11 hours. After multiple doses of 20 mg/day, C_{max} reached 19.21 ng/mL, and AUC over 24 hours reached 361 ng-hours/mL. There is an extensive extravascular distribution and a high protein binding of 98% to 99%. The terminal half-life is of 66 hours, with a steady state being reached after 2 weeks. The drug is catabolized to its major inactive carboxylic acid metabolite mainly through the CYP 2D6 isoenzyme.

Plasma levels are about doubled when administered to poor 2D6 metabolizers or in the presence of 2D6 inhibitors, and doses should be halved in these situations. Plasma levels might be higher when administered with strong 3A4/2C9 inhibitors, and caution is advised in these situations. Vortioxetine does not inhibit or induce any major CYP isozymes, nor is it a substrate of the permeability glycoproteins. Two-thirds of the metabolites are excreted in the urine and one-third in the feces. Only very small amounts of the parent compound are found in the urine. No dose adjustment is necessary for renal or hepatic impairment, although caution is advised, particularly with severe impairment.

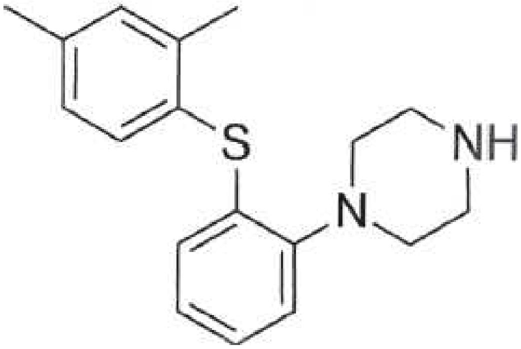


FIGURE 33.5c–2. Chemical structure of vortioxetine.

Mechanisms of Action. Although its exact mechanism of action is not yet fully understood, vortioxetine has been demonstrated to selectively target the 5-HT system, with multimodal 5-HT modulating properties. It was shown to produce the same adaptive changes as vilazodone on the 5-HT system in the rat brain, which led to a gradual increase in 5-HT_{1A} transmission with its sustained administration.

As with SSRI medications, vortioxetine binds to the 5-HT transporter with a high affinity (Ki = 1.6 nM). It also has high and clinically significant affinities for other 5-HT receptors, namely it is a 5-HT_3 antagonist (Ki = 3.7 nM), a full 5-HT_{1A} agonist (Ki = 15 nM), a 5-HT_7 antagonist (Ki = 18 nM), a 5-HT_{1B} partial agonist (Ki = 33 nM), and a 5-HT_{1D} antagonist (Ki = 54 nM).

In positron emission tomography (PET) studies, the mean 5-HT transporter occupancy reached 80% only at 20 mg/day, with an occupancy of 50% and 65% at doses of 5 and 10 mg/day, respectively. However, it is thought that the lower 5-HT transporter occupancy seen with the 5- and 10-mg doses still provides clinically significant effects through synergistic effects with the other 5-HT receptors vortioxetine engages.

Vortioxetine has no clinically significant affinity at the NE transporter (Ki = 113 nM) or at the DA transporter (Ki = >1,000 nM).

Therapeutic Indications

To this day, the only approved indication for vortioxetine is for the treatment of MDD in adults. As is the case for vilazodone, the 5-HT transporter blocker and the 5-HT_{1A} agonist properties of vortioxetine provide a rationale for its use in various anxiety, stress-related, OCD, eating and premenstrual dysphoric disorders. However, the dataset so far is not sufficient to support an indication for these other disorders.

Clinical Drug Studies

Clinical Drug Studies in Major Depressive Disorder. Although the initial dataset which led to the FDA approval of vortioxetine in 2013 included 11 placebo-controlled studies, the complete published dataset now includes 13 placebo-controlled studies which used a depressive symptom rating scale as the primary endpoint. Twelve of these studies were conducted in adult patients, and one study by Katona et al. included only older adult patients (≥65 years old) with a mean age of 71. In these various studies, doses used ranged between 1 and 20 mg/day for a duration of 6 to 8 weeks. All used the MADRS for inclusion in the study, with minimal scores ranging from ≥22 to ≥30, although most studies used the cut-off of ≥26. Most studies used the MADRS as a primary endpoint, and a few studies used the HAMD-24 items. Of these 13 studies, 7 were positive for the primary endpoint, and 6 were failed studies. It is noteworthy that until recently, the dataset included fourteen studies, but one study by Wang et al. 2019 was retracted by the authors, and the editors did not get an answer from the investigators about the source of vortioxetine since it had not been licensed for use in China at the time the study was conducted (Table 33.5c–2).

Overall, there are nine randomized studies that compared vortioxetine directly to another medication with antidepressant properties, using a change in depressive symptoms as the primary endpoint. Of the above 13 placebo-controlled studies, 6 included an active comparator, 5 with duloxetine (60 mg/day) and 1 with venlafaxine XR (225 mg/day). Of these six studies, the venlafaxine XR and three of the duloxetine-referenced studies were positive, whereas one duloxetine-referenced study was negative, and another was a failed study. The remaining three randomized studies were not placebo-controlled, thus comparing vortioxetine head-to-head with another medication. The first study examined the effectiveness of vortioxetine, with a flexible dose of 10 to 20 mg, with agomelatine, a melatonin receptor agonist and 5-HT$_{2B/2C}$ antagonist, in patients that had not responded to prior treatment with an SSRI or a serotonin and norepinephrine reuptake inhibitor (SNRI). Vortioxetine was found superior to agomelatine on the primary outcome (MADRS). In the second and third studies, vortioxetine 10 mg and 15 mg were found to be noninferior to venlafaxine XR 150 mg for 8 weeks in adults and sertraline 75 mg for 6 weeks in older adult patients, respectively.

Table 33.5c–2. Main Short-Term Randomized Controlled Trials of Vortioxetine

Study/Registration #	Key Findings on Primary Endpoint (Scale)	Doses (#Patients Randomized)	Comparator	Duration	Severity
Alvarez et al., 2012 NCT00839423	Positive (MADRS)	P (105); 5 mg (109); 10 mg (101)	P + venlafaxine 225 mg	6 weeks	MADRS > 30
Baldwin et al., 2012 NCT00635219	Failed; duloxetine did not separate (MADRS)	P (145); 2.5 mg (155); 5 mg (155); 10 mg (151)	P + duloxetine 60 mg	8 weeks	MADRS > 26
Henigsberg et al., 2012 NCT00735709	Positive (HAMD-24)	P (140); 1 mg (140); 5 mg (140); 10 mg (140)	P	8 weeks	MADRS > 26
Katona et al., 2012 NCT00811252	Positive (HAMD-24)	P (145); 5 mg (156)	P + duloxetine 60 mg	8 weeks	MADRS > 26
Jain et al., 2013 NCT00672958	Failed (HAMD-24)	P (300); 5 mg (300)	P	6 weeks	MADRS > 30
Mahableshwarkar et al., 2013 NCT00672620	Failed (HAMD-24)	P (153); 2.5 mg (153); 5 mg (153)	P + duloxetine 60 mg	8 weeks	MADRS > 22
Boulenger et al., 2014 NCT01140906	Positive (MADRS)	P (158); 15 mg (152); 20 mg (151)	P + duloxetine 60 mg	8 weeks	MADRS >26
McIntyre et al., 2014 NCT01422213	Positive (DSST 1° endpoint) Positive (MADRS 2° endpoint)	P (196); 10 mg (195); 20 mg (207)	P	8 weeks	MADRS > 26
Montgomery et al., 2014 NCT01488071	Positive (MADRS)	10–20 mg flexible dose (252)	Agomelatine 25–50 mg	8-12 weeks	MADRS > 22
Jacobsen et al., 2015 NCT01163266	Positive (20 mg only) (MADRS)	P (157); 10 mg (155); 20 mg (150)	P	8 weeks	MADRS > 26
Mahableshwarkar et al., 2015 NCT01153009	Positive (20 mg only) (MADRS)	P (161); 15 mg (147); 20 mg (154)	P +duloxetine	8 weeks	MADRS > 26
Mahableshwarkar et al., 2015 NCT01179516	Failed (MADRS)	P (160); 10 mg (157); 15 mg (152)	P	8 weeks	MADRS > 26
Mahableshwarkar et al., 2015 NCT01571453	Positive (DSST 1° endpoint) Positive (MADRS 2° endpoint)	P (194); 10–20 mg (198)	P +duloxetine	8 weeks	MADRS > 26
Wang et al., 2015	Noninferior (MADRS)	Venlafaxine (226); 10 mg (213)	Venlafaxine	8 weeks	MADRS > 26
Inoue et al., 2018	Failed (MADRS)	P (124); 5 mg (119); 10 mg (123)	P	8 weeks 52 weeks extension	MADRS > 26
Nishimura et al., 2018	Failed (MADRS)	P (152); 5 mg (144); 10 mg (150); 20 mg (154)	P	8 weeks	MADRS > 26
Borhannejad et al., 2020	Noninferior (HAMD)	Sertraline (30); 15 mg (30)	Sertraline	6 weeks	HAMD > 19
Inoue et al., 2020	Positive (MADRS)	P (164); 10 mg (165); 20 mg (164)	P	8 weeks	MADRS > 26

This table lists the main short-term randomized controlled trials of vortioxetine, which used a depression rating scale or the Digit Symbol Substitution Task (DSST) as its primary endpoint.
DSST, Digit Symbol Substitution Task; HAMD-24, Hamilton rating scale for Depression; MADRS, Montgomery-Åsberg Depression Rating Scale; P, placebo.

A Cochrane systematic review and meta-analysis by Koesters et al. concluded in favor of vortioxetine over placebo for response (RR 1.35, 95% CI 1.22–1.49; 14 studies, 6,220 participants), remission (RR 1.32, 95% CI 1.15–1.53; 14 studies, 6,220 participants) and depressive symptoms using MADRS (MD –2.94, 95% CI –4.07 to –1.80; 14 studies, 5,566 participants).

A meta-analysis by Baldwin et al. examined the effects of vortioxetine on anxiety levels in patients with MDD and high levels of anxiety. The analysis included data from 10 randomized, placebo-controlled trials, with a total of 1,497 vortioxetine-treated patients (5, 10, and 20 mg) and 860 placebo-treated patients who had a HAM-A baseline of ≥20. There was a significant effect of vortioxetine on MADRS as well as HAM-A total and psychic item subscales for all doses.

There are now two placebo-controlled relapse prevention studies, which are both positive. In the first study, remitted patients, 18 to 75 years old, were randomized to vortioxetine fixed dose (5 or 10 mg, *n* = 204) or placebo (*n* = 192) after an initial 12-week open-label treatment period (*n* = 639) of patients with a major depressive episode of ≥4 weeks duration and initial MADRS ≥26. The primary analysis of time to relapse favored vortioxetine, with a hazard ratio (HR) of 2.01 (95% confidence interval [CI] 1.26–3.21; *p* = .0035). In the second study, remitted patients, 18 to 75 years old, were randomized to vortioxetine fixed dose (5, 10 or 20 mg, *n* = 580) or placebo (*n* = 151) after an initial 16-week open-label treatment period (fixed dose 10 mg/day, *n* = 1,106) of patients with an MDE of 8 to 18 weeks duration and initial MADRS ≥26 and ≥2 prior depressive episodes. Analysis of the primary endpoint of time to relapse and cumulative relapse rates favored vortioxetine and were statistically significant at all doses studied: 32.5% in the placebo group versus 19.3% for vortioxetine 5 mg (HR 0.517; 95% CI 0.323–0.828; *p* = .006 vs. placebo), 17.9% for vortioxetine 10 mg (HR 0.476; 95% CI 0.296–0.767; *p* = .003 vs. placebo), and 17.4% for vortioxetine 20 mg (HR 0.483; 95% CI 0.298–0.782; *p* = .002 vs. placebo). There are also five open-label studies of 52 weeks that have assessed the maintained effectiveness of vortioxetine 5 to 10 mg (*n* = 1,313) and 15 to 20 mg (*n* = 1,144).

Clinical Drug Studies on Cognitive Function. The pharmacologic profile of vortioxetine led to the hypothesis that it could have beneficial effects on cognitive deficits seen in MDD. Thus, many studies of the effects of vortioxetine in MDD included change on various scales of cognitive function either as a primary or secondary endpoint. The most used scale is the Digit Symbol Substitution Task (DSST), which assesses attention, speed of processing and executive function. Other frequently used scales include the Ray Auditory Verbal Learning Test (RAVLT) and the University of California San Diego Performance-Based Skill Assessment (UPSA).

The initial findings on a battery of cognitive tests from three short-term placebo-controlled studies published between 2012 and 2015 led the European Medicine Agency and the FDA to add a cognition claim for patients with MDD to the label for vortioxetine. Of these three studies, two were active referenced with duloxetine 60 mg/day and used the change in the DSST as a primary endpoint. Vortioxetine, but not duloxetine, had a significantly greater effect than placebo on the DSST in all three studies, and the effect was shown through path analysis to be mostly a direct effect. Two meta-analyses (a network meta-analysis and a random effect meta-analysis) also confirmed the positive effect of vortioxetine on cognitive dysfunction versus placebo on the DSST.

Many other studies published since 2016 have assessed the effects of vortioxetine on the DSST or other cognitive, social or workplace functioning scales as a primary or secondary endpoint or through posthoc analysis. Study designs have varied, some studies having a small sample size and lacking power and some studies having a specific focus. Overall, results have been mixed.

Clinical Drug Studies of Other Disorders. Despite the rationale for using vortioxetine in the treatment of many other disorders for which SSRIs or buspirone have shown efficacy, very few studies have investigated this potential.

For the treatment of GAD, there are four short-term placebo-controlled studies, of which only one is positive and one large relapse prevention study which is positive. In meta-analyses of these studies, vortioxetine does not separate from placebo for doses studied of 2.5, 5, or 10 mg. As we know that anxiety disorders generally respond to higher doses of SSRIs and that the inhibition of vortioxetine of the 5-HT transporter is quite low at doses below 20 mg, it would be interesting to study the effects of vortioxetine in GAD at doses of 20 mg.

There is one positive open-label study for the treatment of panic disorder, one positive placebo-controlled RCT for improvement of negative symptoms in schizophrenia patients treated with risperidone 4 to 6 mg daily, and one positive double-blind RCT that showed an improvement in quality of life for patients with irritable bowel syndrome. Other studies for the treatment of social anxiety disorder, PTSD, binge-eating disorder, and attention-deficit disorder were all negative (one study on each).

Precautions and Adverse Reactions

Safety and Tolerability. The safety and tolerability of vortioxetine, as reported in the product monograph, are derived from data collected in patients with MDD treated in short-term clinical trials, with more than 6,700 patients, of whom 3,460 were treated with vortioxetine (5 to 20 mg/day). Also, an article published by Baldwin et al. analyzed the safety and tolerability data from 11 short-term MDD studies, 5 long-term MDD studies and 4 short-term GAD studies, for a total of 3,018 patients treated with vortioxetine in short-term studies and 2,457 patients treated with vortioxetine in long-term studies.

Overall, vortioxetine showed a very favorable profile. Across all studies, the most common treatment-emergent side effect that led to treatment discontinuation was nausea, occurring in about one-fourth to one-third of patients. It led to treatment discontinuation, in a dose-dependent manner, for about 4.5% to 7.8% of patients, reaching the same level as duloxetine 60 mg/day, compared to about 3.5% for placebo. It is noteworthy that with vortioxetine, many of the treatment-emergent adverse events (TEAEs) commonly found with SSRIs were seen at “placebo levels” with no dose effect: headache, dry mouth, dizziness, constipation, insomnia, somnolence, fatigue, sexual dysfunction, and hyperhidrosis.

Given the long terminal half-life of vortioxetine, if a side effect is problematic, it can be withheld for 3 days and restarted at half the dose.

Serious Adverse Events. Although five deaths have been reported in the short-term studies of vortioxetine, none seem to have been related or attributable to vortioxetine. Four of these deaths occurred in the short-term MDD trials. One 74-year-old woman on a vortioxetine 5 mg arm had a known history of cholelithiasis and died from gallbladder cancer 1 month after withdrawal from the study. One 63-year-old male receiving vortioxetine 2.5 mg died from falling from a fourth-floor balcony, an event not judged by the investigator to represent a suicidal act. One 46-year-old man, receiving a flexible dose of vortioxetine 5 to 10 mg, with a history of type II diabetes, died of a pancreatic carcinoma 8 months after withdrawal from the study. One 56-year-old man receiving vortioxetine 5 mg in an open-label long-term extension study died in a traffic collision caused by another driver. The fifth death occurred in a short-term GAD study: one 49-year-old woman randomized to vortioxetine 5 mg/day died from a morphine intoxication 3 days after her baseline visit, but no vortioxetine was found in her stomach or body fluids on autopsy.

Overdose. There are limited data in clinical and postmarketing reports on the effect of an overdose of vortioxetine. With accidental or intentional supratherapeutic doses of up to 40 mg/day for 4 days, adverse effects included increased incidence of nausea, postural dizziness, diarrhea, abdominal discomfort, generalized pruritus, somnolence, and flushing. With doses up to 80 mg, most patients reported absent or mild symptoms, most frequently nausea and vomiting. In doses above 80 mg, seizures and serotonin syndrome have been reported.

Sexual Dysfunction. Rates of sexual dysfunction in clinical trials are often underestimated when based on self-reporting. The use of standardized scales such as the ASEX and the CSFQ allow a much better estimation of the impact of various drugs on sexual function. Using the ASEX in seven short-term MDD studies, vortioxetine in doses of 5 to 10 mg/day had sexual adverse events at rates similar to placebo, whereas with doses of 20 mg/day, the incidence reached that of duloxetine 60 mg/day. With overall pooling of data from eleven short-term RCTs, sexual dysfunction was estimated at 1.6% to 1.8% for vortioxetine 5 to 20 mg versus placebo 1.0%, venlafaxine XR 225 mg 12.4%, and duloxetine 60 mg 4.5%.

A study by Jacobsen et al. examined the effects of switching responders to paroxetine, sertraline, or citalopram who were experiencing sexual dysfunction to either vortioxetine or citalopram (10 or 20 mg/day, with three-quarters of vortioxetine patients taking 20 mg/day). This study used the CSFQ short form and showed that vortioxetine had better rates than escitalopram on four of five dimensions and all three phases of sexual functioning.

Since sexual dysfunction with SSRIs and SNRIs is related to inhibition of the 5-HT transporter, these different findings are consistent with the lower occupancy of vortioxetine of the 5-HT transporter at doses inferior to 20 mg/day, with occupancy reaching 80% only at 20 mg/day.

Weight. No clinically relevant changes in body weight were found in short-term or long-term studies of vortioxetine. In long-term placebo-controlled studies, mean changes in weight were +0.4 kg for vortioxetine 5 to 10 mg, versus +0.1 kg for placebo. The proportion of patients with >7% weight gain was 6.5% for 5 to 10 mg, versus 5.8% for placebo. Proportion of patients with >7% weight loss was 3.5% for vortioxetine 5 to 10 mg, versus 2.6% for placebo.

Cardiac. In studies of vortioxetine, no clinically significant changes in cardiac parameters were found, including QT, QTc, PR and QRS intervals, blood pressure or heart rate, and no arrhythmogenic potential was found. In a thorough study of QTc in 340 healthy subjects, QTc was increased by 4.0 ms at 10 mg/day and 4.6 ms at 40 mg/day. A minor negative chronotropic effect was found of –4.7 beats per minute (BPM) for 10 mg/day and –5.4 BPM for 40 mg/day.

Laboratory Values. Studies of vortioxetine found no clinically significant changes versus placebo in clinical, biochemical values or hematologic parameters.

Platelets. Vortioxetine inhibits the 5-HT transporter and is expected to have similar effects on platelets, as seen with SSRIs or SNRIs. Caution is advised when administering vortioxetine with other drugs that potentiate the risk of bleeding, or with patients that have a history or risk factors of bleeding. No cases of bleeding have been reported in studies of vortioxetine.

Hyponatremia. Although no cases of hyponatremia have been reported in the clinical studies of vortioxetine, medications with serotonergic properties such as SSRIs and SNRIs have been shown to increase the risk of hyponatremia related to the syndrome of inappropriate antidiuretic hormone secretion. Thus, caution is advised when treating patients at higher risk of hyponatremia with vortioxetine. If symptomatic hyponatremia develops, vortioxetine should be discontinued and appropriate medical intervention implemented.

Gastrointestinal. When vortioxetine was developed, it was thought that the 5-HT_3 antagonism properties would eliminate nausea commonly seen with SSRI and SNRI medications. However, nausea has turned out to be the most reported TEAE in clinical trials, with rates between 20.9% and 31.2%, leading to treatment discontinuation in 1% to 4% of patients in a dose-dependent manner. This could be attributable to the 5-HT_{1A} agonist properties, as is seen with the 5-HT_{1A} agonist buspirone. Vomiting was also seen to a lesser extent, with rates of 2.9% to 6.5%.

Suicidality. Vortioxetine carries the same black box warning as other SSRIs regarding suicidal thoughts and behaviors in children, adolescents, and young adults, based on data showing an increased risk of suicidal thinking and behavior (although no completed suicides were observed) in children, adolescents, and young adults (ages 18 to 24) with MDD and other psychiatric disorders treated with SSRIs or other newer antidepressants. No completed suicides were reported in trials of vortioxetine. In short-term placebo-controlled trials of vortioxetine, suicide-related events (such as intentional overdose, self-injurious behavior, and suicide attempts) were reported by 0.4% of vortioxetine-treated patients versus 0.3% of placebo-treated patients, newly emergent suicidal ideation was reported by 2.7% of vortioxetine-treated patients versus 4.1% of placebo-treated patients, and treatment-emergent suicidal ideation in the 18- to 24-year-old group was reported by 15% of vortioxetine-treated patients versus 13.2% of placebo-treated patients.

Activation of Mania/Hypomania. In phase II/III clinical trials of vortioxetine, only 1 out of 3,904 (<0.1%) patients treated with vortioxetine-reported mania/hypomania. However, caution should always be used when initiating any treatment with antidepressant properties as bipolar disorder most often presents with an initial major depressive episode, and bipolar patients are at increased risk of developing mania or hypomania when treated with a medication indicated for MDD.

Discontinuation Syndrome. In studies of vortioxetine, no discontinuation symptoms were reported, which is consistent with its long terminal half-life, as complete elimination takes about 2 weeks. More specifically, three studies used the Discontinuation Emergent Signs and Symptoms (DESS) scale to specifically assess potential discontinuation symptoms when vortioxetine was abruptly stopped at the end of 8 weeks of treatment. No clinically significant differences were seen in this scale for patients who had been taking 10, 15, or 20 mg of vortioxetine at weeks 9 and 10 (thus after 1 and 2 weeks of abrupt cessation).

Serotonin Syndrome. Serotonin syndrome has not been reported in the short-term or long-term clinical trials of vortioxetine. However, one must always consider the risk of 5-HT syndrome when using medications that increase 5-HT availability. This risk is extremely low when the medication is taken alone in therapeutic doses. However, the risk increases in overdose or when co-administration occurs with illicit drugs (such as ecstasy and concentrated tetrahydrocannabinol) or other medications that increase 5-HT availability, such as MAOIs, triptans, opioids, and St. John wort. When serotonin syndrome is diagnosed, all medications increasing serotonin should be immediately stopped and supportive measures implemented.

Nervous System. According to the product label, seizures were reported in <0.1% of patients receiving vortioxetine versus 0% in patients receiving placebo in short-term clinical trials. Caution is advised in patients with epilepsy or a history of seizures, and treatment should be stopped if there is an increased frequency of seizures in these patients.

No significant driving or cognitive impairments relative to placebo were noted in a study of 21 healthy individuals who were administered a battery of neuropsychological tests the day after taking a single dose of 10 mg in the evening.

Sleep. No significant difference was seen between vortioxetine or placebo for insomnia or daytime somnolence. More specifically, insomnia occurred in 4.0% of patients taking placebo versus 2.0% to 5.1%, 15.9%, and 8.1% of patients taking vortioxetine, venlafaxine and duloxetine, respectively, in short-term MDD studies.

Reproductive. There are no published data on vortioxetine during pregnancy or during labor and delivery. Vortioxetine was not teratogenic in rats or rabbits for doses up to 160 and 60 mg/day, although in rats exposed to about six times the Cmax of the MRHD (20 mg/day), lower fetal weight and delayed ossification were observed.

The FDA package insert carries the same warning regarding potential neonatal toxicity as is listed with other medications used to treat MDD. Clinicians must consider the well-documented risks of untreated depression in pregnancy, including during the post-partum period, versus the associated risks of taking medications with serotonergic agents (see chapter on SSRI for more considerations).

Lactation. There are no human published data for breastfeeding while taking vortioxetine. Animal data have shown vortioxetine and its metabolites to be excreted in milk. As this is also expected to be the case in humans, breastfeeding is not recommended when taking vortioxetine. However, as with all medications in pregnancy, the decision should consider the risks and benefits.

Fertility. There are no data on the effect of vortioxetine on fertility in humans. In male and female rats, vortioxetine did not show any effect on fertility, with plasma levels of 24 and 17 times the MRHD.

Drug Interactions

As vortioxetine is metabolized primarily through CYP 2D6, blood levels will increase in 2D6 slow metabolizers and when co-administered with moderate (such as bupropion) or strong (such as fluoxetine) 2D6 inhibitors and decrease in the presence of 2D6 inducers. However, vortioxetine does not inhibit or induce any CYP isozymes and thus is not expected to alter other drug plasma levels through CYP interactions. As with all medications that inhibit 5-HT transporters, MAOIs should be stopped for a minimum of 2 weeks before starting vortioxetine, and vortioxetine should be completely eliminated (2 weeks) before initiating an MAOI or moclobemide. Efficacy of triptans might be reduced when co-administered with vortioxetine, as their therapeutic effects are mediated through activation of 5-HT_{1D} receptors, and vortioxetine is an antagonist of 5-HT_{1D} receptors. However, since the affinity of vortioxetine for the 5-HT_{1D} receptors is quite low (Ki = 54 nM), this pharmacokinetic interaction might not be significant at lower doses of vortioxetine.

Dosage and Administration

Based on the clinical development program, vortioxetine is recommended for the treatment of MDD at doses between 5 and 20 mg/day, usually given morning for convenience, although it can also be given at night. Considering the time to reach a steady state, each dose increase should be done at intervals of ≥2 weeks. For adults 18 to 65 years old, the starting dose is usually 10 mg. For older adult patients, poor 2D6 metabolizers or when co-administered with a 2D6 inhibitor, the starting dose should be 5 mg/day.

Switching Strategies to Vortioxetine. Switching from other medications to vortioxetine has been examined in three studies and seems well tolerated. However, some problems could occur in clinical practice if the other medication is stopped too abruptly since vortioxetine reaches steady state after only about 2 weeks, and it has low 5-HT transporter occupancy at its lower-dose range. Thus, when switching from an SSRI or SNRI medication with a short half-life, discontinuation symptoms could occur in the first weeks of treatment and be misinterpreted as side effects of vortioxetine, thus leading to premature discontinuation of vortioxetine. To prevent this, it is recommended to implement a gradual cross-over which considers the long half-life of vortioxetine.

Geriatric Patients. One trial by Katona et al. studied vortioxetine for the treatment of MDD in older adult patients, and a few other studies included patients aged 18 to 75, thus recruiting some patients >65 years old. So far, these studies have not shown any major safety issues in older adult patients treated with vortioxetine, and as with adult populations, nausea was the only TEAE that occurred with an incidence of ≥5% and >2× the placebo rate (21.8% vs. 8.3%).

Pediatric Patients. Vortioxetine is not recommended in pediatric patients, as its efficacy has not yet been demonstrated in adolescents 12 to 17 years, and its efficacy and safety have not yet been demonstrated in children 7 to 11 years.

ACKNOWLEDGMENTS

This chapter represents an update and revision of previous chapters in this series, most recently by Dr. Lourdes Illa-Sanchez from the last edition. We are indebted to Dr. Illa-Sanchez for her work and retain much of her prose in this current edition.

33.5d Monoamine Oxidase Inhibitors

Ethan F. Karsen, M.D., and Paul E. Holtzheimer, M.D., M.S.

HISTORY

Monoamine oxidase inhibitors (MAOIs) were among the first antidepressants found to be clinically effective in humans. Although MAOI use has declined over time due to the emergence of newer antidepressants with equivalent efficacy and more tolerable side effects, research interest in MAOIs has been rekindled by the development of selective MAOIs, new delivery systems, and the discovery of their neuroprotective role in neurodegenerative diseases.

Development of MAOIs

In 1957, at a regional meeting of the American Psychiatric Association (APA) in Syracuse, New York, two independent research groups presented findings showing that the antitubercular medication iproniazid had antidepressant effects in patients with tuberculosis and comorbid depression. These findings represented a culmination of years of laboratory and clinical research. Emil Fischer first isolated hydrazines, the class to which early MAOIs belong, in the 1870s. In the 1920s and 1930s, several research groups helped identify the enzyme monoamine oxidase (MAO) and showed that it is capable of metabolizing adrenaline through oxidation. In 1952, Albert Zeller demonstrated that iproniazid acts as an MAO inhibitor. The same year, physicians at Staten Island's Seaview Hospital observed that iproniazid had a more powerful stimulating effect than isoniazid in the patients they treated for tuberculosis. That first study of MAOI use in patients without tuberculosis was also presented at the APA meeting in 1957. The study showed substantial improvement of symptoms in 70% of a group of psychotically depressed patients taking iproniazid. By 1958, over 400,000 patients were being treated with iproniazid for depression, then marketed as Marsilid. The clinical use of iproniazid, however, was short-lived as reports of jaundice and hepatotoxicity accumulated, and in 1961 it was withdrawn from the U.S. market.

While iproniazid was entering and leaving the market, pharmaceutical companies were developing several new MAOIs. Hydrazine derivatives similar to iproniazid included: isocarboxazid (Marplan), phenelzine (Nardil), nyalamide, mebanazine, and pheniprazine. Like iproniazid, many of these agents showed hepatotoxicity that limited clinical use. In 1959, researchers discovered that tranylcypromine (Parnate), a cyclopropylamine structurally unrelated to the hydrazines, had MAOI action. Soon after its introduction, however, reports appeared of hypertensive crises and severe headaches associated with subarachnoid intracranial hemorrhage. Barry Blackwell, a psychiatric resident at Maudsley Hospital in London, traced these effects back to ingestion of certain cheeses in patients taking MAOIs, thereafter known as the "cheese effect." Further investigation showed that food rich in amines, especially tyramine, could precipitate hypertensive crises in patients treated with MAOIs. Due to the concern for hemorrhage, tranylcypromine was briefly removed from the U.S. market in 1964, only to be reintroduced a few months later after postmarketing analysis showed an incidence rate of less than 0.001%. Thereafter, all MAOIs included labeling on adverse reactions and suggested dietary restrictions.

The first-generation MAOIs are *irreversible* inhibitors of MAO; they covalently bond to and inactivate the enzyme. After the discovery of two isoforms of MAO, MAO-A and MAO-B (discussed in more detail later in this chapter), in the 1970s, researchers sought to synthesize MAOIs that would be reversible and selective inhibitors with fewer adverse effects. The use of platelets helped identify molecules selective for MAO-B, with evidence suggesting a correlation between platelet MAO-B inhibition and antidepressant response to phenelzine. Pargyline was the first FDA-approved selective MAO-B inhibitor, although it did not show significant antidepressant effects in clinical trials and is no longer available. In 1972, researchers described L-deprenyl (Eldepryl), an irreversible but selective MAO-B inhibitor. However, in clinical trials, L-deprenyl demonstrated antidepressant effect only at doses at which it loses its selectivity for MAO-B. This finding suggested that inhibition of MAO-A, alone or in combination with MAO-B inhibition, is necessary for the antidepressant effect. Interestingly, experimental findings from the 1970s found L-deprenyl to be an effective adjunct to L-dopa in the treatment of patients with Parkinson disease (PD). The FDA licensed the drug in 1996 and renamed it selegiline. Rasagiline (Azilect), with theoretically less adverse effects than selegiline, followed as another irreversible MAO-B inhibitor for use in PD.

Table 33.5d–1.
Classification of Monoamine Oxidase Inhibitors

Drug	Reversibility	Selectivity	Indication
Iproniazid[a] (Marsilid)	Irreversible	MAO-A MAO-B	Depression
Isocarboxazid (Marplan)	Irreversible	MAO-A MAO-B	Depression
Phenelzine (Nardil)	Irreversible	MAO-A MAO-B	Depression
Tranylcypromine (Parnate)	Irreversible	MAO-A MAO-B	Depression
Isoniazid (Nydrazid)	Irreversible	MAO-A MAO-B	Antituberculosis
Nialamide[a] (Niamid)	Irreversible	MAO-A MAO-B	Depression
Procarbazine (Matulane)	Weak irreversible	MAO-A MAO-B	Antineoplastic
Clorgyline[b]	Irreversible	MAO-A only	Depression
Selegiline (Deprenyl)	Irreversible	MAO-B only	Depression, Parkinson disease
Rasagiline (Azilect)	Irreversible	MAO-B only	Parkinson disease
Pargyline[a] (Eutonyl)	Irreversible	MAO-B only	Antihypertensive
Linezolid	Reversible	MAO-A MAO-B	Antibiotic
Lazabemide[c] (Pakio)	Reversible	MAO-B only	Parkinson disease
Moclobemide[c] (Aurorix/Manerix)	Reversible	MAO-A only	Depression
Brofaromine[c] (Consonar)	Reversible	MAO-A only	Depression
Befloxatone[c] (Synthelabo)	Reversible	MAO-A only	Depression
Pirindole[c] (Pirazidol)	Reversible	MAO-A only	Depression
Toloxatone[c]	Reversible	MAO-A only	Depression

(Humoryl)

[a] Discontinued.

[b] Used in research only.

[c] Available outside the United States only.

Following the suggested association between MAO-A inhibition and antidepressant effects, researchers in 1979 identified clorgyline, an irreversible but selective MAO-A inhibitor. It proved effective for depression but caused hypertensive crises as it irreversibly bound MAO in the gut. Moclobemide initially developed for hyperlipidemia, became the first reversible and selective MAO-A inhibitor; it is currently available for use in depression in over 50 countries worldwide. Reversible inhibitors of monoamine oxidase type A (RIMA) are less likely to cause hypertensive crises because they are readily displaced by tyramine in the gut. There are no RIMAs currently available in the United States (see Table 33.5d–1 for MAOI drugs available worldwide). The five MAOIs currently available in the United States are isocarboxazid, phenelzine, tranylcypromine, selegiline, and rasagiline (Fig. 33.5d–1).

CHEMISTRY

MAO is a flavoprotein enzyme system located on the outer mitochondrial membrane of both neurons and nonneuronal cells. In neurons, MAO metabolizes three major neurotransmitters: serotonin, dopamine, and norepinephrine. MAO also serves several other important roles in nonneuronal places, including the metabolism of trace amines in the brain, the peripheral inactivation of biogenic and dietary amines, phase I metabolism, and as an imidazoline receptor.

FIGURE 33.5d–1. Molecular structures of monoamine oxidase inhibitors.

MAO contains an intracellular active site that functions to metabolize amines through oxidation (Fig. 33.5d–2). MAO transfers two hydrogen atoms to a flavin cofactor (FAD). The reduced flavin is reoxidized by oxygen-producing hydrogen peroxide plus the imine, which spontaneously hydrolyzes to the aldehyde (or a substituted amine, in the case of secondary amines like adrenaline) plus ammonia. The aldehyde product is further metabolized for urine excretion.

MAO comes in two forms, MAO-A and MAO-B, encoded by separate genes on chromosome X, originally distinguished by their differing sensitivities to the inhibitors clorgyline and l-deprenyl. Researchers published structures of MAO-A and MAO-B (which share 70% DNA similarity) in 2005 and 2002, respectively.

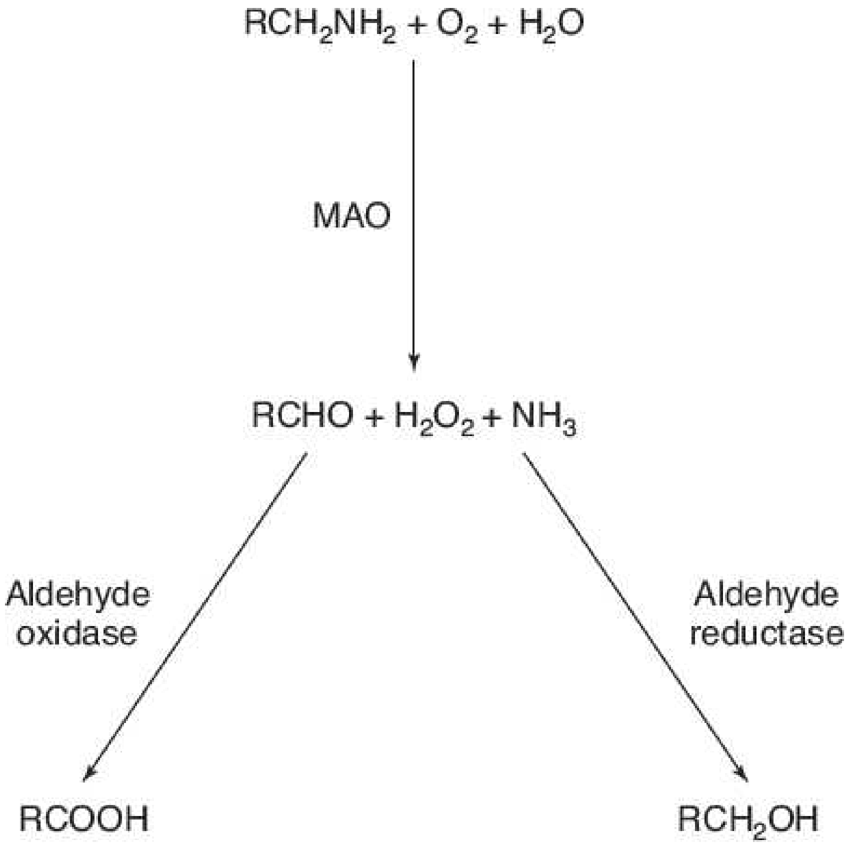

FIGURE 33.5d–2. The reaction catalyzed by monoamine oxidase (MAO), acting on a primary amine.

Researchers have identified four polymorphisms in the gene coding for MAO-A as possible risk factors for psychiatric disorders. The most studied of these polymorphisms is MAO-A-uVNTR, which has been associated with depression in male patients, aggression and impulsivity levels, autism spectrum disorders, alcoholism, and suicide attempts. Studies have also found polymorphisms in intron 13 and exon 14 of MAO-B to be associated with increased risk for PD.

In the central nervous system (CNS), both MAO-A and MAO-B serve to regulate the content of intracellular amine stores, terminate actions of amine neurotransmitters, and protect neurons from exogenous amines. In addition to MAO metabolism, neurotransmitter action may be terminated by catecholamine-o-methyl-transferase (COMT) or vesicular repackaging. Under normal conditions, neurotransmitters are preferentially stored in vesicles, where they are not exposed to MAO. As a result, MAO maintains low neurotransmitter concentration within the cytoplasm of neurons.

MAO-A preferentially deaminates serotonin and norepinephrine and predominates in catecholaminergic neurons in the substantia nigra, locus coeruleus, and periventricular regions of the hypothalamus. MAO-B preferentially deaminates phentylamine and benzylamine and predominates in serotonergic neurons in the dorsal raphe nucleus. Both forms metabolize dopamine, tyramine, and tryptamine. That MAO subtypes populate neurons with neurotransmitters of low affinity suggests a role in preventing the build-up of nonnative neurotransmitters.

In addition to the major monoamines, MAO also serves to metabolize other amines: phenylethanolamine, meta- and para-tyramine and octamine, which are found in the brain at lower levels and collectively known as trace amines. These trace amines can markedly affect the uptake and release of catecholamines and serotonin at nerve endings. There has been increased research into the signaling roles of trace amines with the discovery of specific G-protein–coupled receptors for trace amines in the mammalian brain, which may help regulate the activity of monoamine transporters.

In the periphery, MAO serves to rapidly inactivate biogenic and dietary amines. The most well-known example is MAO-A's role in the intestinal tract. MAO-A inactivates ingested tyramine from the diet, preventing its release into the general circulation. When absorbed, tyramine causes significant release of norepinephrine from peripheral adrenergic neurons leading to vasoconstriction, increased heart rate, and elevated blood pressure. MAO also deactivates peripheral serotonin, epinephrine, and norepinephrine, as it does in the CNS.

In addition to its role in amine regulation, MAO is involved in phase I metabolism of xenobiotics. Like the cytochrome P450 system, MAO can decrease bioactivity. For example, MAO-B in the liver oxidizes sertraline, citalopram, sumatriptan, and phenylephrine.

Finally, recent research has identified MAO as an imidazoline (I2) receptor (IR). The clinical relevance of this finding remains unclear. However, there is some emerging evidence that it may play a role in depression. While IRs are found throughout the brain and on platelets, compounds that have I2-selectivity appear to allosterically inhibit both MAO isozymes, which may explain some anxiolytic and antidepressant effects seen in mice. Additionally, rat models show that chronic treatment with irreversible MAOIs reduces the density of I2 sites. Finally, studies found an increased density of 45-kd I2 receptors in platelets of depressed patients and prefrontal cortices of suicide victims when compared to controls.

MECHANISM OF ACTION

The proposed mechanism of MAOIs efficacy in depression has evolved since its discovery and has expanded with use in other neuropsychiatric disorders.

The "catecholamine hypothesis" or "monoamine theory" of depression postulates that depression in humans is caused by decreased levels of primarily norepinephrine in the synaptic cleft. Several early observations led to this conclusion: the effectiveness of MAOIs in depression, the nearly concurrent discovery of TCAs and their mechanism of norepinephrine reuptake inhibition, and reserpine's depressogenic effect via monoamine depletion. Thus, it was thought that MAOIs alleviate depression by direct inhibition of MAO and an increase in catecholamines available within the synapse. Monoamines, especially dopamine, serotonin, and norepinephrine, have long been known to play an important role in the behavioral regulation of mammals. For instance, in humans, low levels of amines in the brain are associated with hyperactivity and depression, and elevated amines are associated with risk-taking behavior. However, increased monoamine levels can be measured within hours after the first dose of an MAOI, while antidepressant effects take two to four weeks.

Further studies suggest there are secondary adaptations to long-term medication therapy that may be responsible for the antidepressant effect, including the reduced density of alpha-2, beta-adrenergic, and 5-HT$_1$ and 5-HT$_2$ receptors; correction of hypothalamic–pituitary–adrenal (HPA) axis overactivation; increases in BDNF-mediated signaling; and induction of hippocampal neurogenesis. There is also evidence that tranylcypromine at sufficiently high concentrations may act as a monoamine reuptake inhibitor, and phenelzine may inhibit GABA transaminase, increasing levels of GABA within the brain.

Despite evidence challenging a simplistic monoamine-deficiency model, recent imaging studies have renewed interest in the monoamine theory of depression. Researchers using positron emission tomography (PET) have shown increased MAO-A binding (suggesting the decreased presence of monoamines) in the brains of medication-free patients during a major depressive episode compared with healthy controls. A follow-up study found that successful SSRI treatment did not result in normalization of MAO-A levels and that patients who experienced recurrent depressive episodes had increased MAO-A binding in the prefrontal cortex and anterior cingulate cortex compared to those who maintained remission. The authors go on to suggest an advanced monoamine model for depression whose primary mechanism is chronic monoamine loss and associated changes.

CLASSIFICATION

MAOIs may be classified according to chemical structure, reversibility, or selectivity (Table 33.5d–1). Isocarboxazid and phenelzine are hydrazine compounds containing a nitrogen–nitrogen pair on their side chain. All other MAOIs are classified as nonhydrazines. Irreversible MAOIs covalently bind to the enzyme, permanently inhibiting MAO function until new MAO can be produced, usually 2 to 3 weeks. Reversible MAOIs can be displaced by tyramine from the active site of MAO-B, allowing it to be metabolized. Tyramine is not present in high concentrations in the brain and therefore does not inhibit MAOI effects on neurotransmitters. Nonselective MAOIs target both MAO-A and MAO-B, while selective MAOIs target a single isozyme.

Pharmacologic Actions of Specific Agents

Tranylcypromine (Parnate)

Neuroscience-Based Nomenclature (NbN)	
MAO-I	
Pharmacologic domain	Serotonin, Norepinephrine, Dopamine
Mechanism of action	Enzyme inhibitor (MAO-A, MAO-B), releaser (DA, NE)

Tranylcypromine is Food and Drug Administration (FDA)-approved for use in major depressive episodes without melancholia. Off-label uses include other depressive disorders, panic disorder, social anxiety disorder, and posttraumatic stress disorder (PTSD).

PHARMACODYNAMICS

Mechanism of Action. Tranylcypromine is an irreversible and nonselective nonhydrazine MAOI. It covalently binds to both MAO-A and MAO-B. Of note, as a nonhydrazine, its antidepressant effects tend to have a more rapid onset.

PHARMACOKINETICS

Absorption. Tranylcypromine is readily absorbed from the GI tract.

Distribution. There are no clear data on the distribution of tranylcypromine.

Metabolism and Elimination. Tranylcypromine has peak plasma concentrations 1 to 3 hours after ingestion. Its elimination half-life is 2.5 hours. Metabolites are excreted in the urine.

DOSING. Dosing generally starts at 10 mg twice a day (see Table 33.5d–2). If there is no improvement within 2 to 3 weeks, then the dose can be increased by 10 mg every 2 to 3 weeks with a total maximum daily dose of 60 mg.

Tranylcypromine is contraindicated in patients with abnormal liver function tests, hepatic impairment, or a history of liver disease. Tranylcypromine is also contraindicated in patients with severe renal impairment. In patients with mild to moderate renal impairment, tranylcypromine should be used with caution due to the potential for accumulation of active metabolites.

MONITORING PARAMETERS. Complete metabolic panel at baseline, 1 and 3 months.

PREGNANCY AND LACTATION. Tranylcypromine is classified as FDA pregnancy risk category C. According to the manufacturer, tranylcypromine is excreted in human milk, and the potential benefit of the drug should be weighed against the potential hazards to the mother and infant during breastfeeding.

COMMON ADVERSE EFFECTS. Agitation, anxiety, constipation, diarrhea, dizziness, headache, impotence, insomnia, loss of appetite, mania, nausea, orthostatic hypotension, somnolence, weight gain, and xerostomia.

Table 33.5d–2.
Typical Dosage Forms and Recommended Dosages for Currently Available Monoamine Oxidase Inhibitors

Drug	Usual Dose (mg/day)	Maximum Dose (mg/day)	Dosage (Oral) Formulation
Tranylcypromine (Parnate)	20–60	60	10-mg tablets
Phenelzine (Nardil)	30–60	90	15-mg tablets
Isocarboxazid (Marplan)	20–40	60	10-mg tablets
Selegiline (Eldepryl)	10	30	5-mg tablets
Transdermal selegiline (Emsam)	6	12	6-, 9-, or 12-mg patch
Rasagiline	0.5–1.0	1.0	0.5- or 1.0-mg tablets

Phenelzine

Neuroscience-Based Nomenclature (NbN)	
MAO-I	
Pharmacologic domain	Serotonin, Norepinephrine, Dopamine
Mechanism of action	Enzyme inhibitor (MAO-A, MAO-B)

Phenelzine is FDA-approved for use in depressed patients clinically characterized as “atypical,” “nonendogenous,” or “neurotic.” Off-label uses include other depressive disorders, panic disorder, social anxiety disorder, and obsessive-compulsive disorder (OCD).

PHARMACODYNAMICS

Mechanism of Action. Phenelzine is an irreversible and nonselective hydrazine MAOI. It covalently bonds both MAO-A and MAO-B.

PHARMACOKINETICS

Absorption. Phenelzine is well absorbed following oral administration.

Distribution. There is insufficient data on phenelzine's distribution.

Metabolism and Elimination. Peak levels are reached in approximately 2 to 4 hours. The mean half-life is approximately 12 hours. Phenelzine is eliminated in the urine as metabolites.

DOSAGE. The initial dosage of phenelzine is generally 15 mg two to three times per day. It may be increased rapidly, as tolerated, to a maximum dose of 30 mg three times a day. Many patients do not show response until treatment at 60 mg has been continued for at least 4 weeks. Historically, it has been recommended that after the maximum effect is achieved, the dosage should be slowly reduced to the lowest dose needed to maintain clinical effectiveness.

Due to the potential for drug accumulation and associated effects, phenelzine is not recommended in patients with hepatic disease or severe renal impairment.

PREGNANCY AND LACTATION. Phenelzine is classified as FDA pregnancy risk category C. According to the manufacturer, the safe use of phenelzine during breastfeeding has not been established, and the potential benefit of the drug should be weighed against the possible hazards to the mother and nursing infant.

MONITORING PARAMETERS. Complete metabolic panel at baseline, 1 and 3 months.

COMMON ADVERSE EFFECTS. Constipation, disorders of ejaculation or orgasm, dizziness, edema, fatigue, headache, hyperreflexia, impotence, elevated values on liver function tests, orthostatic hypotension, sleep disorders, somnolence, tremor, weight gain, and xerostomia.

Isocarboxazid

Neuroscience-Based Nomenclature (NbN)	
MAO-I	
Pharmacologic domain	Serotonin, Norepinephrine, Dopamine
Mechanism of action	Enzyme inhibitor (MAO-A, MAO-B)

Isocarboxazid is FDA-approved for use in major depressive disorder. Off-label use includes panic disorder and social anxiety disorder.

PHARMACODYNAMICS

Mechanism of Action. Isocarboxazid is an irreversible and nonselective hydrazine MAOI. It covalently bonds both MAO-A and MAO-B.

PHARMACOKINETICS

Absorption. Isocarboxazid is readily absorbed from the GI tract.

Distribution. There is insufficient data on the distribution of isocarboxazid.

Metabolism and Elimination. Isocarboxazid reaches peak plasma concentrations in 3 to 5 hours. The half-life is approximately 2.5 hours. It is metabolized by the liver and excreted as metabolites in the urine.

DOSAGE. The initial dose of isocarboxazid is 10 mg twice a day. The dose may be increased from 10 mg daily up to a maximum dosage of 60 mg total daily in divided doses. If a therapeutic response is not seen in 3 to 6 weeks, it is unlikely to develop. After maximum benefit is achieved, the dose should be reduced to the lowest effective dose.

Isocarboxazid is not recommended in patients with hepatic impairment or renal impairment.

PREGNANCY AND LACTATION. Isocarboxazid is classified as FDA pregnancy risk category C. According to the manufacturer, the amount of excretion of isocarboxazid and its metabolites in human milk have not been determined; therefore, isocarboxazid should only be used during breastfeeding if clearly needed.

MONITORING PARAMETERS. Complete metabolic panel at baseline, 1 and 3 months.

COMMON ADVERSE EFFECTS. Anxiety, blurred vision, constipation, dizziness, headache, insomnia, mania, somnolence, weight gain, and xerostomia.

Selegiline

Neuroscience-Based Nomenclature (NbN)	
MAO-I	
Pharmacologic domain	Dopamine, Norepinephrine, Serotonin
Mechanism of action	Enzyme inhibitor (MAO-B, MAO-A)

Selegiline is FDA-approved for use in PD in combination with levodopa. Off-label use includes Alzheimer disease (AD), depression, and ADHD.

PHARMACODYNAMICS

Mechanism of Action. Selegiline is an irreversible and selective MAO inhibitor. At doses lower than 10 mg, it covalently binds MAO-B. At doses above 10 mg, it covalently binds both MAO-A and MAO-B. Of note, selegiline is metabolized to amphetamine compounds, which may explain its effectiveness in the treatment of attention-deficit hyperactivity disorder (ADHD).

PHARMACOKINETICS

Absorption. Selegiline is readily absorbed in the GI tract.

Distribution. Up to 85% of plasma selegiline is reversibly bound to proteins.

Metabolism and Elimination. Peak serum concentrations are found in 0.5 to 2 hours. At a steady state, the elimination half-life is approximately 10 hours. The drug is rapidly and completely metabolized to three active derivatives with the following half-lives: *N*-desmethyldeprenyl, 2 hours; 1-amphetamine, 17.7 hours; and 1-methamphetamine, 20.5 hours.

DOSAGE. Effective antidepressant doses of oral selegiline are not usually achieved until the range of 20 to 30 mg/day is used, at which point selegiline loses its selectivity and requires dietary monitoring.

For ADHD, trials have used 2.5 mg twice a day for children under 5 years old and 5 mg twice a day for children over 5 years old.

Specific guidelines for dosage adjustments of selegiline in patients with hepatic impairment and renal impairment are not available.

PREGNANCY AND LACTATION. Selegiline is classified as FDA pregnancy risk category C. According to the manufacturer, it is unknown if selegiline is excreted into breast milk, and a decision should be made whether to discontinue the drug or discontinue breastfeeding, taking into account the importance of the drug to the mother.

MONITORING PARAMETERS. None.

COMMON ADVERSE EFFECTS. Nausea, dizziness, and insomnia.

Transdermal Selegiline. Transdermal selegiline is FDA-approved for use in major depressive disorder.

PHARMACODYNAMICS

Mechanism of Action. Transdermal selegiline is an irreversible and selective MAOI. At doses less than 6 mg, it covalently binds MAO-B only. At doses above 9 mg, it covalently binds MAO-A and MAO-B.

PHARMACOKINETICS

Absorption. Approximately 23% to 30% of the medication is absorbed through the skin over 24 hours.

Distribution. Once absorbed, it is 90% protein bound, rapidly distributed throughout the body, and crosses the blood–brain barrier. Transdermal administration avoids first-pass metabolism and results in much higher bioavailability (74%) compared to the oral form (4%).

Metabolism and Elimination. Selegiline is metabolized via *N*-dealkylation or *N*-depropargylation by several CYP450 enzymes (2A6, 2B6, 2C9, 3A4, and 3A5). Under steady-state conditions, the median elimination half-life increases to 10 hours. The half-life is approximately 18 to 25 hours. The final metabolites are methamphetamine and amphetamine, which are excreted in the urine.

DOSAGE. The initial dose is 6 mg/24 hr. Although the maximum dose is 12 mg, there is little evidence for doses above 6 mg. If clinically indicated, dose increases should be made in 3 mg increments every 2 to 3 weeks. In older adult patients, the recommended dose is 6 mg per 24 hours. At a dose above 9 mg, the manufacturer suggests following a diet modified for reduced tyramine intake.

Dose adjustments for transdermal selegiline are not needed in patients with mild to moderate hepatic impairment or any degree of renal impairment.

PREGNANCY AND LACTATION. Transdermal selegiline is classified as FDA pregnancy risk category C. According to the manufacturer, it is not known if transdermal selegiline is excreted into human milk, and caution is advisable if administering selegiline to a nursing woman.

MONITORING PARAMETERS. None.

COMMON ADVERSE EFFECTS. Application site reaction, decreased systolic blood pressure, diarrhea, headache, indigestion, insomnia, orthostatic hypotension, weight loss, and xerostomia.

Rasagiline

Neuroscience-Based Nomenclature (NbN)	
MAO-I	
Pharmacologic domain	Dopamine, Serotonin
Mechanism of action	Enzyme inhibitor (MAO-B)

Rasagiline is FDA-approved for use in PD as monotherapy or an adjunct to levodopa.

PHARMACODYNAMICS

Mechanism of Action. Rasagiline is an irreversible and selective MAOI. It covalently binds MAO-B.

PHARMACOKINETICS

Absorption. Rasagiline is rapidly absorbed and reaches peak levels in 1 hour.

Distribution. Plasma protein binding ranges from 88% to 94%.

Metabolism and Elimination. Rasagiline is metabolized by the cytochrome P450 system in the liver, predominately CYP1A2, and is mainly excreted via urine.

DOSING. For monotherapy in PD, rasagiline may be started at 1 mg daily. In patients taking levodopa, the recommended initial dose is 0.5 mg daily, which, if tolerated, may be increased to 1 mg daily if needed.

In patients taking a CYP1A2 inhibitor such as ciprofloxacin, dosages should not exceed 0.5 mg daily.

In patients with mild hepatic impairment, dosage should not exceed 0.5 mg daily, and it should not be used in patients with moderate or severe hepatic impairment.

No dose adjustment is required for patients with mild or moderate renal impairment, and it has not been studied in patients with severe renal impairment.

At recommended doses, rasagiline retains MAO-B selectivity, and although the manufacturer does not recommend dietary restrictions, it suggests foods with high tyramine content may cause hypertensive cries.

PREGNANCY AND LACTATION. Rasagiline is pregnancy category C, and there are no adequate studies on the use of the medication in pregnant women. It is not known whether rasagiline is excreted in human milk.

MONITORING PARAMETERS. Liver function test at baseline, 1 and 3 months.

COMMON ADVERSE EFFECTS. Weight loss, orthostatic or postural hypotension, dry mouth, abnormal involuntary movements, and hallucinations.

Drug Level Monitoring

MAOI plasma levels may be measured, but there is little evidence that levels correspond to treatment response and may be difficult to interpret given the short half-life of MAOIs.

There is evidence that platelet MAO inhibition is a predictor of response. However, its use is not recommended. Several studies have shown that patients taking phenelzine who have more than 80% platelet MAO inhibition after 2 weeks of treatment showed higher response rates. However, researchers point out that the moderate effect size means that this accounts for only 9% to 16% of treatment outcomes. MAO-B platelet inhibition is most likely an epiphenomenon as it has been shown in studies of selegiline that 100% inhibition can occur in the absence of antidepressant effects.

Laboratory Interference

Laboratory interference is not a major problem with the use of MAOIs. They may lower blood glucose values. They have also been associated with a minimal false elevation in thyroid function test results.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System

Commonly reported CNS effects include: dizziness, headache, drowsiness, sleep disturbance, fatigue, weakness, twitching, myoclonus, and hyperreflexia. Uncommon but serious CNS effects include ataxia, shock-like coma, toxic delirium, acute anxiety reaction, psychosis, transient respiratory and cardiovascular depression following electroconvulsive therapy, confusion, memory impairment, hypomania, and mania. Rasagiline may cause increased impulsive or compulsive behaviors such as gambling, sexual activity, and binge eating.

Cardiovascular

Common side effects include orthostatic and postural hypotension, syncope, palpitations, and tachycardia.

Skin

Adverse dermatologic effects include rash, pruritus, and hyperhidrosis. Rasagiline may increase the risk for melanoma, and regular screening is recommended.

Gastrointestinal

Commonly reported GI effects include: constipation, diarrhea, nausea, xerostomia, and elevated hepatic enzymes. Severe but less frequent events include glottis edema, progressing necrotizing hepatocellular damage, and reversible jaundice, the last two more likely with hydrazine derivatives.

Genitourinary

Common urinary symptoms include urinary retention and hesitancy. Commonly reported sexual side effects include: impotence, ejaculation dysfunction, and anorgasmia. Clinical experience shows fewer sexual side effects with tranylcypromine. There have been case reports of priapism in patients taking phenelzine. Impaired water excretion compatible with the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been associated with antidepressant use.

Optic

Glaucoma and blurred vision have been infrequently reported.

Hematologic

There are reports of rare occurrences of anemia, leukopenia, agranulocytosis, and thrombocytopenia.

Table 33.5d–3.
Relative Restrictions in Food and Beverages With Irreversible MAOI Use

Restriction	Foods
Absolute (high risk)	Aged cheeses; aged and cured meats; banana peel; broad bean pods; improperly stored or spoiled meats, poultry or fish; Marmite; sauerkraut; soy sauce and soybean condiments; tap beer
Moderate (moderate risk)	Red or white wine; bottle or canned beer
Unnecessary (low to no risk)	Avocados; bananas; beef/chicken bouillon; chocolate; fresh and mild cheeses; fresh meat, poultry and fish; gravy; monosodium glutamate; peanuts; properly stored pickled or smoked fish; soy milk; yeast extracts other than Marmite

Neurologic

Tremor is a commonly reported side effect of phenelzine. Peripheral neuropathy, sometimes associated with a pyridoxine deficiency, has been reported in patients receiving phenelzine. There are case reports that suggest an association between MAOI use and pseudoparkinsonism with symptoms of bradykinesia, tremor, cogwheel rigidity, and dysarthria.

WARNINGS AND PRECAUTIONS

Food–Drug Interactions

Nonselective and irreversible MAOIs, when combined with food rich in tyramine, can cause increased release of catecholamines, resulting in a hypertensive crisis characterized by an occipital headache, palpitations, nausea, vomiting, diaphoresis, and tachycardia. Severe reactions can lead to cardiac arrhythmias, stroke, and intracranial hemorrhage. Prior to recommendations on dietary restrictions, rates of hypertensive reactions were estimated to occur in 2.4% to 25% of patients treated with MAOIs.

After observation of hypertensive reactions in the 1960s, clinical use of MAOIs dropped dramatically. At the height of concern over drug–food interactions, more than 70 different types of food and beverages were on the list of foods to be avoided. However, over the past 20 years, a critical review of reports of adverse effects and analysis of tyramine levels in food and beverages has refined the list of dietary restrictions (Table 33.5d–3).

Drug–Drug Interactions

Hypertensive Crisis. Similar to tyramine-induced hypertensive crises, there are dangers in drug–drug interactions. Any medication that increases adrenergic stimulation by a mechanism other than MAO inhibition can lead to a hypertensive crisis (Table 33.5d–4). The list includes decongestants that contain alpha-1 agonists, stimulants that increase the release of norepinephrine, antidepressants that block norepinephrine reuptake, and appetite suppressants and analgesics with norepinephrine-reuptake inhibition properties.

Table 33.5d–4.
Medications Contraindicated With MAOI Use due to Risk of Hypertensive Crisis

Decongestants: phenylephrine, oxymetazoline, ephedrine, pseudoephedrine, phenylpropanolamine
Stimulants: methylphenidate, amphetamines
Antidepressants: SSRIs, SNRIs, TCAs, bupropion, buspirone
Appetite suppressants: sibutramine, phentermine
Analgesics: tramadol
Centrally acting antihypertensives: guanethidine, methyldopa
Antiparkinson agents: levodopa

Serotonin Syndrome. Concomitant administration of serotonergic agents with MAOIs, especially those with MAO-A inhibition, can result in dangerous levels of serotonin, leading to serotonin syndrome. Increased activation at postsynaptic serotonin receptors causes a disruption in thermoregulation, leading to a syndrome of fever, altered mental status, myoclonus, diaphoresis, and diarrhea. In extreme cases, symptoms may include hypothermia, seizures, coma, cardiovascular collapse, permanent brain damage, and death. MAOIs should not be prescribed in combination with SSRIs, SNRIs, TCAs, certain narcotics, and other medications with serotonergic properties (Table 33.5d–5).

In addition, care must be taken when changing antidepressants to or from MAOIs. A washout period of 2 weeks is required for all SSRIs prior to starting an MAOI, except for fluoxetine, which due to its long half-life, requires a 5-week washout period. A 2- to 4-week waiting period is also required when switching from an MAOI to another antidepressant or when discontinuing an MAOI prior to ending the restricted diet. The selegiline patch loses its selectivity at higher doses, so the manufacturer recommends dietary restrictions with doses of 9 mg or higher and for 2 weeks following any discontinuation.

Weight Gain

In a retrospective review, weight gain occurred in 35.7% of patients taking phenelzine and 10.5% taking tranylcypromine.

Orthostatic Hypotension

All nonselective MAOIs may reduce blood pressure, likely due to central alpha-adrenergic agonist effects of increased norepinephrine levels. Rates of orthostasis may be higher in phenelzine. Hypotension usually develops gradually over the first 2 to 3 weeks of treatment and correlates with peak plasma levels. The side effect may be reduced with divided dosing and resolves hours to days after discontinuation.

Insomnia

MAOIs, especially tranylcypromine, are associated with insomnia. MAOIs are known to reduce the time spent in REM sleep. Transdermal selegiline also shows this side effect in a dose-dependent relationship. Insomnia may be alleviated by avoiding evening dosing.

Table 33.5d–5.
Medications Contraindicated With MAOI Use due to Risk for Serotonin Syndrome

Antidepressants: SSRIs, SNRIs, TCAs
Other TCAs: cyclobenzaprine, carbamazepine
Appetite suppressant: sibutramine
Cough suppressant: dextromethorphan
Opioids: meperidine, tramadol, methadone, propoxyphene
Antihistamines: chlorpheniramine, brompheniramine

Application Site Reaction

The most common side effect of transdermal selegiline is an application site reaction, which occurs in a dose-dependent relationship, and occurs in 24% of patients.

Hepatotoxicity

Postmarketing monitoring showed an increased risk for hepatotoxicity for hydrazine MAOIs (isocarboxazid and phenelzine) compared to the nonhydrazine (tranylcypromine). However, the absolute risk appears to be low (less than 1 in 30,000).

Psychosis

The combination of MAOIs and dextromethorphan has been reported to cause brief episodes of psychosis and bizarre behavior.

Overdose

Signs and symptoms of overdose include dilated pupils, fever, diaphoresis, drowsiness, agitation, headache, hallucinations, trismus, opisthotonos, seizures, coma, fever, tachycardia, hypertension, hypotension, respiratory depression/failure, shock, and death. Signs and symptoms may be absent or minimal during the initial 12-hour period following ingestion and may develop slowly, reaching a maximum in 24 to 48 hours. In some cases, symptoms may persist for 8 to 14 days. Disseminated intravascular coagulation, rhabdomyolysis, and acute tubular necrosis can also occur. Treatment of overdose is mainly supportive. Inducing vomiting or gastric lavage with charcoal may be helpful in early poisoning.

Withdrawal

Common withdrawal symptoms include nausea, vomiting, and malaise. Abrupt withdrawal for patients on long-term treatment with MAOIs can result in a withdrawal syndrome characterized by increased arousal, mood disturbance, psychosis, and convulsions within 24 to 72 hours after drug discontinuation.

Contraindications

Contraindications to MAOI use include cardiac disease, cerebrovascular disease, hypertension, headache, hepatic disease, pheochromocytoma, renal disease, and general anesthesia with certain opioid analgesics.

THERAPEUTIC INDICATIONS AND CLINICAL DRUG STUDIES

A significant number of studies on MAOIs occurred prior to the publication of DSM-II, making interpretation difficult due to inconsistency in mood disorder diagnoses across studies. Reviewed here are studies with clear inclusion criteria and, when possible, a control group. Limitations are noted where they arise. Meta-analyses are generally not used as they usually include RIMA studies. Evidence for the efficacy of MAOIs not available in the United States, most notably moclobemide and brofaromine, is not discussed.

MAOIs were first used psychiatrically to treat patients with depression. However, given concerns over efficacy, side effects, drug–drug interactions, and dietary restrictions, MAOIs as a class generally fell out of favor. SSRIs have largely replaced MAOIs for psychiatric use. MAOIs are more frequently prescribed for atypical major depressive disorder and treatment-resistant depression (TRD). Less common uses include typical major depressive disorder, psychotic depression, dysthymia, bipolar depression, eating disorders, PTSD, social anxiety disorder, and panic disorder. Selective MAO-B inhibitors are used regularly in the treatment of PD and AD.

Atypical Depression

Early observations on groups of depressed patients who responded to MAOIs but not to TCAs sparked interest in identifying the characteristics of this subset of depressed patients. Studies reported that these "atypical" patients had depressed mood with anxiety and phobia or reactive mood with reversed vegetative symptoms. Subsequent controlled trials by a group at Columbia codified patients with atypical features of depression, defining criteria as reactive mood plus at least two of four associated features: hyperphagia, hypersomnolence, leaden paralysis, and sensitivity to rejection. They also identified a second group characterized by depression plus panic attacks for which MAOIs also appeared to show an advantage over TCAs. However, replication studies by the same group failed to show a difference between MAOIs and TCAs in mixed depressive/anxiety states.

Acute Treatment. The Columbia group summarized their findings in a 1993 paper. From the data of 269 patients, they compared response rates on Clinical Global Improvement scales for patients taking phenelzine (72%), imipramine (44%), and placebo (26%). They concluded that rather than an enhanced response to MAOIs, patients with atypical depression show substandard responses to TCAs. Through stratification, they also demonstrated that the presence of anxiety symptoms did not factor into response rates, despite previous suggestions of superior MAOI response in depression with anxiety.

Since that review, two controlled studies have been published, one comparing an MAOI to cognitive-behavior therapy (CBT) and another to an SSRI. A 1999 study randomized patients with atypical depression to phenelzine, CBT, or placebo for 10 weeks. Response rates for phenelzine (58%) and CBT (58%) were equivalent to each other and superior to placebo (28%). An analysis found similar results for reduction in Hamilton Rating Scale for Depression (HAM-D) scores. Patients taking phenelzine had higher rates of marked side effects (92%) compared to placebo (53%).

The only trial that has compared an MAOI available in the United States to an SSRI is a randomized, double-blind, non–placebo-controlled trial comparing fluoxetine and phenelzine. Forty patients with atypical depression randomized to fluoxetine or phenelzine showed no difference in response (80% vs. 85%) or remission (80% vs. 70%). The only patient who dropped out due to an adverse effect (confusion) was taking phenelzine. Dizziness, asthenia, arthralgias, somnolence, and blood pressure changes were more common in the phenelzine group. Tremor and weight gain were more common in the fluoxetine group.

Maintenance Treatment. In addition to acute atypical depression treatment, there is one long-term study of relapse prevention in atypical depression. In this study, 60 patients who had improved with phenelzine or imipramine over 6 months were randomly assigned to the same medication or placebo for an additional 6 months. Recurrence rates were 23% for those receiving phenelzine, 41% for imipramine, 47% for those who switched from imipramine to placebo, and 87% for those who switched from phenelzine to placebo.

Treatment-Resistant Depression

Recently, the use of MAOIs in typical depression has been limited to TRD. Most controlled trials have focused on tranylcypromine after early case studies found a benefit from tranylcypromine for patients with TCA-refractory depression. Response rates in these trials vary greatly, which may reflect the difficulty in defining this group, and it is a challenge to make firm conclusions about specific advantages of MAOIs in TRD.

In a 1988 study, 21 patients with major depressive disorder who had not responded to oxaprotiline or fluvoxamine were randomized to tranylcypromine or nomifensine. Compared to the nomifensine group, the tranylcypromine group showed statistical superiority in a reduction in HAM-D scores but not response rate (45% vs. 10%) at 4 weeks.

A 1993 study compared brofaromine and tranylcypromine in 39 patients with major depressive disorder who had previously not responded to 4 weeks of maprotiline or nortriptyline. Of note, 12 patients had psychotic features and 23 melancholic features. There was no difference in response rates for brofaromine (45.5, 59.1%) and tranylcypromine (52.9, 58.9%) as measured by Hamilton Depression Subscale and Clinical Global Improvement, respectively. Melancholic features did not predict response. Brofaromine was better tolerated.

A second study in 1993 also compared brofaromine and tranylcypromine. In this case, 93 inpatients who had failed two classes of antidepressants were treated for 6 weeks. There were no differences between the two groups on reduction in HAM-D scores or response rates (nearly 74% for both groups). There were no differences in tolerability.

A 38-year-old divorced mother of two teenage daughters presented at the Mood Disorders Clinic with a history of failed antidepressant treatment trials. Two years earlier, she had become increasingly irritable, exhausted, and tearful after the breakup of her marriage. She could not tolerate fluoxetine (Prozac) or sertraline and discontinued each of these SSRIs after only a few days because of GI symptoms. Although she could tolerate desipramine (Norpramin) up to 300 mg daily, she felt no benefit after 4 months and was reluctant to continue this TCA medication because of adverse effects (weight gain and sweating, in particular). Because of her increasing fatigue, increasing sleep needs, and generally atypical profile, she was offered a trial of phenelzine. After 4 weeks, at a dosage of 60 mg daily, she reported significant improvement in her energy level, mood, and sleep pattern. Two years later, she continues to take 45 mg of phenelzine daily with some adverse effects (occasional insomnia and anorgasmia).

A 2004 study enrolled 77 patients who had failed either of two phases: (1) a double-blind, randomized trial of imipramine or fluvoxamine, followed by augmentation with lithium or (2) an open trial with a TCA. They were randomized to either tranylcypromine or phenelzine for 5 weeks. Results showed no difference in response rate between tranylcypromine (44%) and phenelzine (47%) or remission rates (18% and 11%, respectively). About 21% of patients reported “severe” side effects, including dizziness, agitation, and insomnia, though there were no differences between the two groups.

Level 4 of the STAR*D trial compared tranylcypromine versus extended-release venlafaxine plus mirtazapine in 109 patients who had not responded to three prior medication trials. The results showed no difference in response (13.8% vs. 15.7%) or remission (6.9% vs. 13.7%) between the two groups. Patients in the tranylcypromine group were more likely to exit the study (41.4% vs. 21.6%), and almost half had less than 6 weeks of treatment, suggesting that MAOI treatment may be less tolerable than other antidepressant treatment. However, patients did not differ in ratings on side effect burden scales. Critics of the study point out that the average tranylcypromine dose was only 36.9 mg, less than in similar studies, and may explain the lower response rates.

Finally, a crossover study compared selegiline to placebo in 16 treatment-resistant (failed at least two clinical trials of antidepressant) older patients with depression. Patients received selegiline 60 mg or placebo in two 3-week phases. During the active treatment phase, patients showed significant improvement in HAM-D scores. Overall, 8 of 16 patients responded to treatment. Responders were more likely to be older, less depressed, less anxious, and more cognitively intact. Researchers also performed cognitive tests with no changes during active treatment. There were no differences in side effect rates in each group.

Major Depressive Disorder

Early clinical observation suggested that MAOIs tend to be more effective than TCAs in the treatment of atypical depression and less effective than TCAs in melancholic or endogenous depressions. A particularly large and influential early study from the United Kingdom showed phenelzine 45 mg to be marginally inferior to placebo in a group of depressed inpatients of unspecified type. Subsequent trials with higher doses showed more equivalent efficacy for MAOIs to TCAs in the treatment of endogenous or melancholic depression. Discussed here are trials investigating groups of patients with unspecified type of major depressive disorder or endogenous/melancholic subtype. Of note, there are no trials comparing MAOIs available in the United States with second-generation antidepressants.

Acute Treatment. Early studies of MAOI use in depression were characterized by limited size, short duration, and low dosages. A 1960 study crossed over 25 moderately or severely endogenously depressed patients to receive phenelzine 45 mg or placebo for 2 weeks each. Improvement rates were significantly higher for the second phenelzine group compared to placebo, but not the first. In a 1961 study, 21 consecutively admitted patients diagnosed with depression (13 with endogenous type) were given phenelzine or placebo for 3 weeks and then switched. On a seven-point improvement scale, a higher proportion of patients showed “complete recovery” or “marked improvement” in the phenelzine (50%) group versus placebo (15%). Fifty-three percent of the endogenous depressed patients improved or remitted.

Later trials appear to show equivalence for acute depression, in endogenous or mixed groups, when comparing MAOIs to TCAs, without clear evidence of a difference in side-effect burden. In 1981, researchers randomized 49 inpatients diagnosed with depression (33 nonendogenous) to phenelzine or imipramine for 3 weeks after a 1-week placebo-response period. Both groups showed an equal and statistically significant response as measured by the HAM-D. There was no subgroup analysis.

A 1986 study of 75 depressed patients over age 55 compared phenelzine and nortriptyline to placebo. Response rates found phenelzine and nortriptyline superior to placebo (59.1% vs. 60.0% vs. 10.7%) as measured by HAM-D. A majority of patients in each group had the endogenous subtype, but a subgroup analysis was not performed. Of note, only two patients from each active arm dropped out of the study due to side effects.

A 1987 study investigated the use of phenelzine or imipramine for 6 weeks after a 1-week placebo-response period in 83 patients with a diagnosis of major depression with melancholia or dysthymic disorder. In subgroup analysis for melancholia, reduction in scores on the HAM-D did not significantly differ between phenelzine (58.2%) and imipramine (71.4%) treatment. Side effects were not reported.

Finally, two short-term studies established the efficacy of transdermal selegiline for major depressive disorder. A 6-week trial of 6 mg versus placebo showed significant results (HAM-D reduction of 9 vs. 6.5 points), and an 8-week trial with doses from 6 to 12 mg also showed significant changes (HAM-D reduction of 10.9 vs. 8.6 points). Oral selegiline has been found to be effective in treating depression only at doses higher than 20 mg daily, a dose where selective enzyme inhibition is lost, and a tyramine-restricted diet is required.

Maintenance Treatment. Few studies have investigated the long-term use of MAOIs for the prevention of recurrent depressive episodes.

A 1991 study looked at maintenance on phenelzine versus placebo. After acute unblinded treatment with phenelzine, responders were entered into a 16-week continuation phase followed by double-blind randomization to phenelzine 60 mg, phenelzine 45 mg or placebo for a 2-year maintenance phase. Forty-seven patients entered the maintenance phase. Both phenelzine doses showed significant protection against relapse within 3 months but not against recurrence (symptom onset beyond 3 months of continuation of treatment). Generalization from this study is limited as 36% of patients who initially responded to treatment discontinued during continuation therapy prior to enrollment in the maintenance phase.

Fifty-two adults over 55 years old with depression who had responded to acute treatment with phenelzine or nortriptyline in the 1986 study were randomized to maintenance on the study drug or tapered to placebo. Results showed significantly less recurrence for patients taking phenelzine (13.3%) versus nortriptyline (53.8%) and placebo (65.2%) over 1 year. The phenelzine group had only two dropouts due to side effects.

A 52-week study investigated relapse rates for 322 patients who had responded to acute treatment with transdermal selegiline 6 mg daily and who were randomized to continued treatment or placebo. Significantly fewer patients on transdermal selegiline (16.8%) relapsed compared to placebo (30.7%).

Psychotic Depression

It is unclear that patients diagnosed with psychotic depression in early trials would meet contemporary criteria, and those early trials found no efficacy for MAOIs in the treatment of psychotic depression. There are no controlled studies. The only more recent study is an open-label trial examining the use of phenelzine in depressed inpatients. The researchers classified patients into three groups: definitely psychotic, probably psychotic, and nonpsychotic. Response rates were 22%, 43%, and 68%, respectively. This inpatient study showed increased effectiveness for phenelzine in nonpsychotic versus psychotic patients. MAOIs are not usually considered for this indication.

Dysthymia

There is limited evidence for the use of phenelzine in dysthymic disorder. Three prospective studies have investigated the use of MAOIs for dysthymia, but only one used an MAOI available in the United States. A 1993 study comparing phenelzine to imipramine in dysthymic disorders over 6 weeks found superior response in the phenelzine group when measured by the response on the HAM-D.

A retrospective analysis by the Columbia group studying atypical depression identified 37 patients meeting DSM-III criteria for dysthymic disorder. The researchers found response rates of 22%, 50%, and 17% for phenelzine, imipramine, and placebo, respectively. However, this study was limited by a small number of subjects, a short duration of only 6 weeks for a chronic illness, and the exclusion of patients with melancholic features. The same group found in a pooled group analysis that phenelzine was more effective than imipramine and placebo (83% vs. 45% vs. 21%) in double depression.

Bipolar Depression

There are three positive prospective studies for MAOI use in bipolar depression, one negative prospective study and one positive retrospective analysis.

A 1982 study on “anergic” depression, defined as depressed mood with motor retardation, fatigue, volitional inhibition, and reversed neurovegetative features, included 59 patients, 29 of whom met the criteria for bipolar disorder. The other 30 were classified as “pseudounipolar” or “borderline syndromes.” Researchers randomized patients to tranylcypromine or a placebo. They did not report subgroup analysis. Twenty of twenty-four patients (83%) on an active drug responded, and only 4 of 31 (13%) on placebo. The same group, in 1991, conducted a double-blind study comparing tranylcypromine to imipramine for patients with anergic bipolar depression. Fifty-six patients were treated with either tranylcypromine or imipramine without a mood stabilizer over the 6-week acute treatment phase and 10-week maintenance phase. Tranylcypromine outperformed imipramine in acute response (81% vs. 48%) and in sustained response (71% vs. 20%). Of note, 21% of tranylcypromine and 25% of imipramine patients developed mania or hypomania. Significantly more (7 vs. 2) patients taking imipramine dropped out than those taking tranylcypromine. They also conducted a crossover trial involving 16 patients who did not respond to the original treatment. Nine of twelve patients who failed imipramine responded to tranylcypromine and had categorical improvement at similar rates to the original tranylcypromine group (75% and 81%). Two developed hypomania. Only one of four patients who crossed over to imipramine responded; two withdrew due to side effects, and the other withdrew due to a mixed state.

The other prospective trial for bipolar disorder failed. Researchers compared tranylcypromine to lamotrigine in patients with bipolar depression who had previously failed a 6-week trial with an SSRI, TCA, venlafaxine, or bupropion added to an adequate dose of mood stabilizer. This study was severely limited by the small number who enrolled (20) and completed (11). However, response rates, though not statistically significant partly due to the small power of the study, were consistent with the response rates of trials discussed above: 62.5% for tranylcypromine and 36% for lamotrigine. Two patients in the lamotrigine group developed mania.

Finally, a retrospective analysis of data from the Maintenance Therapies in Bipolar Disorder (MTBD) study compared the addition of MAOIs or paroxetine in 52 patients with bipolar depression who had already failed to respond to a mood stabilizer alone (usually lithium). Rates of durable recovery (defined as a period of 8 weeks of euthymia starting within the first 16 weeks of treatment) were significantly higher in the MAOI group (70%) versus the paroxetine group (33%). The authors did not report adverse events.

Eating Disorders

Two controlled trials and a reanalysis have found efficacy for phenelzine and isocarboxazid in bulimia nervosa. Despite concerns about adherence to diet, the studies reported no hypertensive crises. There are no controlled trials of MAOI use in anorexia nervosa or binge eating disorder.

A 1986 crossover study compared isocarboxazid to placebo over 12 weeks in patients with bulimia nervosa. Isocarboxazid significantly decreased the number of binge episodes (7.0 to 2.8) compared to placebo (7.5 to 4.5). There were no adverse food or drug interactions, but 40% experienced insomnia or hypotension.

A 1987 study enrolled 82 patients with bulimia to receive phenelzine or placebo over 8 weeks following a 2-week placebo washout phase. Twenty dropped out before randomization, and another 12 did not complete at least 2 weeks of treatment. Although the number of binges per week at the study end did not differ between the two groups, the phenelzine group showed a statistically significant reduction in change in binge frequency (64%) versus placebo (5%). A covariate analysis showed that this response was not related to antidepressant effects. Nine of thirty-one patients taking phenelzine did not complete the 8-week trial due to side effects. There were no reports of hypertensive crisis.

Finally, the Columbia group reanalyzed their data on treatment with phenelzine, imipramine, or placebo for atypical depression. They identified 24 patients who met the criteria for comorbid bulimia. The study is limited by outcome measures that relied on chart review for notes indicating at least a 50% reduction in bingeing and purging and the overeating question on the Hopkins Symptoms Checklist (SCL-90). Phenelzine was found to be statistically superior to both imipramine and placebo on both endpoints.

Posttraumatic Stress Disorder

There are two controlled trials, one negative and one positive, of MAOI use for PTSD. A 1987 study enrolled 13 patients with PTSD in a double-blind crossover trial comparing phenelzine and placebo. Response to phenelzine and placebo did not differ as measured by either the PTSD Scale or the Impact of Events Scale. Only 10 patients completed treatment, and each phase lasted only 5 weeks. A second trial compared phenelzine and imipramine to a placebo. At the 8-week follow-up, phenelzine showed superiority to both imipramine and placebo on the Impact of Events Scale, with 45%, 25%, and 5% reductions, respectively. Of note, PTSD was combat-related for all patients in this trial.

Social Anxiety Disorder

Until the introduction of SSRIs, MAOIs were widely considered to be the most effective medication for the treatment of social anxiety disorder. Four of five controlled trials have found positive results for the use of phenelzine in social anxiety disorder or social phobia.

In a 1992 study, 74 patients with social phobia were randomized to phenelzine, atenolol, or placebo for 8 weeks. Response rates for phenelzine (64%) were statistically higher than atenolol (30%) and placebo (20%).

Another 1992 study compared phenelzine and moclobemide to placebo over three 8-week phases. At week 8, both phenelzine and moclobemide showed statistically superior results compared to placebo on the Social Phobia Scale. During the next 8 weeks, mean scores continued to improve in both active treatments with no difference between the two with remittance rates of phenelzine (91%), moclobemide (82%), and placebo (43%). Finally, in the last phase, during which patients were randomized to continue active treatment or switch to placebo, relapse rates were significantly higher for those who switched from either group to placebo. Finally, the phenelzine group showed the highest side effect rates and had two severe adverse events, urinary retention and hypertensive crisis, that led to discontinuation of treatment.

The negative result came in a 1991 study that randomized 65 patients with social phobia to weekly cognitive-behavioral group therapy (CBGT) or alprazolam, phenelzine, or placebo with instruction for self-exposure to phobic stimuli for 12 weeks. On self-rating scales of social avoidance, no difference was found between groups. On the physician-rated Work and Social Disability Scale, phenelzine and alprazolam were found to be superior to placebo (CBGT was not included as it could not be blinded).

Two more studies compared phenelzine to CBGT. A 1998 study randomized 133 patients with social phobia to CBGT, phenelzine, placebo, or education-supportive group therapy (ES) over 12 weeks. Independent ratings on the Social Phobic Disorders Severity and Change Form found response rates to be statistically significant for phenelzine (65%) and CBGT (58%) compared to placebo (33%) and ES (27%). On self-report measures, phenelzine was found to be superior on four of six anxiety rating scales, with no difference between the other three groups. No serious adverse effects occurred. Researchers then continued responders in the phenelzine and CBGT group in 6 months of maintenance treatment and 6 months of treatment-free follow-up. Of 28 patients in the maintenance phase, relapse rates did not differ significantly between groups: phenelzine (21%) and CBGT (14%). In the follow-up phase, there was a nonsignificant trend toward less relapse in CBGT (0%) versus phenelzine (30%).

The same researchers followed up with a 2011 study that randomized 166 patients to one of 4 groups: phenelzine, CBGT, phenelzine plus CBGT, or placebo. Remission rates on the Liebowitz Social Anxiety Scale (LSAS) were measured at 12 weeks and found that combined therapy (59.4%) was superior to placebo (11.1%), which also could not be distinguished from monotherapy phenelzine (20.0%) or CBGT (20.6%). Insomnia, light-headedness, dry mouth, weight gain, constipation, anorgasmia, and nervousness rates were all higher in patients taking phenelzine.

A 2003 meta-analysis of pharmacologic treatment for social anxiety disorder combined results from the two phenelzine trials. The moderate effect size (0.66) was not statistically different from SSRIs, gabapentin, or clonazepam. The authors concluded that given SSRIs tolerability and safety, they should remain the first-line treatment for social anxiety disorder.

Panic Disorder and Agoraphobia

Early studies on MAOI treatment for panic disorder are difficult to interpret as they often clumped phobias together or examined mixed anxiety and depressive states. However, the result of these early studies was that clinicians regarded MAOIs as more effective antipanic agents than TCAs.

The first prospective study on “endogenous anxiety” (characterized by spontaneous panic attacks and agoraphobia) in 1980 compared imipramine and phenelzine to placebo. All three groups received supportive group therapy. At 12 weeks, results showed both active groups to be superior to placebo. The phenelzine group showed trends toward superiority on all measures and a statistically significant improvement on the Work and Social Disability Scale and Symptom Severity and Phobic Avoidance Scale.

A double-blind study compared four treatment conditions: phenelzine/exposure, phenelzine/no exposure, placebo/exposure, and placebo/no exposure in a group of 40 patients with agoraphobia and social phobia. Exposure, with or without phenelzine, was found to be superior in reducing anxiety symptoms compared to no exposure groups.

The Columbia group compared the response to phenelzine, imipramine, and placebo in 104 patients with atypical depression with and without spontaneous panic attacks. In patients with panic, the response at 6 weeks was significantly higher for phenelzine (77%) compared to imipramine (2%) and placebo (15%) as measured by Clinical Global Improvement. It is unclear from the data whether the response is related to decreased panic or depression, although stratified subgroup analysis suggests that response to phenelzine was independent of pretreatment anxiety levels.

Since the introduction in 1981 of panic disorder to DSM-III, there have been no published prospective trials on MAOIs. However, there are two studies that may provide some information.

A 1987 open-label study treated 40 patients with panic disorder or agoraphobia with phenelzine. Thirty-four of thirty-five patients who completed the study showed statistically significant responses on the Hamilton Rating for Anxiety. This study is limited by its open-label design, and its high response rate suggests an unaccounted-for confounder. Patients also showed significant adverse effects with postural hypotension (64.3%), insomnia (44.3%), dry mouth (42.9%), sexual dysfunction (27.3% men, 16.7% women), and weight gain (17.1%).

A 2010 study compared tranylcypromine 30 mg and 60 mg without placebo control in a group of patients with panic disorder and comorbid social anxiety disorder. Both doses reduced panic attacks by about 70% from baseline, without statistical significance between the two. However, the higher dose reduced social anxiety symptoms by double the lower dose. Again, adverse effect rates were significant: orthostatic dizziness (58.8%), insomnia (47.1%), decreased libido (41.2%), and somnolence (35.3%).

Overall, the evidence is mixed, without clear antipanic effects from phenelzine. Studies are difficult to interpret given the inclusion of comorbidities and mixed treatment modalities. Still, guidelines suggest MAOIs as third-or fourth-line agents for panic disorder.

FUTURE DIRECTIONS AND INVESTIGATIONAL DRUGS

Despite evidence for MAOI effectiveness in a number of psychiatric illnesses and consensus guidelines that continue to recommend their use as third- or fourth-line agents, MAOIs have fallen out of favor as SSRI use has increased. A population-based study in Ontario showed that from 1997 to 2007, only 348 older adults were started on an MAOI, accounting for only 1/500 older adults started on an antidepressant. A 2021 review of active clinical trials showed a few dozen active trials on MAOIs, mostly tranylcypromine and selegiline; a majority investigated their use in treatment-refractory depression or bipolar depression.

Although MAOIs have fallen out of favor with prescribing clinicians, research continues in the area. Recent clinical trials have focused on new indications for MAOIs, including negative symptoms in schizophrenia, amyotrophic lateral sclerosis, metastatic breast cancer, hair regrowth, prostate cancer, muscular dystrophies, tobacco cessation, and cocaine addictions. Though not covered in this chapter, selective MAO-B inhibitors continue to be investigated for use in PD, AD, and other neurodegenerative disorders.

33.6 Monoamine Modulators

33.6a Trazodone

JOHN T. VERNON, M.D., AND SUSAN G. KORNSTEIN, M.D.

Neuroscience-Based Nomenclature (NbN)	
Serotonin Multimodal	
Pharmacologic domain	Serotonin
Mechanism of action	Receptor antagonist (5-HT_{2A}) and partial agonist (5-HT_{1A})

HISTORY

Developed in Italy in 1966, trazodone (Desyrel) is considered the first of the SGAs, possessing a novel triazolopyridine chemical structure that distinguished it from the TCAs that preceded it. This structural uniqueness was associated with pharmacologic properties that also differentiated it from the TCAs in its performance on animal antidepressant screens, proposed mechanism of action, and adverse effect profile. Trazodone was first marketed in Europe in the 1970s and received FDA approval in 1981 for the treatment of major depression in the United States. Its improved safety and tolerability compared to TCAs was most likely responsible for trazodone's rapid rise in clinical use after its introduction. However, with the increased popularity of SSRI antidepressants, trazodone has fallen out of favor as a first-line treatment for depression in the United States. A once-a-day formulation of trazodone (Oleptro—trazodone/Contramid) was introduced by Labopharm Inc. in 2010 and approved by the FDA for the treatment of major depressive disorder; however, it was withdrawn from marketing in the United States by 2015. Other formulations include trazodone immediate-release liquid formulation, trazodone injectable solution, and trazodone delayed-release RP-AC.

CHEMISTRY

Trazodone is a triazolopyridine derivative, designated as 2-[3-[4-(3-chlorophenyl)-1-piperazinyl] propyl]-1,2,4-triazolo[4,3-a]pyridin-3(2H)-one hydrochloride. Its empirical formula is C19H22ClN5O•HCl, and its molecular structure is depicted in Figure 33.6a–1. Trazodone's molecular weight is 408.3. It is soluble in water, possessing a pKa of 6.7.

PHARMACOLOGY

Pharmacokinetics

Trazodone is absorbed efficiently by the human digestive tract after oral administration, reaching peak plasma concentration in about 1 hour. When consumed with food, the total amount of drug absorption is increased, maximum plasma concentration is decreased, and time to peak concentration is doubled. Since some adverse effects such as dizziness are related to peak plasma levels, this strategy has been shown to increase tolerability. Trazodone exhibits a linear pharmacokinetic profile in the dosage range of 50 to 150 mg twice daily. When administered twice daily, initial steady-state concentrations are achieved in approximately 36 hours, with restabilization at new levels in 12 hours after dosage adjustment. There may be up to a fourfold difference in steady-state plasma levels between individuals maintained on identical dosages. Steady-state AUC of trazodone IR 100 mg three times daily and Oleptro 300 mg daily were similar, although steady-state C_{max} and C_{min} after 1 week were not found to be equivalent.

Trazodone is approximately 90% bound to plasma proteins and distributes without selective localization in any tissue. Trazodone and its major metabolite, meta-chlorophenylpiperazine (mCPP), both cross the blood–brain barrier. Trazodone is also excreted into breast milk, with one study reporting that the concentration is about 14% of the maternal plasma concentration.

Trazodone is primarily metabolized via hydroxylation and oxidation by the hepatic cytochrome P450 (CYP) system. Several studies implicate the CYP 3A4 microsomal enzyme in the production of its major, active metabolite, mCPP, while reports on the role of CYP 2D6 are conflicting. The elimination of trazodone is biphasic, with half-lives of 3 to 6 hours and 5 to 9 hours, respectively. It is eliminated primarily via the kidneys as metabolites, with only about 1% excreted as the parent compound. The half-life of mCPP is about 14 hours. The half-life of Oleptro is reported at 10 hours.

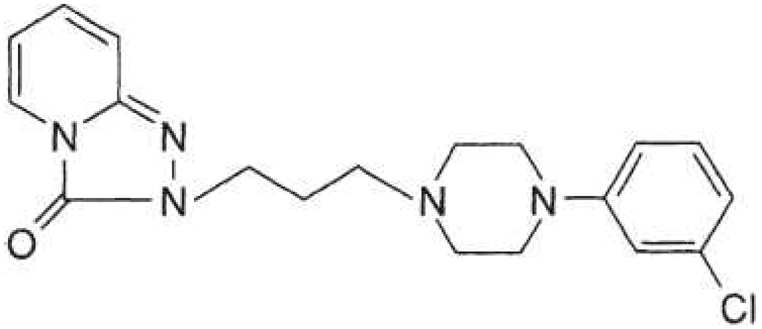

FIGURE 33.6a–1. Molecular structure of trazodone (Desyrel).

Pharmacodynamics

Trazodone's main pharmacologic effects are believed to be mediated through its actions at postsynaptic serotonin (5-hydroxytryptamine [5-HT]) 5-HT$_2$ receptors. Although it exhibits weak in vitro effects at the presynaptic serotonin transporter, which is responsible for the main therapeutic effects of the SSRIs, in vivo studies suggest that this is of negligible significance in humans. Trazodone is a potent 5-HT$_{2A}$ receptor antagonist, with 100-fold selectivity for the 5-HT$_2$ relative to the 5-HT$_1$ binding site. Chronic administration causes downregulation of 5-HT$_2$ as well as β-adrenergic receptors, similar to the actions of some other antidepressant compounds.

Trazodone's major metabolite, mCPP, is also active at serotonin receptors. It is an agonist at 5-HT$_{1B}$ and 5-HT$_{1C}$, and possibly, 5-HT$_{1A}$

and 5-HT_{1D} receptors. Research suggests that the parent compound, and not its metabolite, is responsible for the antidepressant effects. In fact, mCPP has been shown to be behaviorally activating and anxiogenic in experimental animals and human subjects.

Trazodone is an antagonist at peripheral α-adrenergic receptors, which is most likely responsible for its adverse effects of orthostatic hypotension and dizziness, dry mouth, and priapism. It has no significant activity at noradrenergic or dopaminergic receptors. Antagonism at acetylcholine and histamine type-1 (H_1) receptors is negligible. One in vitro study suggests that inhibition of T-type calcium channels may contribute to trazodone's psychiatric and neurologic effects.

There is no established consensus regarding the relationship between steady-state blood levels of trazodone and therapeutic response. One study in older adult subjects reported that a threshold concentration of 650 ng/mL predicts clinical efficacy, but studies in other populations produced conflicting results. An open-label, 3-week treatment study in a Japanese population of 26 adult patients with major depression reported a linear relationship between trazodone (but not mCPP) steady-state plasma concentration and both the final Montgomery Asberg Depression Rating Scale (MADRS) score and the percentage improvement at study completion. Also, the proportion of responders was significantly higher in the patients whose plasma concentration exceeded 714 ng/mL, consistent with the above study. No relationship between adverse effects and either trazodone or mCPP levels was seen. This finding suggests that, although not common in clinical practice, measuring trazodone levels to ensure that they exceed a threshold of 650 to 700 ng/mL may help improve outcomes in patients with inadequate response to the usual dosage regimen.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Major Depressive Disorder

The majority of clinical research on trazodone has focused on its use in the treatment of major depressive disorder. After a series of open trials suggesting the efficacy of trazodone in depressive syndromes, double-blind comparison trials of trazodone were carried out first in Europe and then in the United States. Some, but not all, of the studies included a placebo comparison arm, as some investigators considered it unethical to withhold active medication from seriously depressed patients. Comparator drugs included amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan), mianserin (Tolvon), dothiepin (Prothiaden), and diazepam (Valium). The studies were conducted in inpatient, outpatient, and general practice settings. Most, but not all, of these studies found trazodone to possess efficacy that is comparable to the TCAs. Several reviews and meta-analyses that attempted to overcome the limitations of the individual studies concluded that trazodone was indeed as efficacious as TCAs for the acute treatment of major depression. One such meta-analysis calculated the pooled odds ratio for response to trazodone compared to imipramine as 0.93 (95% confidence interval: 0.64 to 1.36), supporting the hypothesis of near-equivalent efficacy of the two medications. In addition, a 12-month, double-blind maintenance study found trazodone to be superior to imipramine on endpoint efficacy measures.

Later studies have compared trazodone to other newer antidepressants. Two double-blind, randomized, 6-week comparisons between trazodone and fluoxetine (Prozac) in 43 and 126 patients, respectively, reported equivalent response rates for the two medications, although trazodone demonstrated better HAM-D sleep subscale scores in the first study. One double-blind, placebo-controlled multicenter trial compared trazodone (50 to 300 mg) and venlafaxine (Effexor) (25 to 150 mg) in 225 patients in a 6-week acute treatment phase followed by a 1-year continuation phase for responders. Subjects in the venlafaxine group were more likely to respond sufficiently to enter the continuation phase and more likely to remain in the continuation phase. Trazodone proved more effective on measures of sleep, and venlafaxine proved more effective on measures of cognition and psychomotor slowing. Another 6-week, parallel, double-blind, randomized trial compared trazodone 50 to 300 mg to bupropion (Wellbutrin) 225 to 450 mg in 126 moderately to severely depressed outpatients, finding no significant differences in efficacy measures between the two treatments at the endpoint but greater improvement with trazodone at 7 days based on sleep measures. However, a 6-week, double-blind comparison of trazodone (150 to 450 mg per day) and mirtazapine (Remeron) (24 to 72 mg per day) in 200 inpatients with a *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III) diagnosis of moderate to severe major depressive episode found mirtazapine to be superior to trazodone on most efficacy measures. Since the introduction of controlled-release trazodone in 2000, two small, 6-week, double-blind studies reported equal efficacy in response and remission rates between this and both paroxetine (Paxil) and sertraline (Zoloft). When Oleptro was studied in a 2009 randomized placebo-controlled trial, a statistically significant improvement in HAM-D 17 scores was demonstrated; antidepressant efficacy was independent of baseline insomnia or reduction in insomnia. A 2007 meta-analysis detected no significant differences between trazodone and its sister 5-HT$_2$ receptor antagonist, nefazodone (Serzone), compared with SSRIs for the treatment of major depression. A 2018 study with once-daily trazodone (Trazodone-XR-COAD) in 85 patients with moderate to severe depression showed efficacy based on reduction of MADRS and CGI scores.

Trazodone has been systematically studied in older adult depressed patients, as its low potential for anticholinergic and cardiovascular side effects suggested greater tolerability compared with tricyclics in this population. Trials comparing trazodone with various tricyclic and heterocyclic antidepressants found comparable efficacy and a generally lower side-effect burden for trazodone. The most frequently reported side effect in the older adults was dizziness, which may have been the result of orthostatic hypotension, expected from trazodone's pharmacologic profile. This symptom can be significant in the older adults for its potential to produce falls and, therefore, may limit the use of trazodone in those most sensitive to it, particularly if exacerbated by physical illness or concomitant medications such as antihypertensives. In addition, studies have compared antidepressants for their effects on cognitive performance in the older adults. One review of such studies found evidence of impaired ability to concentrate or sustain attention for sedating antidepressants, including trazodone, but little or no effects on memory with trazodone compared with tricyclics. In comparison, that review reported no cognitive adverse effects for MAOIs or SSRIs, suggesting that trazodone may not be the best choice for geriatric depression since the introduction of the SSRIs. Regarding the treatment of symptoms of depression in children, it should also be noted that a 2003 survey of 1,273 child and adolescent psychiatrists indicated that trazodone was the most frequently prescribed medication for insomnia for children with sleep disturbance associated with mood disorders despite very limited evidence for the efficacy and safety of trazodone for use in children.

During clinical studies of trazodone’s antidepressant properties, several double-blind trials compared the efficacy of single bedtime dosing and divided daily dosing. One smaller study compared single bedtime dosing with thrice-daily dosing in a 4-week trial of 56 patients with major depression. That study reported equivalent therapeutic efficacy and tolerability for the two dosing regimens; a trend for greater improvement in onset and duration of sleep was noted for the bedtime dose group, as well as more side-effect complaints in the thrice-daily dosing group. In a larger trial of 146 depressed patients, twice-daily dosing was the comparison with single bedtime dosing over a period of 6 weeks. That study similarly reported equivalent antidepressant efficacy for both regimens as well as improvements in sleep for both overall. During the early weeks of the study, the single bedtime dosing group reported significantly superior sleep, while the twice-daily dosing group reported significantly greater daytime fatigue.

In a systematic review and network meta-analysis evaluating the comparative efficacy and acceptability of 21 antidepressant drugs for the acute treatment of adults with MDD, trazodone was among the least effective medications (along with fluoxetine, fluvoxamine, and reboxetine) with OR 0.51 to 0.84; agomelatine, amitriptyline, escitalopram, mirtazapine, paroxetine, venlafaxine, and vortioxetine were comparatively better (OR 1.19 to 1.96).

Overall, trazodone is an effective treatment for major depression. There is no clear indication that its effectiveness differs from that of the TCAs or SSRIs. Some studies suggest that its tolerability, and perhaps its overall effectiveness, is maximized by limiting doses to the more moderate ranges (300 mg per day or less). Adverse effects of sedation can be minimized via bedtime dosing, which also utilizes its beneficial effects for early relief of depression-related insomnia.

Anxiety Disorders

Although most clinical trials with trazodone have been undertaken for major depression, many of those studies gave an early indication that trazodone possesses antianxiety as well as antidepressant effects, as evidenced by significant reductions in anxiety-related symptom scales. In addition, small, uncontrolled studies in patients with prominent anxiety symptoms or anxiety neurosis suggested its potential as an anxiolytic. However, few controlled trials of trazodone in samples meeting diagnostic criteria for anxiety disorders exist.

Generalized Anxiety Disorder. Two hundred and thirty patients with DSM-III GAD, in whom major depression and panic disorder were excluded, were treated with trazodone, imipramine, or diazepam in a randomized, double-blind, placebo-controlled 8-week trial. Although diazepam produced the greatest improvement in anxiety ratings during the first 2 weeks, both trazodone and imipramine attained comparable efficacy to diazepam in weeks 3 through 8, but only imipramine was significantly better than placebo at the endpoint. Among completers, 73%, 69%, and 66% of imipramine-, trazodone-, and diazepam-treated patients reported moderate to marked improvement, respectively, compared to only 47% of patients treated with placebo. The antidepressants tended to provide greater improvement in the psychic symptoms of worry, tension, and apprehension compared to diazepam.

Panic Disorder. Data regarding the efficacy of trazodone for panic disorder are limited and conflicting. A small, uncontrolled, single-blind 8-week trial of trazodone in 11 patients with DSM-III diagnoses of panic disorder or agoraphobia with panic attacks reported significant improvements in ratings of panic and generalized anxiety, phobias, avoidance, and depression. However, in a double-blind study of 74 panic disorder patients, comparing trazodone to imipramine and alprazolam (Xanax), only the latter two effectively reduced panic and anxiety symptoms, with a high dropout rate for trazodone-treated patients primarily due to nonresponse.

Obsessive-Compulsive Disorder. Similarly, the data for trazodone’s antiobsessional efficacy are mixed. Several case reports and small case series reported trazodone to be helpful for patients with obsessive-compulsive neurosis or disorder (OCD), including one report of nine patients who had failed to respond to clomipramine (Anafranil). However, a double-blind, placebo-controlled trial of trazodone in 21 patients with OCD reported no significant difference in OCD symptoms between those treated with trazodone (mean daily dose 235 mg) and those receiving a placebo.

Posttraumatic Stress Disorder. Several small trials of trazodone use in patients with PTSD have been published. One study retrospectively surveyed 74 chronic PTSD patients who had ever been prescribed trazodone for insomnia or nightmares. Of the 60 patients who had tolerated trazodone, 72% reported it to be helpful for nightmares, and 92% reported improvement in sleep. A correlation of 0.57 between these two measures suggests that trazodone’s beneficial effect on nightmares in PTSD may be partially independent of its sleep benefits. An open-label trial of trazodone in six patients with combat-related PTSD rated four of the six as much improved after 4 months of treatment. A 2011 literature review informing an algorithm for the treatment of PTSD proposed the use of low-dose trazodone following a trial of prazosin (Minipress) for nightmares and nighttime hyperarousal or for (persisting) initial insomnia (without nightmares) or after resolution of nightmares.

Adjustment Disorders

Two nearly identical studies of trazodone versus clorazepate (Tranxene) for the treatment of adjustment disorders in medically ill patients have been published. Both were randomized, double-blind, 28-day trials in patients meeting DSM-III-R criteria for adjustment disorder with anxious or depressed mood or mixed disturbance of emotion and conduct but without a significant history of more serious psychiatric disorders. One population consisted of 18 patients receiving treatment for breast cancer, and the other 21 HIV-positive subjects. The outcomes were similar, each reporting significant symptom benefits from both medications, with nonsignificant trends suggesting greater efficacy from trazodone.

Bulimia Nervosa

Like other serotonergic antidepressants, trazodone has been tested for the treatment of bulimia nervosa, with some success. Several case studies have reported benefits on a range of illness measures. In an open-label, flexible-dose study of 13 subjects diagnosed with DSM-III bulimia, trazodone produced a significant decrease in the number of bingeing and purging (vomiting) episodes, carbohydrate cravings, and urges to binge eat. Bingeing and purging episodes were reduced to zero in four of ten subjects available for analysis and decreased by more than 50% in two others after about 8 weeks on the medication. In a 6-week, placebo-controlled study of 42 women meeting DSM-III-R criteria for bulimia nervosa, trazodone was superior to placebo in decreasing the frequency of bingeing and purging. In both of these trials, adverse effects were relatively mild and consistent with other studies of trazodone (sedation and dizziness) and in no cases resulted in withdrawal from the study, despite some isolated case reports of delirium in bulimic patients treated with trazodone. No trials exist to date that compare trazodone to other agents, such as the SSRIs.

Schizophrenia

Although it has no significant effects on the dopamine system, trazodone's actions at 5-HT_2 receptors are similar to those of atypical antipsychotics, suggesting a potential for efficacy in psychosis. However, this has not been borne out in clinical studies. One research group tested the efficacy of trazodone in the management of chronic schizophrenia in two small double-blind, controlled trials of 20 patients each. The first reported that trazodone produced significantly less deterioration than placebo in the Excitement and Hallucinatory Behavior item scores of the Brief Psychiatric Rating Scale (BPRS) over a 12-week period. The second compared trazodone to chlorpromazine (Thorazine), finding that chlorpromazine was significantly superior to trazodone in total BPRS score and several individual factor scores, although trazodone did improve depression scores on the BPRS. Subsequently, another group examined the potential for adjunctive trazodone use to reduce negative symptoms in chronic, residual schizophrenia using a double-blind, placebo-controlled design. Those investigators found a modest (10% to 15%) but the beneficial effect for trazodone on two of three negative symptom scales, with only moderate clinical improvement seen in 3 of 26 trazodone-treated patients. Trazodone did not appear to worsen positive symptoms of schizophrenia. Of additional note, trazodone 100 mg has demonstrated some efficacy in reducing acute neuroleptic-induced akathisia in a small, placebo-controlled, double-blind crossover study in 2010.

Insomnia

From 1999 through 2010, trazodone was found to hold a stable (off-label) second position to the increased use of nonbenzodiazepine GABA-A omega-1 agonists as the most commonly prescribed medication for insomnia (from the National Health and Nutrition Examination Survey of 32,328 adults) despite limited availability of double-blind, placebo-controlled trials demonstrating clear efficacy and safety of trazodone for insomnia treatment. This reflects physician prescriptions of trazodone for the treatment of primary insomnia, depression/anxiety/withdrawal-related insomnia, and antidepressant-induced insomnia, especially for patients at higher risk of sedative/hypnotic/anxiolytic use disorders or patients with comorbid depression. While trazodone is not associated with physiologic dependence or withdrawal, a 2008 randomized, placebo-controlled trial of trazodone at 50 to 150 mg over the course of 12 weeks in patients with alcohol use disorder advised caution. The study found that trazodone was helpful for the treatment of insomnia during early recovery, with rates of relapse similar to placebo. However, at 6 months post detoxification, the prior trazodone-treatment group demonstrated an increased number of drinks per drinking day compared to placebo.

Trazodone is a 5-HT$_{2A}$ antagonist that increases slow-wave sleep, shortens sleep latency, improves sleep continuity and does not suppress REM sleep. In a 3-week, within-subjects randomized, double-blind trial, 16 patients with primary insomnia were given trazodone 50 mg or placebo 30 minutes before bedtime for 7 days and administered polysomnograms and MSLT on days 1 and 7. Trazodone produced small but significant impairments of short-term memory, verbal learning, equilibrium, and arm muscle endurance across time points. Compared to placebo, trazodone was associated with less middle insomnia, decreased stage 1 sleep, increased slow-wave sleep (by day 7), less daytime drowsiness (by day 7), and improved subjective experience of sleep by self-report. In another study of 14 patients with primary insomnia and Beck Depression Inventory (BDI) score >10 and 15 patients with primary insomnia and BDI score <10, trazodone CR 25 to 150 mg daily for 3 months improved sleep; however, for patients with elevated BDI scores, discontinuation of trazodone resulted in worsening sleep, while improvement in sleep quality was sustained for patients with lower BDI scores with trazodone. Compared to other off-label 5-HT$_{1/2A}$ antagonists, such as the atypical antipsychotic quetiapine, trazodone may have favorable efficacy with longer mean total sleep time hours and fewer nighttime awakenings (although more frequent GI upset) with trazodone compared to quetiapine based on a nonrandomized, unblinded 2013 study. A 2018 meta-analysis of 429 patients in seven randomized controlled trials (quality assessment low to moderate) between 1994 and 2014 indicated that trazodone did not improve sleep efficiency (although one trial showed improved perceived sleep quality) but did improve the number of awakenings (without improvement in sleep latency, total sleep time, or waking time after sleep onset) with no difference from placebo in discontinuation for adverse events or tolerability/acceptability measures. Trazodone has also been applied with some efficacy in the treatment of insomnia in the postpartum period. In 54 postpartum patients with insomnia during the third trimester of pregnancy but without depression, EPDS scores were lower in patients treated with trazodone 50 mg or diphenhydramine 25 mg compared to placebo, with no significant difference between the two active treatment groups.

Pain

Trazodone is among the various antidepressants that have been examined for their analgesic potential in a wide variety of chronic pain syndromes. Two case series of open-label trazodone trials for painful diabetic neuropathy, with sample sizes of 6 and 31 patients, respectively, reported fairly dramatic symptom relief in the majority of patients. Trazodone has also been reported to be beneficial in a double-blind, comparative study with amitriptyline for deafferentation pain and in a double-blind, placebo-controlled study of pediatric migraine prophylaxis, although two systematic literature reviews question these latter findings. Two uncontrolled open-label studies in 2010 and 2011 suggest that trazodone may help with aspects of fibromyalgia. In one study, pain interference with daily activities, sleep, and depression were improved without direct mitigation of pain intensity. In the other study, pregabalin (Lyrica) added to trazodone reduced overall fibromyalgia severity, depression, pain interference with daily activities, and pain intensity. Trazodone did not prove to be effective in double-blind, placebo-controlled trials for fibromyalgia, chronic low-back pain, dysesthetic pain following traumatic myelopathy, or rheumatoid arthritis. Thus, little evidence exists supporting the use of trazodone in most chronic pain syndromes.

Behavioral Disturbances

Trazodone and other serotonergic medications have been used in place of sedative-hypnotics and antipsychotics to manage aggression and other behavioral disturbances in certain patient populations, such as children with disruptive behavioral disorders and geriatric patients with cognitive disorders. It is postulated that trazodone targets disturbed serotonergic brain pathways that are believed to underlie such behaviors.

Childhood Disruptive Behavioral Disorders. One uncontrolled open trial studied the effectiveness of trazodone in the management of impulsive and aggressive behaviors in an inpatient group of 22 children diagnosed with DSM-III-R disruptive behavioral disorders (ADHD, conduct disorder, and oppositional-defiant disorder) comorbid with other psychiatric symptomatology. These children, aged 5 to 12, had been unresponsive to other inpatient and outpatient therapeutic interventions, including an average of 4.7 documented medication trials. Thrice-daily dosing of trazodone at an average dose of about 5 mg/kg per day for a duration of 3 to 4 weeks resulted in clinical improvement in 65% of the children, with most maintaining this benefit (per parental report) at 3 to 14 months follow-up. The medication was well tolerated by the majority of the children, with transient orthostatic hypotension being the most frequently noted adverse effect (50%). A larger (also uncontrolled) study examining the connection between sleep and behavioral disturbances in 51 young children with opsoclonus-myoclonus syndrome reported that trazodone improved sleep in 95% and reduced rage attacks in 33% of those children treated.

Neurocognitive Disorders. Several open-label case series and double-blind, controlled trials have been published examining the effect of trazodone on agitation in older adult patients with neurocognitive disorders. These case series, typically small and with a mixed population of older adult patients with various neurocognitive disorders, overall reported beneficial effects of trazodone. A Cochrane Database Review of the existing controlled studies found similarity in efficacy and tolerability of trazodone to placebo and haloperidol as a treatment of behavioral disturbances of neurocognitive disorders, and subsequently, the review concluded that trazodone might improve some measures of agitation and psychosis for some patients with neurocognitive disorders. Some studies have examined the potential for trazodone to decrease the risk of neurocognitive disorder; a 2019 study concluded that trazodone inhibits tau amyloidogenesis in vitro, although another 2019 U.K. population cohort study found no evidence of reduced risk of neurocognitive disorder in 4,596 primary care patients prescribed trazodone compared to 22,980 patients taking other antidepressants.

Sexual Dysfunction

Trazodone has been associated with an increased risk of priapism and also has been the subject of several case reports of enhanced sexual desire and functioning in both sexes. These findings have led researchers to evaluate its potential benefit for treating disorders of sexual function, particularly male erectile dysfunction. In general, studies of treatments for sexual disorders in women have been disproportionately sparse; however, trazodone is being studied in combination with bupropion for the treatment of female hypoactive sexual desire disorder; a phase 2a trial completed in 2019 showed favorable response and tolerability compared to bupropion alone. In 2009, one small open-label preliminary study of SSRI-induced sexual dysfunction in men and women with depressive/anxiety/somatic symptom disorders found significant improvements in both men and women for all domains of sexual function and satisfaction measured. In this study, the improvement was additionally noted to be independent of improvement in measures of depressive/anxiety symptoms. In vitro, trazodone has been shown to have a high affinity for human penile α_1 receptors and moderate affinity for α_2-adrenergic receptors, lending experimental support to this endeavor.

Trazodone reportedly improved objectively assessed erectile measures in several small, uncontrolled case series of patients with impotence. However, double-blind, placebo-controlled trials of trazodone use for erectile dysfunction present different results. Three separate double-blind, placebo-controlled trials, the first in 69 patients taking 150 mg daily for 4 weeks, the second in 51 patients with 50 mg daily dosing for 3 months, and the third in 34 patients taking 200 mg daily for 4 weeks, all failed to find significant differences between active medication and placebo. The results of a review and meta-analysis of the literature on trazodone treatment for erectile dysfunction reported a nonsignificant trend of improvement with trazodone, particularly at higher doses, with a subgroup analysis favoring benefit if the dysfunction is psychogenic in origin.

Other Disorders

Trazodone has been studied as a potential treatment for a wide range of other psychiatric and medical syndromes, mostly via case reports or open-label trials. These include dysthymia, depression following stroke, tic disorders, chest pain due to esophageal dysmotility, sleep apnea, menopausal symptoms, benzodiazepine, alcohol, and opiate use disorders or withdrawal. Although varying degrees of efficacy have been reported, the overall lack of data, particularly from trials with more stringent study methodology, prevents one from drawing any firm conclusions regarding trazodone’s potential use in these conditions.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

In both premarketing trials and postmarketing surveillance, the adverse effects seen with trazodone therapy have generally been benign, mostly limited to dry mouth, headache, nausea, drowsiness, fatigue, and dizziness, the latter in part secondary to orthostatic hypotension. Unlike TCAs, trazodone is virtually devoid of anticholinergic side effects, including major cardiac conduction abnormalities, thus explaining its benign profile following overdose. The adverse reaction for which trazodone is most widely recognized, although infrequent, is priapism.

Cardiovascular System

Trazodone appears to have a relatively benign cardiovascular profile. The most troublesome cardiovascular adverse effect is postural hypotension, which can be severe enough to produce syncope in susceptible patients, particularly the older adults or those with concurrent medical illness or taking other medications with cardiovascular effects. Adjustments in the dosage or dosing intervals of trazodone or concurrent medications, together with precautions regarding postural changes, can usually mitigate this problem if trazodone use is otherwise warranted.

No consistent effects of trazodone on cardiac contractility or the interventricular conduction system in humans or animals have been noted, except for possible nonspecific lengthening of the PR interval. However, several case reports of cardiac abnormalities associated with trazodone use exist in the literature, including ventricular arrhythmias, QT prolongation, and complete heart block. Most, but not all, of these effects were seen either associated with trazodone overdose or in individuals with pre-existing heart disease, suggesting caution in this latter category of patients.

Genitourinary System

The most concerning side effect attributed to trazodone is priapism, a painful unremitting erection that requires emergency medical attention. It can occur as a complication of various medical illnesses such as sickle cell disease, but a majority of cases have implicated medication use. The α-adrenergic receptor antagonists, such as trazodone, chlorpromazine, and prazosin, are hypothesized to induce priapism by inhibiting sympathetically controlled detumescence. The incidence of priapism during trazodone therapy is estimated at 1 in 1,000 to 1 in 10,000 cases. Although it is most likely to occur within the first 28 days of initiating treatment with trazodone, it has occurred as late as 18 months into treatment and at a wide range of therapeutic dosages. A past history of prolonged erections appears to be a general risk factor for priapism. At least two cases of clitoral priapism associated with trazodone use have also been reported in the literature.

All patients on trazodone therapy need to be warned of the risk and medical significance of priapism, as patients may be reticent to acknowledge it and seek treatment. Once priapism develops, it is considered a urologic emergency requiring immediate medical intervention. Patients should be advised to discontinue trazodone and seek emergency care in the event of an erection lasting more than 1 hour. The likelihood of morbid complications of impotence, cavernosal fibrosis, and gangrene is directly related to a delay in initiating treatment. Various medical interventions (ice packs, oral adrenergic medications) have produced inconsistent results but are usually attempted before more definitive surgical procedures are instituted. One of two surgical interventions (intracavernosal irrigation with an α-adrenergic agonist or shunting between the corpus cavernosa and spongiosum) will usually produce detumescence, but impotence may still be the outcome in as many as half of these cases.

Central Nervous System

Trazodone frequently produces CNS side effects of drowsiness (20% to 40%) and dizziness or light-headedness (20% to 30%), particularly early in treatment. Drowsiness has been the side effect most frequently leading to discontinuation, although it can be a welcome benefit for those patients with severe insomnia. Headache, fatigue, nervousness, and confusion have lower incidence. Isolated cases of delirium induced by trazodone have been reported in patients with pre-existing cerebral or metabolic abnormalities.

Trazodone shows little, if any, risk for lowering the seizure threshold in patients. There have been isolated case reports of increased seizure activity associated with trazodone use, although these are far less prevalent than with TCAs. In patients with a known history of seizure disorder, it is prudent to initiate therapy with trazodone at lower doses and titrate the dose more gradually.

As is the case with other antidepressants, trazodone has been reported to precipitate manic episodes in patients with diagnoses of both major depressive disorder and bipolar disorder. Trazodone's potential for increasing the risk for hypomania or mania appears to be lower than that of TCAs. Finally, trazodone also carries the black box warning (applied to all antidepressant medications) for increased risk of suicidal ideation, especially in children, adolescents, and young adults.

THERAPEUTIC INDICATIONS

Trazodone has an FDA indication for major depressive disorder, and research supports its general efficacy and tolerability for this indication. Currently, the most common off-label use of trazodone is for the treatment of insomnia, particularly insomnia associated with the use of other antidepressants such as the SSRIs, for which it remains a reasonable option for some patients. For other conditions, as described above, the findings are tentative and would require replication in larger samples before treatment recommendations can be made.

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effect reported by patients using trazodone is drowsiness. Patients should be warned that this side effect may be exacerbated by alcohol or other concomitant medications, thus impairing their ability to safely engage in potentially hazardous tasks, such as driving. Orthostatic hypotension resulting in syncope can occur, particularly in the older adults or medically ill, and may cause significant injury through falls. Adjusting the dosage of trazodone or concurrent medications and ingesting trazodone with meals may diminish this effect, but continued caution should be exercised when prescribing trazodone to older adult patients. There are no reported withdrawal or discontinuation syndromes associated with trazodone. A 2014 review found some cases of dose-independent trazodone-induced liver injury (hepatocellular by immuno-allergic mediation), with one resulting in a liver transplant. A 2011 meta-analysis indicated that trazodone was correlated with higher all-cause mortality compared to SSRIs and TCAs in the treatment of elder depressed patients.

Priapism, although infrequent, is the side effect that is most concerning due to its potential for producing serious, irreversible injury. All patients should be strongly cautioned to discontinue trazodone and seek immediate medical attention in the event of prolonged or painful erections.

There is no evidence that trazodone possesses mutagenic or carcinogenic potential based on studies in rats receiving doses up to 300 mg/kg for 18 months. Trazodone is designated pregnancy category C, as it has produced fetal anomalies in animal studies at 15 to 50 times the maximum human dose, but it has not been adequately evaluated in human pregnancy. One multicenter study compared the pregnancy outcomes of 147 women who had exposure to either trazodone (n = 58) or the related phenylpiperazine antidepressant, nefazodone (n = 89), with the outcomes from women exposed to other antidepressants (n = 147) or nonteratogenic medications (n = 147). They found no statistically significant differences among the three groups for any of the endpoints of interest, including miscarriage rate, rate of major malformations, gestational age, and birth weight. As with all medications that have an unclear potential for fetal effects, use in pregnancy should only be considered if the potential benefit outweighs the risk. Trazodone is excreted into human breast milk, with one study in six lactating women reporting a milk/plasma ratio of about 15%, indicating that exposure to nursing infants would be low.

Trazodone has a very high therapeutic index, with an LD_{50} of around 500 mg/kg in experimental animals. Data from hundreds of documented cases of overdose support its safety in all but a small fraction of cases, with the majority of those involving other concurrent medications. The main symptoms that occur when trazodone is taken in overdose are excessive drowsiness and vomiting, although isolated cases of seizures, hyponatremia, priapism, respiratory arrest, QT prolongation, cardiac arrest, and coma have been reported. One postmortem toxicologic review of trazodone-related deaths concluded that trazodone played a primary role in the deaths by massive overdose of only three individuals who attained blood concentrations above 9 mg/L.

DRUG INTERACTIONS

Significant changes in prothrombin time (PT) and international normalized ratio (INR) in patients receiving warfarin (Coumadin) therapy and increased levels of digoxin (Lanoxin) and phenytoin (Dilantin) have been reported in isolated cases of patients receiving trazodone concurrently, most likely due to interactions via trazodone's high binding to plasma proteins. An in vitro study reported that the metabolism of trazodone to its principal metabolite (mCPP) via CYP3A-mediated clearance was significantly inhibited by ketoconazole (Nizoral), ritonavir (Norvir), and indinavir (Crixivan), suggesting caution in prescribing trazodone to individuals treated with CYP 3A4 inhibitors, including HIV-infected individuals who are commonly prescribed these medications. One patient taking fluoxetine and trazodone developed sedation and an unsteady gait, with the finding of a 30% increase in trazodone levels. However, this was an isolated report, as most patients tolerate this combination without difficulty.

As discussed earlier, trazodone may potentiate the sedative or hypotensive effects of other pharmacologic agents, requiring caution when used in such combinations. In combination with MAOIs to treat insomnia, trazodone appears to be safe. No cases of hypertensive crisis have been reported, and one reported case of nocturnal myoclonus resolved after discontinuation of trazodone. There have been several isolated reports of serotonin syndrome associated with trazodone use. Most of these occurred when trazodone was prescribed in combination with a variety of serotonergic psychotropic medications, including buspirone (BuSpar), fluoxetine, sertraline, paroxetine, venlafaxine, nefazodone, and amitriptyline with lithium (Eskalith). One case occurred when trazodone alone was prescribed to a 73-year-old patient who was later suspected of suffering from Lewy body dementia.

LABORATORY INTERFERENCE

Trazodone generally exhibits no interference with urinalysis, spectrometry, or other laboratory tests. There is one isolated report of trazodone-related decreases in hematocrit, hemoglobin, red blood cell count, serum cholesterol, calcium, and albumin during a 6-week comparison trial with fluoxetine, with the development of clinically insignificant pseudoanemia in 36% of the trazodone-treated and 20% of the fluoxetine-treated groups, respectively. Trazodone has also been reported to result in a false-positive urine drug screen for amphetamine.

DOSAGE AND ADMINISTRATION

The manufacturer's package insert recommends initiating trazodone at 150 mg per day in divided doses (after meals), increasing by 50 mg per day in intervals of 3 to 4 days up to a maximum dose of 400 mg per day in outpatients and 600 mg per day in inpatients. Elder patients should use a starting dose of 100 mg daily. There are not yet approved dosage recommendations for children or adolescents.

Trials of trazodone for the treatment of major depression suggest that the majority of patients begin to respond within the first 2 weeks of therapy, although this finding was in the context of objective, controlled studies, many with higher initial dosages. However, patients with significant insomnia or agitation may show an early response to trazodone's sedating effects. For the treatment of primary or medication-related insomnia, doses in the 50- to the 100-mg range are usually sufficient.

Trazodone is available in scored 50- and 100-mg tablets and in 150- and 300-mg tablets that can be divided into halves or thirds for convenient dosing adjustment and administration. Oleptro is available in 150- and 300-mg tablets.

33.6b Nefazodone

AMIR A. KHAN, M.D., AND SUSAN G. KORNSTEIN, M.D.

Neuroscience-Based Nomenclature (NbN)

Serotonin Modulator

Pharmacologic domain	Serotonin
Mechanism of action	Receptor antagonist (5-HT$_{2A}$) and Partial Agonist (5-HT$_{1A}$)

Nefazodone (Serzone) is a serotonin modulator developed to improve the side-effect profile of the analogous, second-generation antidepressant trazodone (Desyrel) by using receptor-binding techniques. It has unique effects on the serotonergic system that are distinct from other antidepressants. It became available in the United States in early 1995. Following the issuance of a black box warning regarding rare but potentially life-threatening hepatotoxicity and the availability of generic nefazodone, the original manufacturer of Serzone (Bristol–Myers Squibb) discontinued the production of Serzone in June 2004, citing declining market share as a primary reason. Generic nefazodone remains available in the U.S. market, although its clinical utilization continues to decline. Sales of nefazodone in Canada were discontinued in 2003.

Nefazodone is a phenylpiperazine compound with some structural similarity to trazodone. It is structurally unrelated to other antidepressants. Nefazodone's mechanism of action is attributed to its antagonism of the 5-hydroxytryptamine, type 2A (5-HT$_{2A}$) receptor and inhibition of the serotonin transporter. It has a limited affinity for the α_1-adrenergic receptor, hence the decreased incidence of postural hypotension compared with trazodone.

CHEMISTRY

Nefazodone is a synthetically derived phenylpiperazine antidepressant. The chemical name for nefazodone hydrochloride is 2-[3-[4-(3-chlorophenyl)-1-piperazinyl]propyl]-5-ethyl-2,4-dihydro-4-(2-phenoxyethyl)-3H-1,2,4-triazol-3-one monohydrochloride. The molecular formula is $C_{25}H_{32}ClN_5O_2$•HCl with a molecular weight of 506.5 (Fig. 33.6b–1).

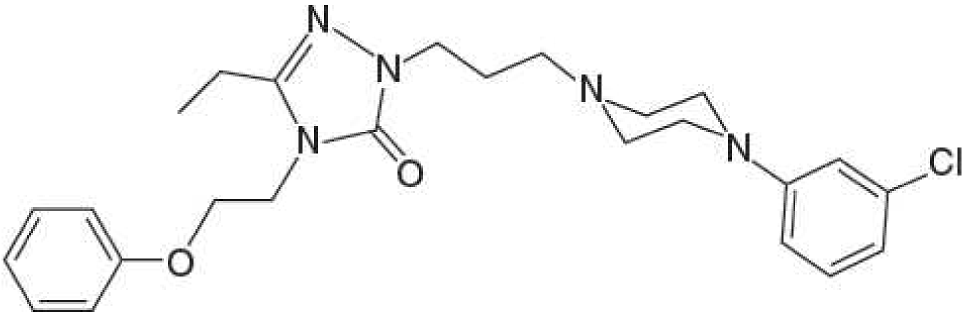

FIGURE 33.6b–1. Molecular structure of nefazodone (Serzone).

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Absorption. Nefazodone is rapidly and completely absorbed after oral intake. The absolute bioavailability, however, is low at about 20% and variable because of its extensive metabolism. The presence of food in the GI tract delays absorption and further reduces bioavailability. The clinical significance of this finding is unclear and probably not important. Peak plasma concentration occurs in about 1 hour.

Distribution. Nefazodone is widely distributed in body tissues, including the CNS. The volume of distribution for nefazodone is 0.22 to 0.87 L/kg. It readily crosses the blood–brain barrier. Nefazodone is extensively (>99%) but loosely bound to plasma proteins. It does not tend to displace other protein-bound drugs when studied in vitro, but this property in vivo is not well studied. It does decrease the protein binding of haloperidol by 5%, which is unlikely to be of any clinical importance.

Metabolism and Elimination. Nefazodone is extensively metabolized by n-dealkylation and aliphatic and aromatic hydroxylation. Less than 1% of the drug is excreted unchanged in the urine. Nefazodone’s three major pharmacologically active metabolites are hydroxynefazodone, meta-chlorophenylpiperazine (mCPP), and triazole-dione. Both nefazodone and hydroxynefazodone have a relatively short half-life (1.5 to 4 hours) and exhibit nonlinear kinetics. Compared to a single dose, multiple dosing, as well as dosage increases, produce a disproportional increase in the maximum concentration ($C_{\max}$) of the drug. This property signifies greater-than-predicted accumulation of the drug and its hydroxy metabolite with multiple dosing. Nefazodone and its metabolites attain steady-state concentration within 4 to 5 days of initiation of BID dosing or changes in previous regimens.

The pharmacologic profile of hydroxynefazodone is similar to that of nefazodone. mCPP is also somewhat similar to nefazodone, with the notable difference of possessing agonist activity at some serotonergic receptor subtypes. It has a half-life of 4 to 8 hours. The actions of triazole-dione are not yet well characterized. However, it has a longer half-life of 18 hours.

Nefazodone should not be used in patients with hepatic disease. Pharmacokinetic studies have shown reduced drug clearance in patients with hepatic cirrhosis; a dose reduction should be considered in such patients, as the steady-state concentrations of nefazodone and hydroxynefazodone are 25% higher than in normal controls. Exposure to mCPP is about two- to threefold higher in patients with hepatic cirrhosis. Patients with renal dysfunction do not show a significantly different pharmacokinetic profile. Older adult patients show a 10% to 20% increase in steady-state plasma levels; therefore, the starting dose for older patients, particularly women, should be half the usual dose. Nefazodone does not utilize the CYP 2D6 metabolic pathway; hence, dosage adjustment for poor metabolizers is not required.

Pharmacodynamics

Nefazodone has a multimodal, complex mechanism of action. It inhibits neuronal uptake of serotonin and norepinephrine; however, its antidepressant effects are presumably exerted only through the serotonergic system. Presynaptically, it inhibits 5-HT reuptake, which increases the 5-HT level within the synapse and results in increased availability of serotonin. Postsynaptically, it occupies 5-HT_{2A} receptors as an antagonist, hence downregulating the receptor. The latter property is believed to be responsible for the antidepressant action of nefazodone. Its ability to block 5-HT_{2A} receptors also provides a potential mechanism for the low likelihood of treatment-related activation and sexual dysfunction.

Hydroxynefazodone has an almost identical pharmacologic profile to the parent compound and probably contributes to the antidepressant action of nefazodone. mCPP is a minor metabolite, but it appears to have important pharmacologic properties. It binds potentially to all 5-HT_1, 5-HT_2, and 5-HT_3 receptors. It acts as an agonist at the 5-HT_{1A}, 5-HT_{2C}, and 5-HT_3 receptors and as a mixed agonist and antagonist at the 5-HT_{2A} site. It is believed to possess anxiogenic properties. Animal studies, as well as the direct administration of mCPP to patients with anxiety disorders and normal controls, generally support this finding.

Nefazodone has weak α_1-adrenergic antagonism that may cause postural hypotension, though this effect is much less pronounced compared to trazodone. Nefazodone does not have significant affinity for α_2-adrenergic, β-adrenergic, cholinergic, dopaminergic, 5-HT_{1A}, or benzodiazepine receptors. This receptor affinity profile offers distinct clinical advantages with regard to minimizing potential side effects.

THERAPEUTIC INDICATIONS

Nefazodone was approved for the treatment of major depression in the United States in 1994. This approval was granted based on the results of five well-controlled premarketing clinical trials. Since its approval, many small and large-scale studies, including both inpatient and outpatient populations, have documented its efficacy in the treatment of depression.

Major Depression

Nefazodone was evaluated in four phase III, double-blind, active (imipramine) and placebo-controlled trials to study its efficacy and safety as an antidepressant in outpatients with major depression. Primary efficacy measures were the 17-item Hamilton Rating Scale for Depression (HAM-D) and the Clinical Global Impression (CGI) scale. Three of the four studies showed nefazodone to be superior to placebo and comparable to imipramine in efficacy. The fourth trial failed to show a significant difference between both active drugs and placebo. The incidence of side effects and premature treatment discontinuation was higher with imipramine than with nefazodone. Two dose-finding studies, as well as other phase II/III studies, determined the optimal treatment dosage range to be between 300 and 500 mg/day.

Nefazodone has been directly compared with the SSRIs in both short-term (6 to 8 weeks) and maintenance studies (up to 46 weeks). A meta-analysis of six studies reported that nefazodone (n = 523) and SSRIs (fluoxetine, paroxetine, and sertraline; n = 513) were comparable in efficacy for the treatment of moderate to severe major depression. Differences were noted in the side-effect profile favoring nefazodone, particularly with regard to sleep disturbances, weight gain, and sexual dysfunction. An additional meta-analysis involving nine studies comparing nefazodone/trazodone with SSRIs for the treatment of major depression (n = 998) confirmed these findings.

There is considerable evidence for the efficacy of nefazodone in the treatment of various subtypes of depression. A meta-analysis of four clinical trials comparing nefazodone (n = 247), imipramine (n = 166), and placebo (n = 251) showed that nefazodone is effective for the treatment of severe depression as well as melancholic and recurrent depression. A placebo-controlled study evaluated the efficacy of nefazodone in 120 hospitalized patients with severe depression. Significant improvement was noted in patients treated with nefazodone compared to placebo (CGI-I response rates of 50% vs. 29%) in this 6-week study.

Nefazodone has been studied in direct comparison with psychotherapy and combination treatment in patients with chronic depression. In this study, 681 outpatients with chronic, nonpsychotic major depression were assigned to 12 weeks of treatment with nefazodone, The Cognitive Behavioral Analysis System of Psychotherapy, or their combination. In patients who completed the study (*n* = 519), the response rates were 55% in the nefazodone group, 52% in the psychotherapy group, and 85% in the combined treatment group. The response rates for the monotherapy groups are comparable to other studies of chronic depression. The level of response for combination treatment is the highest ever reported in this patient population. A subset of these patients who did not respond to the initial trial of either psychotherapy or nefazodone treatment showed an improved response when treatments were switched (from nefazodone to psychotherapy and vice versa).

Other Mood Disorders

Nefazodone has not been systematically evaluated for the treatment of bipolar depression. One small open-label trial studied nefazodone as an add-on treatment for bipolar depression in 13 patients and showed positive results. The reason to use nefazodone, despite its well-known hepatotoxicity, was to study the underlying mechanism of postsynaptic 5-HT(2A) antagonism as a potential mechanism to develop future therapies for bipolar depression. There are several case reports of nefazodone-induced mania. Caution should be exercised in using nefazodone for the treatment of bipolar depression.

Two small open-label studies reported the efficacy of nefazodone in the treatment of premenstrual dysphoric disorder (PMDD). One small randomized, controlled trial compared its efficacy in PMDD versus buspirone and placebo. This study did not find significant efficacy for nefazodone in the treatment of PMDD, except that it was modestly effective in controlling PMDD-associated irritability; however, the small sample size renders these findings inconclusive.

Symptoms of anxiety during depressive episodes are common. There is evidence from controlled trials that nefazodone helps the comorbid symptoms of anxiety in depressed patients. A meta-analysis of six randomized, controlled trials of nefazodone in patients with major depression showed that nefazodone produced earlier and more sustained improvement in the symptoms of agitation and somatic anxiety compared to imipramine and placebo. This finding was replicated by another retrospective analysis of over 300 patients with major depression. In this analysis, imipramine and nefazodone were both effective in alleviating depressive symptoms; however, nefazodone showed a superior response for comorbid anxiety symptoms. Additional evidence from the nefazodone chronic depression study also supports this beneficial effect of nefazodone on comorbid anxiety, particularly early (first or second week) in the course of treatment.

Anxiety Disorders

Although a number of studies have looked at anxiety symptoms during an episode of major depression, there has been little study of nefazodone for the treatment of primary anxiety disorders. Most of the evidence available is from small, open-label trials.

A meta-analysis of six open-label trials consisting of 105 patients with PTSD (both civilians and combat veterans) showed that nefazodone was effective for a broad spectrum of PTSD symptoms at a dosage of up to 600 mg/day. This finding has been replicated in four additional, small, open-label trials. Randomized controlled trials are needed to determine if nefazodone is superior to placebo and comparable to other treatments for PTSD. An interesting finding in one of the open-label trials was that although patients with chronic PTSD reported improvement in the symptoms of nightmares and other sleep disturbance as well as depression and other PTSD symptoms, the objective, polysomnographic sleep measures did not change, which is in contrast to the sleep studies of depressed patients on nefazodone.

There are two open-label studies of nefazodone use in panic disorder and an additional study in panic disorder comorbid with depression. The total number of patients enrolled in these studies was 39, with study durations of 8 to 12 weeks. Two of the three studies found nefazodone to be beneficial for the treatment of panic disorder, with or without agoraphobia and with or without depression. However, one study reported that the response rate of nefazodone was lower compared to some other antipanic medications such as paroxetine or low-dose venlafaxine.

A clinical case series of five patients suggested the potential efficacy of nefazodone for the treatment of social phobia. An open-label study consisting of 23 patients reported a response rate of about 70% (*n* = 16) for social phobia. However, a double-blind placebo-controlled study for the treatment of social phobia (*n* = 102) reported no significant difference in response rate between nefazodone and placebo-treated patients. Another open-label trial of nefazodone was conducted on 21 patients with generalized anxiety disorder (GAD). Of 15 subjects who completed the trial, 12 were considered significantly improved. An open-label study of nefazodone in patients with depression and comorbid OCD did not report significant antiobsessional effects. Another retrospective study evaluated the efficacy of nefazodone for the treatment of nonparaphilic compulsive sexual behavior. Of the 14 subjects studied, 6 reported good control of sexual obsessions and compulsions and 5 reported remission of those symptoms.

In summary, nefazodone can potentially be useful for a variety of anxiety disorders; however, the existing evidence is not rigorous. If a patient fails the standard treatment, then nefazodone can be used as a second- or third-line treatment, with the understanding that the data regarding its efficacy are very limited.

Substance Abuse and Dual Diagnosis

There is one double-blind, placebo-controlled study of nefazodone in patients with comorbid major depression and alcohol dependence. This study enrolled 64 subjects who were actively drinking alcohol and had a history of at least one episode of depression when abstinent. Patients were randomized to receive 12 weeks of treatment with nefazodone or placebo. All patients continued once-weekly psychoeducational group therapy. The results indicated that nefazodone is efficacious for the treatment of depression in this population, but it did not show any advantage over placebo with regard to alcohol outcome. There was also an increased incidence of nonserious, drug-related side effects (sedation, visual trails, dizziness, and dry mouth). Another larger study of 183 patients with alcohol dependence compared nefazodone with naltrexone and placebo. This study did not find any beneficial effects of nefazodone for the treatment of alcohol dependence. There is one case series reporting successful treatment with nefazodone for depression in four patients who were on methadone maintenance treatment and whose depression had not responded to other medications.

Two double-blind, placebo-controlled studies investigated the use of nefazodone in cocaine-dependent patients. The first study included 69 subjects with cocaine dependence and depressive symptoms, and the primary objective was to determine the efficacy of nefazodone in reducing cocaine use. The second study included 210 subjects. Both trials indicated no specific efficacy of nefazodone in treating cocaine dependence.

A small double-blind study investigated the efficacy of nefazodone and bupropion-sustained release for treating cannabis dependence. The sample size was relatively small. The study did not show any specific benefit of nefazodone or bupropion for the treatment of cannabis dependence in the studied population.

From these reports, it can be concluded that nefazodone does not possess specific efficacy for the treatment of alcohol or substance abuse. However, it can be used for the treatment of comorbid depression in this population. Extreme caution should be exercised in using nefazodone for patients who have alcohol use disorders because of the rare but life-threatening adverse effect of liver failure.

Pain

One open-label study evaluated the efficacy of nefazodone for the treatment of chronic daily headaches in 52 patients. Most of the patients enrolled (*n* = 48) had a history of migraine, based on the criteria established by the International Headache Society. The remainder of the patients had chronic tension-type headaches. The median dose used was 300 mg/day. At the end of the 12th week, 71% of the patients showed at least a 50% improvement in their headache index. Patients who were depressed or anxious showed significantly greater improvement in their headache as well as in the symptoms of depression and anxiety. There is another small, open-label study of 10 patients with diabetes mellitus type II with painful diabetic neuropathy but who did not meet the criteria for major depression. These patients received up to 450 mg/day of nefazodone for 8 weeks. At the end of the treatment period, the patients showed improvement in pain, parasthesias and numbness, as well as slightly improved diabetic control. Both of these studies indicate a potential analgesic effect of nefazodone. However, whether this effect is independent of antidepressant action remains unclear.

Other Uses

There are case reports and small, open-label studies of nefazodone use for the treatment of mood disorders in children and adolescents. The results show that nefazodone is effective for the symptoms of depression in this population and is well tolerated. However, these studies also indicate that the pharmacokinetic properties of nefazodone in children and adolescents are highly variable.

There are also small open-label trials of nefazodone use as an adjunct treatment for schizophrenia in patients who were on a stable dose of antipsychotic medication. There is also one study of nefazodone use in somatization disorder. These studies not only suffer from the limitations common to open-label trials, but they also do not have adequate power to establish the efficacy of nefazodone independent of the comorbid depression present.

A published analysis of nefazodone and cognitive behavioral analysis system of psychotherapy trial showed an interesting finding supporting patient preference as a potent moderator of treatment response for patients with chronic forms of MDD (i.e., patients who preferred psychotherapy responded better to psychotherapy and patients who preferred medication treatment responded better to that intervention).

From the above discussion, it is reasonable to conclude that nefazodone is comparable to other treatments for major depression. However, there is clearly a need for randomized, controlled trials before nefazodone can be recommended for routine use for conditions other than depression.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

General

Premarketing clinical trials with nefazodone in almost 3,500 patients showed that it has a relatively low incidence of adverse events. In these trials, about 16% of participating patients discontinued treatment due to adverse experiences. The commonly observed adverse events that differed significantly from placebo were somnolence (25% vs. 14%), dry mouth (25% vs. 13%), nausea (22% vs. 12%), dizziness (17% vs. 5%), constipation (14% vs. 8%), asthenia (11% vs. 5%), light-headedness (10% vs. 3%), blurred vision (9% vs. 3%), confusion (7% vs. 2%), and abnormal vision, consisting of scotoma and visual trails (7% vs. 1%). The most common reasons for treatment discontinuation were nausea, dizziness, asthenia, and agitation. The incidence of adverse events increases with the dosage of nefazodone. An analysis of three placebo-controlled trials in which two different dosage ranges were used (low ≤300 mg/day; high 300 to 600 mg/day) showed that the incidence of somnolence, nausea, dizziness, constipation, abnormal vision, confusion, and tinnitus was comparable to placebo in the low dosage range. However, the incidence of these adverse events increased significantly in patients treated at the higher dosage range (300 to 600 mg/day).

In 2004, FDA mandated that a boxed warning be placed on the labels of all antidepressants indicating an increased risk of suicidal thoughts and behavior in youth taking these medications and in 2006, it added young adults aged 24 years or less to this list. There are no data indicating a specific increase in this risk by nefazodone; however, caution should be exercised, particularly in children.

Central Nervous System

The most common adverse events pertaining to the CNS are somnolence, dizziness, confusion, insomnia, and lightheadedness. Less frequently reported events include memory impairment, paresthesias, flushing and feeling warm, abnormal dreams, ataxia, and tremors. There is at least one report of a nefazodone-induced acute dystonic reaction, which responded well to standard anticholinergic treatment.

There are reports of rare incidences of seizures after nefazodone administration, particularly in patients who have a seizure disorder; however, a causal relationship has not been established. Controlled data for combining antidepressant drug therapy and ECT are sparse. In a case report from Australia, one patient with treatment-resistant dysthymia underwent ECT while taking 600 mg/day of nefazodone and 15 mg of midazolam without significant problems. There was no adverse outcome, and the patient showed a good response.

Sleep disturbance is one of the most frequent and distressing symptoms of depression. Many antidepressants tend to cause or worsen sleep disturbances. Their effects include decreased REM sleep, increased REM latency, increased stage I sleep, and decreased sleep efficiency. Nefazodone, on the other hand, appears to possess unique and potentially beneficial effects on sleep architecture. It shows minimal effects on REM sleep, decreases stage I sleep and improves sleep efficiency. These effects have been observed in both normal as well as depressed subjects. In comparison with fluoxetine, nefazodone produced significantly greater improvement in sleep on both subjective and objective (sleep EEG) measures. The beneficial effects of nefazodone on sleep tend to appear early in treatment, during the first 2 weeks. The differences between nefazodone and SSRIs on sleep parameters have been shown to remain significant even after patients have responded to the antidepressant treatment. However, a study comparing nefazodone and paroxetine found no difference in subjective sleep improvement after 8 weeks of treatment.

Preclinical studies on human volunteers were carried out to determine the effects of nefazodone on daytime sleepiness, highway driving, and cognitive performance. Results of these early studies showed minimal impact of nefazodone on these measures. Clinical experience in patient populations shows that somnolence is frequently observed, particularly early in the treatment. However, it does not appear to result in an actual increase in daytime sleepiness. The incidence of adverse events related to motor performance and cognitive tasks is also minimal but has a dose–response relationship and tends to increase for doses over 300 mg/day.

Cardiovascular System

Nefazodone has limited effects on the cardiovascular system. It can cause a slightly increased incidence of postural hypotension and hypotension. These effects are much less pronounced compared to the TCAs or trazodone. In a pooled analysis of almost 800 patients, the incidence of postural hypotension with nefazodone was 4%, compared to 1% with placebo. In the same study, the incidence of hypotension was 2%.

There were no clinically significant ECG changes noted in placebo-controlled trials involving 1,153 patients taking nefazodone. Asymptomatic sinus bradycardia was noted in 1.3% of nefazodone-treated patients, compared to 0.4% of placebo-treated patients. The specific cardiac effects of nefazodone in patients with existing cardiovascular disease, particularly of recent onset, are not fully known. Nefazodone inhibited hERG channel activity in a concentration-dependent manner **in HEK-293 cells**, suggesting the theoretical possibility of QTc prolongation. There is a potential for QTc prolongation if nefazodone is combined with terfenadine, astemizole, cisapride, or pimozide.

Genitourinary System

Antidepressant medications are often associated with treatment-related sexual dysfunction, including effects on desire, arousal, and orgasmic function. These side effects are particularly common with SSRIs. In clinical studies, nefazodone has been associated with a low incidence of sexual side effects in both men and women. In one study comparing nefazodone and sertraline in depressed outpatients, 47% of women on sertraline reported difficulty achieving orgasm compared to 17% of women on nefazodone. In the same study, significantly more men taking sertraline (67%) reported ejaculatory difficulty than did men taking nefazodone (19%). The incidence of sexual side effects reported with nefazodone was also low (3.5%) in a study of patients with chronic depression.

Priapism, a recognized side effect of trazodone, has been very rarely reported with nefazodone. There is one case report of nefazodone-precipitated clitoral priapism.

It is believed that the relatively low affinity of nefazodone for α_1-adrenergic receptors is the reason for the low likelihood of treatment-related priapism or postural hypotension.

In premarketing clinical trials, the incidence of urinary frequency, retention, and infection was slightly increased with nefazodone compared to placebo. However, the overall incidence of these adverse events was low.

Gastrointestinal System

Rare cases of life-threatening hepatic failure have been reported in patients treated with nefazodone. The reported rate in the United States is about one case of liver failure resulting in death or transplant per 250,000 to 300,000 patient-years of nefazodone treatment. This rate is considered an underestimate by some because of potential under-reporting. This finding prompted a mandatory black box warning by the FDA and a revision of the product labeling and patient information packet in 2002. This warning is based upon the postmarketing experience of over seven million patients in the United States. The reported rate represents about three to four times the estimated background rate of liver failure. Most liver failures were reported between 1 and 8 months after drug initiation. The common clinical symptoms of hepatotoxicity included jaundice and increases in ALT (10x), AST (10x), total bilirubin (mostly conjugated), and prothrombin time. Dark urine and clay-colored stool were also reported. Available histologic evaluations of livers demonstrated centrilobular necrosis and bile-duct proliferation with cholestasis. Inhibition of bile acid transport by nefazodone has been proposed as an indicator of potential hepatotoxicity in animal models. The radiochemical in vitro methods are available to detect and quantify covalent binding (CB) to liver proteins for a drug or its metabolites and are being studied to predict the risk of liver injury. Nefazodone impairs oxygen consumption by inhibiting the complex I of the electron transport chain in hepatic mitochondria. Additionally, at higher extracellular concentrations, nefazodone could also inhibit anaerobic glycolysis resulting in cell death. During preclinical drug development, all new molecular entities are screened for possible mitochondrial damage by measuring ATP content and mitochondrial membrane potential in primary cultures of human hepatocytes to identify the risk of liver injury. The potential clinical application of these techniques remains to be seen. The risk factors for drug-induced hepatic injury include age and polypharmacy. Given the seriousness of hepatotoxicity, it is clinically important to obtain a complete pretreatment history of any underlying liver disease. Periodic serum testing of liver enzymes has not been shown to prevent serious liver injury. However, early detection of drug-induced hepatic injury and immediate withdrawal of the suspected drug is likely to improve the potential for recovery. Nefazodone should be discontinued in patients showing signs of hepatic toxicity. These patients should not be rechallenged with nefazodone.

More common GI problems associated with nefazodone use include dry mouth (25%), nausea (22%), and constipation (14%).

Other Systems

Nefazodone is generally considered to be weight-neutral. Evidence from both short-term and long-term studies comparing nefazodone with either placebo or other antidepressants supports this conclusion. A pooled analysis of six clinical trials comparing nefazodone (n = 523) and SSRIs (fluoxetine, sertraline, or paroxetine n = 523) as well as three trials comparing nefazodone (n = 224) with imipramine (n = 224) evaluated the impact of these antidepressants on weight. The criterion for clinically significant weight change was a 7% increase or decrease in weight from the baseline measurement. The results showed that in short-term trials, SSRI-treated patients showed more weight loss than nefazodone-treated patients; however, during long-term treatment, more patients gained weight on SSRIs compared to nefazodone. Imipramine was also found to be associated with more weight gain than nefazodone.

Abnormal vision, usually consisting of scotoma and visual trails (palinopsia), has been associated with nefazodone use. This adverse event was noted in up to 10% of the patients taking nefazodone, compared to 2% to 3% of patients on placebo. It is generally considered benign and is probably dose-dependent. It can usually be managed by lowering the medication dose or changing the time of the day the dose is given.

In a retrospective study, joint disorders were considerably more frequently reported adverse effects of 5-HT(2A)-blocking antidepressants, including nefazodone, than of other comparable drugs, suggesting a possible association between the use of 5-HT(2A)-blocking antidepressants and joint disorders.

PRECAUTIONS AND ADVERSE EFFECTS

Overdose

The limited information available regarding the effects of nefazodone overdose during premarketing trials consisted of seven reports of overdose ranging from 1,000 to 11,200 mg, alone or in combination with other drugs. Since its approval, one study has analyzed data on nefazodone from the American Association of Poison Control Centers. It contained over 1,300 human exposures to nefazodone overdose after excluding patients with concomitant agent overdose. Commonly reported symptoms of overdose included drowsiness (17.3%), nausea (9.7%), and dizziness (9.5%). The most common serious clinical effect was hypotension (1.6%). None of these patients died. Most of them were treated with GI decontamination. The study concluded that nefazodone appears to be of low toxicity during poisonings.

There are rare reports of fatalities, predominantly in patients taking an overdose of nefazodone in combination with alcohol and/or other substances. There is no specific antidote available to treat a nefazodone overdose. The mainstay of treatment consists of supportive measures, including adequate airway management and monitoring cardiac rhythm and vital signs.

Used in medically compromised patients during premarketing trials, the pharmacokinetics of nefazodone and its metabolites were studied in a small number of normal healthy volunteers, both younger and older, as well as in patients with biopsy-proven hepatic cirrhosis and patients with impaired renal function. The results of these studies indicate that older adult or cirrhotic patients may require lower doses of nefazodone to achieve and maintain therapeutic effectiveness. Patients with mild to moderate renal impairment (based upon creatinine clearance) appear to tolerate the usual dose without difficulty.

There are no systematic studies of nefazodone treatment of depression in patients with compromised hepatic or renal function. Given the potential for life-threatening hepatotoxicity, nefazodone should be avoided in patients with existing liver disease. It should be used with caution in patients with renal impairment and in patients on hemodialysis. There is one case report of the use of nefazodone to treat depression in a 59-year-old patient on hemodialysis who had not responded to an adequate trial of fluoxetine. Treatment was initiated with nefazodone at a dose of 50 mg BID, which was increased to 100 mg after 1 week and 150 mg after 4 weeks. This patient responded well to nefazodone treatment with minimal adverse events. Pre- and postdialysis nefazodone serum concentrations in this patient suggested that drug levels may be affected by this procedure. Additional studies are needed to confirm the efficacy and safety of nefazodone for the treatment of depression in such patients.

One open-label study evaluated the efficacy of nefazodone in 15 HIV-seropositive patients with major depression. Eleven patients completed the 12-week study. The results showed that HIV-seropositive outpatients respond well to nefazodone and comparably to other outpatient populations. Potential drug interactions with protease inhibitors should be considered before initiating nefazodone therapy in this patient population.

There are anecdotal reports of nefazodone use for depression in patients with cancer on chemotherapy and in patients with epilepsy and cardiac problems. However, systematic studies are not available. Aside from taking routine precautions, increased potential for drug–drug interactions as well as the need for lower dosage and slow titration should be important considerations in instituting nefazodone therapy in medically ill patients.

Use During Pregnancy and Lactation

Nefazodone is classified as a pregnancy category C medication. It has been shown to increase early pup mortality in rabbits at a dose approximately five times the human dose. A decrease in pup weight was also seen at this dose as well as at lower doses. There are no systematic human studies evaluating nefazodone during pregnancy. Nefazodone should be used in pregnancy only if the potential benefit justifies the potential risk to the fetus.

Very little information is available regarding the excretion of nefazodone in human breast milk. One small study of two lactating mothers reported that nefazodone is excreted in human milk; no metabolites were found. The levels of nefazodone in breast milk were not related to the maternal medication dose. Drug levels in the infants were not assayed; however, there was no indication of developmental difficulty in those infants. A case report of a premature, breast-fed infant described drowsiness, lethargy, poor feeding, and difficulty maintaining body temperature attributed to maternal use of nefazodone. Until more information becomes available, a careful risk–benefit analysis must be performed before recommending the use of nefazodone in lactating mothers.

Discontinuation Syndrome

Animal studies using monkeys trained for self-administration of cocaine as a reinforcer did not show this behavior when nefazodone was substituted for cocaine, suggesting that nefazodone has no abuse liability. Its potential for tolerance, physical dependence, or withdrawal has not been studied systematically in humans.

There are case reports suggesting possible withdrawal symptoms resulting from abrupt discontinuation of nefazodone. Typical symptoms reported include dizziness, nausea, vomiting, fatigue, insomnia, and paresthesias. Some unusual symptoms such as brief moments of disorientation and shock-like or electrical sensations have also been reported. Patients generally recover within a few days without any serious problems, and the symptoms can usually be prevented by tapering the medication. The incidence of discontinuation symptoms with nefazodone appears to be much less common than with SSRIs and venlafaxine. In a relapse prevention study of 259 patients who had been maintained on nefazodone treatment for 16 weeks and were randomly assigned to continuation treatment with nefazodone or placebo, there were no significant differences in new-onset or worsened adverse experiences between the nefazodone and placebo groups at 14 and 28 days after randomization.

DRUG INTERACTIONS

There are various mechanisms involved in the drug–drug interactions of nefazodone. Most of these interactions involve Cytochrome P450 (CYP) isoenzymes. Another potential mechanism involves drugs that are highly bound to plasma proteins, such as warfarin. Different metabolites of nefazodone also play a role in drug interactions; for example, the plasma concentration of mCPP is increased in individuals who have decreased activity of CYP2D6.

Psychotropic Agents

Nefazodone and its metabolites, hydroxynefazodone, mCPP, and triazoledione, inhibit CYP3A4, both in vitro and in vivo. This inhibition can result in increased bioavailability of medications metabolized by this pathway. Therefore, caution should be exercised when administering nefazodone with other compounds metabolized by CYP3A4. This interaction becomes even more important for drugs that are exclusively or predominantly metabolized by the CYP3A4 pathway. Two such benzodiazepines, alprazolam and triazolam, show a substantial and clinically important increase in blood levels when administered with nefazodone. When triazolam was coadministered with nefazodone, triazolam’s half-life increased by threefold, AUC increased by fourfold, and peak concentration increased by 1.7-fold. Likewise, there was a 1.6-fold increase in peak concentration and a twofold increase in the AUC of alprazolam. Nefazodone plasma concentration was unaffected by either medication. Given these interactions, the manufacturer recommends that triazolam be avoided during nefazodone treatment in most patients. If alprazolam is used with nefazodone, a 50% reduction in the initial dose of alprazolam is recommended. This effect has not been observed with lorazepam.

One of the metabolites of nefazodone, mCPP, is present in relatively small quantities and is metabolized by the CYP2D6 pathway. When a patient is switched from an antidepressant that is an inhibitor of CYP2D6 (e.g., fluoxetine) to nefazodone, the metabolism of mCPP may be inhibited for some time. This can result in an increased level of mCPP, which is an anxiogenic compound, and may lead to increased anxiety and agitation. This problem can be minimized by using an adequate washout period before switching antidepressants. The interaction between nefazodone and MAOIs has not been systematically studied in humans or animals. The existing evidence with SSRIs or TCAs, when combined with MAOIs, suggests a potential for a serious, sometimes fatal, reaction. This serotonin syndrome consists of hyperthermia, rigidity, myoclonus, autonomic instability with rapid fluctuation of vital signs, and mental status changes that may include extreme agitation progressing to delirium and coma. This reaction has also been reported in patients who have recently discontinued an SSRI or TCA and have been started on MAOI. Some cases present with symptoms resembling neuroleptic malignant syndrome, including severe hyperthermia and seizures. Given the existing evidence with other antidepressants, it is recommended that nefazodone not be used in combination with an MAOI or within 14 days of discontinuing treatment with an MAOI. In addition, a minimum of 1 week should be allowed after discontinuing nefazodone before starting an MAOI.

Coadministration of lithium and nefazodone resulted in only a slight decrease in the concentration of two metabolites of nefazodone, mCPP and triazoledione, which was not clinically significant. The combination of nefazodone and carbamazepine, although well tolerated in a small number of healthy volunteers, resulted in a very significant decrease in the steady-state C_{max} and AUC of nefazodone (86% and 93%, respectively), along with a similar but modest reduction in its metabolites. At the same time, the steady-state C_{max} and AUC of carbamazepine were each increased by 23%, while the steady-state C_{max} and AUC of its metabolite, 10,11-epoxycarbamazepine, decreased by 21% and 20%, respectively. Because the decrease in nefazodone and its metabolites is likely to result in a loss of antidepressant efficacy, this combination should be avoided. There are no systematic studies to evaluate the impact of coadministration of valproic acid and nefazodone. One case report suggested a potentially dangerous interaction of these two medications in a patient with bipolar disorder. This patient suffered from symptoms that were suggestive of serotonin syndrome. Whether this occurrence was incidental or represents a real interaction remains unclear. The impact of combining phenytoin and nefazodone has not extensively been studied. It appears that a single-dose administration of phenytoin with steady-state nefazodone does not alter the pharmacokinetic properties of phenytoin. However, due to the nonlinear pharmacokinetics of phenytoin, this combination should be avoided if possible, or the dose should be adjusted carefully, according to usual clinical practices.

Nefazodone tends to decrease the protein binding of haloperidol by 5%. However, this interaction is unlikely to be of any clinical significance. Human experience with clozapine and nefazodone in a small number of patients suggests that clozapine levels are increased by 4% and norclozapine levels by 16%. This relatively modest increase in levels is considered to be clinically insignificant. There are other small studies of concomitant antipsychotic and nefazodone use that have shown no significant difficulties. However, an important and potentially dangerous interaction may occur between nefazodone and pimozide, resulting in a prolonged QT interval, as described in detail in the following section.

Other Medications

Terfenadine, astemizole, cisapride, and pimozide are metabolized via the CYP3A4 pathway. Drugs such as ketoconazole or erythromycin inhibit this enzyme and block the metabolism of terfenadine, astemizole, cisapride, and pimozide, resulting in increased plasma concentrations of these medications. Increased plasma concentrations of these four medications are associated with QT prolongation and rare cases of cardiovascular adverse events, including death, due principally to ventricular tachycardia of the torsades de pointes type. Nefazodone is a potent inhibitor of CYP3A4. Consequently, nefazodone must not be used in combination with terfenadine, astemizole, cisapride or pimozide. At the present time, terfenadine, astemizole and cisapride have been removed from the U.S. market by the FDA.

Nefazodone was coadministered with digoxin to healthy volunteers who were genotyped as extensive CYP2D6 metabolizers. This combination resulted in an increased C_{max}, C_{min}, and AUC of digoxin by 29%, 27%, and 15%, respectively. There was no effect on the pharmacokinetics of nefazodone or its active metabolites. Since digoxin has a narrow therapeutic index, caution should be exercised in combining it with nefazodone. Plasma level monitoring of digoxin is also recommended. Coadministration of nefazodone and propranolol in healthy volunteers resulted in a decrease in the level of propranolol but did not impact the level of nefazodone or its active metabolites with the exception of mCPP, which was increased. Hence, initial dosage adjustment is not needed for either of the medications; however, subsequent dosage should be adjusted based upon the clinical response.

Simvastatin and atorvastatin are substrates of CYP3A4. When nefazodone was combined with either of these medications, it resulted in a 20-fold increase in the concentration of simvastatin and simvastatin acid and a 4-fold increase in atorvastatin and atorvastatin lactone. This effect appears to result from the inhibition of CYP3A4 by nefazodone. Nefazodone did not significantly affect the level of pravastatin, another HMG-CoA reductase inhibitor. Metabolic interactions are unlikely between nefazodone and HMG-CoA reductase inhibitors such as pravastatin, fluvastatin, or rosuvastatin that undergo little or no metabolism by the CYP3A4 isoenzyme; therefore, dosage adjustment for these agents should not be necessary. However, dose adjustment is needed for simvastatin and atorvastatin because the increased concentrations of these medications might result in a greater risk of rhabdomyolysis and other adverse events associated with HMG-CoA reductase inhibitors.

There have been reports of increased blood concentrations of cyclosporin and tacrolimus into toxic ranges in patients who received concomitant nefazodone. These are immunosuppressive agents that are substrates of CYP3A4. If nefazodone is combined with either of these medications, the level should be monitored, and the dose should be adjusted accordingly.

When nefazodone was administered with warfarin, there was no change in prothrombin or bleeding time despite a modest decrease in $C_{\max}$ of warfarin. This finding suggests a clinically insignificant interaction.

DOSAGE AND ADMINISTRATION

Nefazodone is indicated for the treatment of major depression. Based on the results of clinical trials, the recommended starting dose of nefazodone is 200 mg/day in divided doses (BID). The effective dosage range is usually between 300 mg to 600 mg/day in divided doses. The starting dose can be increased by 100 to 200 mg/day at intervals of no less than 1 week. In order to minimize adverse events, it is preferable to start at 100 mg/day and then increase by 100 mg/day every week. The usual therapeutic dosage range is 400 to 600 mg/day. Doses higher than 600 mg/day are not recommended. As with all antidepressants, several weeks of treatment at a reasonable therapeutic dose are required for antidepressant response. As with other antidepressants, a long-term study (up to 1 year) with nefazodone as a maintenance treatment suggests that the therapeutic dose should be continued as the maintenance dose. Once-daily dosing has been attempted in patients who were previously maintained on BID dosing as well as in patients starting nefazodone. The results did not show significant differences with once- versus twice-daily dosing of nefazodone. Since these were open-label trials, this finding needs to be replicated in double-blind studies.

The recommended starting dose for older adults or debilitated patients is 50 mg BID. The increase in dosage should be slower and tailored to the individual patient's symptoms and side effects. The final therapeutic range in older adult patients may be similar to younger patients.

Nefazodone is supplied in 50, 100, 150, 200, and 250 mg strengths.

33.6c Mirtazapine

Mousa Sobhy Azer Botros, M.D., Radu V. Saveanu, M.D., and Michael E. Thase, M.D.

Neuroscience-Based Nomenclature (NbN)	
Monoamine Multimodal	
Pharmacologic domain	Norepinephrine, Serotonin
Mechanism of action	Receptor antagonist (Ne alpha-2, 5-HT_2, 5-HT_3)

Mirtazapine (Remeron) is a tetracyclic piperazinoazepine compound (Fig. 33.6c–1) that the FDA approved in 1995 for the treatment of depression. Unlike most newer antidepressants, mirtazapine has virtually no effect on monoamine uptake. Rather, therapeutic effects are thought to be mediated by inhibition of α_2-adrenergic receptors and blockade of postsynaptic serotonin type 2 (5-HT_2) and type 3 (5-HT_3) receptors. The former action diminishes the inhibitory effects of both α_2-autoreceptors (located on presynaptic norepinephrine [NE] neurons) and α_2-heteroreceptors (located on cell bodies of dorsal raphe 5-HT neurons). Inhibition of inhibitory cellular mechanisms thus increases the firing rates of noradrenergic and 5-HT neurons. This effect differs markedly from that of most other antidepressants, which tend to suppress cell firing rates until autoreceptors are downregulated.

Blockade of 5-HT_2 and 5-HT_3 receptors may enhance therapeutic effects directly (e.g., relief of insomnia or enhancement of appetite) or indirectly by dampening side effects attributable to disinhibited 5-HT release (e.g., agitation or nausea). Antagonism of 5-HT_2 receptors also may enhance the availability of neurotransmitters to interact with serotonin type 1 (5-HT_1) receptors. Mirtazapine is the only newer antidepressant that is a potent antagonist of histamine-1 receptors, which adds to sedative and appetite-enhancing properties. The sleep effects of mirtazapine in major depression have been studied. Mirtazapine therapy has been shown to lessen nocturnal awakenings and prolong total sleep time. Mirtazapine administration increased total slow wave sleep (SWS), REM latency, the duration of the first REM episode, and stage 3 sleep. It decreased the number of REM episodes. Simultaneously, it reduced wake time after sleep onset.

First synthesized in the early 1980s, mirtazapine is related to one older antidepressant, mianserin (Tolvon). Mianserin is available throughout most of the world (although not in the United States or Canada). Mianserin is a more potent antagonist of α_1-receptors than the newer compound, which is thought to explain why mianserin has less effect on 5-HT neurotransmission than mirtazapine.

PHARMACOLOGY

Mirtazapine has a half-life of approximately 30 hours and reaches steady state after 6 days of therapy. Linear pharmacokinetics is observed across the therapeutic dose range (i.e., 15 to 60 mg/day). Mirtazapine is essentially completely absorbed after oral dosing, and food has little effect on the rate or extent of absorption. Approximately 85% of circulating drug is bound to plasma protein.

Mirtazapine is metabolized in the liver via cytochrome P450 (CYP) 2D6, CYP 1A2, and CYP 3A4 pathways. The primary metabolite, *N*-

desmethylmirtazapine, is substantially less active than the parent compound and has trivial pharmacologic effects. Cimetidine, which inhibits CYP 2D6, CYP 1A2, and CYP 3A4, raises plasma levels of mirtazapine by more than 50%. Even greater increases in mirtazapine concentrations result from concomitant administration of the potent CYP 1A2 inhibitor fluvoxamine (Luvox).

The original formulation of mirtazapine is available in 15-, 30-, and 45-mg tablets. An alternative formulation, an orally disintegrating tablet (ODT), was introduced in 2001 to facilitate compliance and to aid therapy for patients who have difficulty swallowing.

INDICATIONS

Antidepressant Efficacy

The minimum effective dose of mirtazapine in placebo-controlled clinical trials of major depressive disorder (MDD) is 15 mg/day. The maximum approved dose ranges from 45 mg/day (United States) to 60 mg/day (some European countries). There is some evidence of an ascending dose–response relationship for antidepressant efficacy, although this has not been definitively established.

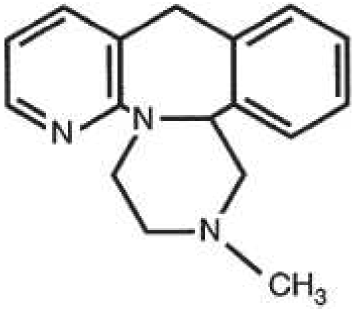

FIGURE 33.6c–1. Chemical structure of mirtazapine (Remeron).

The relative efficacy of mirtazapine has been established against older and newer antidepressants. Mirtazapine was found to be significantly more effective than trazodone (Desyrel) and as effective as the TCAs: amitriptyline (Elavil), doxepin (Sinequan), clomipramine (Anafranil), and nortriptyline (Aventyl). Therapy with the TCA, imipramine (Tofranil), was significantly more effective than mirtazapine treatment in one inpatient study. However, in this trial, dosages of both drugs were titrated in relation to plasma levels, which is a valid strategy for the TCA but of uncertain value for mirtazapine.

There are a number of published studies comparing mirtazapine and SSRIs, including citalopram (Celexa), paroxetine (Paxil), sertraline (Zoloft), fluvoxamine, and fluoxetine (Prozac). Several meta-analyses have been completed and have confirmed that, on average, the two types of antidepressants are comparably effective (less than 5% difference in response or remission rates) after 6 to 8 weeks of therapy, although patients treated with mirtazapine received an earlier therapeutic benefit. It is not clear if this temporal difference is primarily due to a relatively nonspecific advantage in improving sleep and appetite or if it is attributable to the difference in mechanism of action.

Two studies have contrasted mirtazapine with the serotonin-norepinephrine reuptake inhibitor (SNRI) venlafaxine (Effexor). In the first study, mirtazapine (mean dose: 50 mg/day) and the immediate-release formulation of venlafaxine (mean dose: 255 mg/day) were compared in 157 depressed inpatients with melancholic features. Trends favored the mirtazapine-treated group on most outcome measures, but only the difference on the Hamilton Rating Scale for Depression (HAMD) sleep disturbance factor reached statistical significance at the study endpoint. Significantly fewer patients did, however, withdraw from the mirtazapine group during the first 6 weeks of therapy because of side effects. The second study, which was conducted on 242 depressed outpatients, contrasted the ODT formulation of mirtazapine (45 mg/day) with the extended-release formulation of venlafaxine (225 mg/day). Although the efficacy of the study drugs again did not differ at the end of the trial, results consistently favored mirtazapine therapy during the first 2 weeks of double-blind therapy, with significant differences in overall symptom improvement, response rates, and changes in sleep.

Combining SSRIs/SNRIs and Mirtazapine

Almost from the time of introduction, it was speculated that mirtazapine could be combined with SSRIs to obtain synergistic or additive effects. Subsequently, a number of studies have examined the clinical utility—both effectiveness and tolerability—of combining mirtazapine with other antidepressants, including SNRIs and bupropion as well as SSRIs.

The first RCT to evaluate mirtazapine in combination with other antidepressants (predominantly SSRIs) studied patients with a documented history of nonresponse to antidepressant therapy in the current depressive episode. In this pilot study, 26 outpatients were randomly assigned to 4 weeks of additional double-blind therapy with either active mirtazapine (15 to 30 mg/day) or a matching placebo, in addition to ongoing therapy with the first antidepressant. The investigators found that the patient group receiving adjunctive therapy with active mirtazapine had significantly greater improvement in depressive symptoms than the group receiving adjunctive placebo. Although the difference in remission rates was not statistically significant in this small study, the magnitude of the difference (45% vs. 13%)—if replicable in a larger study—would be clinically meaningful.

Another study tested the hypothesis that starting patients on the combination of mirtazapine and an SSRI would deliver a more rapid and/or larger response than monotherapy. This outpatient RCT randomly assigned 61 participants with MDD to 6 weeks of double-blind therapy with one of three options: (1) mirtazapine (30 to 60 mg/day) plus placebo; (2) paroxetine (20 to 40 mg/day) plus placebo; or (3) mirtazapine plus paroxetine. The group receiving combined therapy of mirtazapine obtained a significantly larger reduction in depressive symptoms than the groups that received mirtazapine and paroxetine monotherapy groups. The remission rate for the combined therapy group at week 6 was 43%, as compared to 19% and 26% for the mirtazapine and paroxetine monotherapy groups, respectively. Although again not statistically significant, such a difference in remission rates would be considered clinically significant if confirmed in a larger study.

A second study on the value of combining antidepressants from the outset of therapy randomly assigned 105 MDD outpatients to receive 6 weeks of therapy with one of four strategies. One group received fluoxetine (20 mg/day) plus a placebo; this group served as the active comparator. A second group received fluoxetine (20 mg/day) in combination with mirtazapine (30 mg daily); this group directly tested the value of combining mirtazapine with the SSRI. Two other groups received mirtazapine (30 mg/day) in combination with either venlafaxine (225 mg/day) or bupropion (150 mg/day); these groups permitting a preliminary comparison of the utility of combining mirtazapine with other first-line antidepressants. This study again tested the hypothesis that patients receiving combination antidepressant therapy would show a more rapid or more complete remission than monotherapy from the outset of therapy. At the end of 6 weeks of double-blind therapy, the fluoxetine plus placebo group had a remission rate of 25%. Across all outcome measures, trends favored the groups that received mirtazapine in combination with fluoxetine (52% remission rate), venlafaxine XR (58% remission rate), or bupropion (46% remission rate).

The combination of mirtazapine and venlafaxine was evaluated in two other studies. The first study was part of the STAR*D project. In this open-label trial, 109 MDD outpatients who had not obtained adequate benefit from three rounds of antidepressant therapy were randomized to receive 12 weeks of therapy with mirtazapine (mean dose: 36 mg/day) and venlafaxine XR (mean dose: 210 mg/day) or the monoamine oxidase inhibitor tranylcypromine (mean dosage: 37 mg/day). Outcomes were assessed by self-report and by blinded independent evaluators. At the study endpoint, neither group did particularly well, though the remission rate in the mirtazapine plus venlafaxine XR group was twice that of the group that received the MAOI (14% vs. 7%). Patients receiving combination therapy were more likely to complete the trial and did show a statistically significant difference in improvement in depressive symptoms. A relatively few patients completed 12 weeks of treatment with tranylcypromine at a therapeutic dose (i.e., at least 40 mg/day); one implication is that physicians in contemporary practice are better able to implement a trial of combined therapy than execute a successful switch to an MAOI.

A subgroup of the STAR*D investigators completed a second, larger study of the value of combining antidepressants at the beginning of treatment. This trial, known by the acronym COMED, randomized 220 MDD outpatients to 12 weeks of treatment with escitalopram plus placebo (i.e., the active comparison group), mirtazapine (mean dose: 18 mg/day) plus venlafaxine XR (mean dose: 178 mg/day), or escitalopram plus bupropion (i.e., an alternative widely used combination that had performed reasonably well in STAR*D). This trial found no evidence to support the routine use of antidepressant combinations from the outset of therapy, which reported significantly greater side effects.

Prophylactic Therapy

Two studies have evaluated longer-term treatment with mirtazapine. The first report examined the outcomes of patients who received extended therapy after responding to double-blind, acute-phase therapy with mirtazapine, amitriptyline, or placebo. Results indicated that patients who remained on mirtazapine had a significantly lower risk of relapse than patients who continued to take a double-blind placebo. The amitriptyline-treated group had an intermediate outcome.

The second study was a formal relapse prevention trial in which 156 patients who had remitted during 8 to 12 weeks of acute-phase therapy were randomized to remain on active mirtazapine ($N = 76$) or to switch to placebo ($N = 80$). Across the subsequent 40 weeks of double-blind therapy, 44% of the placebo group relapsed, compared to 20% of the group receiving active continuation-phase therapy. The effects of continuation-phase mirtazapine therapy were of the same magnitude observed in studies of other effective antidepressants.

OTHER INDICATIONS FOR MIRTAZAPINE

Mirtazapine is not formally indicated for the treatment of any other disorder. Nevertheless, mirtazapine may be useful for the treatment of insomnia, panic disorder, generalized anxiety disorder, PTSD, and OCD, as well as autism and other pervasive developmental disorders. A number of small studies and case series have evaluated the utility of mirtazapine in treating anxiety and depression in cancer patients. Blockade of 5-HT_3 and histamine receptors may have particularly useful effects in the symptomatic management of anxiety and depression in cancer patients. Improvements in pain, nausea, appetite, insomnia, depression, and anxiety have been reported.

A study of 12 adult outpatient subjects with comorbid MDD/alcohol dependence was recently conducted. Subjects were given 15 mg of mirtazapine for the first 2 weeks and 30 mg for the last 6 weeks of the medication trial. Mirtazapine improved depression on the Beck Depression Inventory (BDI) and decreased the number of alcoholic drinks per week. These preliminary findings suggest that mirtazapine may be efficacious in reducing both depressive symptoms and excessive alcohol use in comorbid MDD and alcohol dependence. Two years later, 10 of the 12 patients who entered the acute-phase study participated in the follow-up study. The significant improvements initially observed in depressive symptoms (BDI), drinking, and sleep disturbance persisted at the follow-up evaluation. A study of depressed cocaine-dependent subjects who received either mirtazapine (11 subjects) or placebo (13 subjects) for 12 weeks suggested that mirtazapine is superior to placebo in improving sleep in patients with comorbid depression and cocaine dependence but is not more effective than placebo in reducing cocaine use.

In another study, 16 agitated patients with Alzheimer disease (AD) were enrolled in a 12-week open-label pilot study. Patients were given 15 to 30 mg/day of mirtazapine. The study found that agitated patients with AD could be treated with mirtazapine without significant adverse events or cognitive deterioration. Larger-scale studies are now warranted.

MIRTAZAPINE USE DURING PREGNANCY AND LACTATION

In a series of case reports, mirtazapine seems to be an effective treatment for mothers with hyperemesis gravidarum that failed to respond to conventional antiemetic treatment.

It is not known whether mirtazapine may cause harm to the unborn baby. Three reports (*n* = 266) referred to increased risk for preterm birth or shorter duration of pregnancy after exposure to mirtazapine. In an unadjusted analysis, mirtazapine was associated with spontaneous abortion (RR 2.23, 95% CI 1.34–3.70). The authors suggested this may be a reflection of disease severity. No correlation between mirtazapine exposure and spontaneous or therapeutic abortion, intrauterine death or infant death has been found when investigating the sole effects of mirtazapine exposure. Six papers reported no neurobehavioral developmental adverse effects in 22 infants exposed to mirtazapine when assessed from 1.5 months to 12 months, except for one case report that described an insignificant trend toward lower scores on both fine and gross motor function (p = .07 and .09).

Data on the neonatal risk of mirtazapine during lactation are scarce. In a study of eight women who were taking a median dose of 38 mg of mirtazapine per day while breastfeeding, concentrations of mirtazapine or desmethylmirtazapine were measured in milk and plasma. All infants were clinically examined, and four infants had blood drawn for analysis. No adverse effects were seen. Mirtazapine was detected in only one of four infants tested. The study suggested that mirtazapine use by lactating women is safe for breastfed infants. Four papers reported on 11 cases of mothers exposed to mirtazapine during lactation. The relative infant dose ranged from undetectably low to 2.9%. No adverse events were detected in three of the reports. One case report referred to possible prolonged sleep and weight gain when compared to older siblings. Given the poverty of evidence, the long-term safety and effects of mirtazapine in lactation require further assessment. Nevertheless, each decision to breastfeed should always be made on the basis of individual risk–benefit analysis.

TOLERABILITY, SAFETY, AND TOXICITY

Attrition from mirtazapine therapy because of adverse events generally was less than that observed in comparison groups treated with tricyclic antidepressants but somewhat greater than that observed in comparative studies versus SSRIs. Mirtazapine and venlafaxine have comparable attrition rates in controlled studies. The specific side-effect profile of mirtazapine is quite different, however, from that associated with SSRIs and SNRIs.

The most common side effects reported during mirtazapine therapy are sedation, increased appetite, weight gain, and dry mouth. The drug’s antihistaminic effects primarily cause these side effects. Approximately 50% of patients report sedation during the first week of mirtazapine therapy. This side effect can be clinically significant, as demonstrated in studies of reaction time or automotive driving performance. Sedation usually is not minimized by slow upward titration of the dose, and lower and higher starting doses of mirtazapine have similar rates of sedation. If early sedation can be tolerated, however, most patients adapt to this side effect without difficulty. When compared to SSRIs or SNRIs, mirtazapine therapy is associated with significantly lower rates of gastrointestinal disturbance and a lower incidence of treatment-emergent sexual dysfunction.

Mirtazapine-provoked periodic leg movements (PLMS) in 67% of young, healthy males. The effect was most pronounced in the first few days but gradually decreased in the first week. The indirect increase in central dopamine via 5-HT$_{1A}$ receptor activation may explain why mirtazapine-induced PLMS decreased over time. Further, diphenhydramine, another first-generation H$_1$ antagonist, provoked PLMS during wake time in subjects with restless legs syndrome, pointing to a possible antihistaminergic mechanism in the induction of PLMS.

Mirtazapine may cause withdrawal syndrome upon sudden discontinuation. Symptoms include depression, anxiety, restlessness, irritability, decreased appetite, insomnia, diarrhea, nausea, and vomiting. Therefore, reduction in dose should be gradual and slow.

Mirtazapine is not approved for use in children under the age of 18 years.

Perhaps 15% to 25% of patients gain an unacceptable amount of weight during mirtazapine therapy. This annoying adverse effect may occur more commonly among younger patients, and, interestingly, weight gain was not a problem in one study of depression in late life. The likelihood of problematic weight gain can usually be predicted within the first 4 to 6 weeks of therapy. A small study of seven women with MDD treated with mirtazapine for 6 weeks concluded that mirtazapine was associated with a significant increase in body weight, body mass fat and leptin concentration. Interestingly, glucose metabolism remained unaffected in this study, in contrast to other psychotropic medications inducing weight gain.

The effects of mirtazapine and venlafaxine on leptin plasma levels were recently contrasted. After 28 days of treatment, mirtazapine treatment was strongly associated with an increase in leptin concentrations. There was also a significant effect on the leptin/body mass index (BMI) ratio elevated in mirtazapine-treated patients and slightly declining in venlafaxine-treated patients. Blockade of histamine synthesis may contribute to leptin resistance, as well as via possible histamine H_1-receptor–mediated dysregulation of hypothalamic nuclei integrating central and peripheral signals relevant to energy balance.

The only significant effect of mirtazapine therapy on clinical chemistry profiles has been increased blood lipid levels. As this effect occurred with approximately twice the frequency seen in patients randomly assigned to treatment with amitriptyline, weight gain alone does not appear to be the cause.

The most controversial severe adverse effect possibly associated with mirtazapine therapy is agranulocytosis. Although concern has existed about this as a potential problem in the early (premarketing) studies, a definite association has not been established over the subsequent two decades.

Mirtazapine is remarkably safe in overdose. The principal problems following ingestion of as much as 5 g of mirtazapine are sedation, aspiration pneumonia, delirium, and tachycardia. No cases of seizure or abnormal heart rhythms have been reported. In the only reported fatal overdose, the patient also had ingested toxic levels of several other drugs.

FUTURE DIRECTIONS

Mirtazapine is distinctly different from the remainder of the newer antidepressants. It is at least as effective as the SSRIs and most likely conveys earlier symptomatic benefits. It also differs dramatically from the SSRIs and venlafaxine with respect to tolerability. Virtually free from causing side effects commonly associated with 5-HT uptake inhibitors (e.g., gastrointestinal disturbances, insomnia, and sexual dysfunction), mirtazapine therapy is complicated by sedation (in as many as half of all patients) and weight gain (in as many as a fourth of all patients). Mirtazapine is increasingly used for the treatment of older depressed people, for whom these effects are more likely to be therapeutic than problematic. Moreover, mirtazapine's antiemetic benefits may offer relief for mothers with treatment-resistant hyperemesis gravidarum.

One study demonstrated that the interaction between HTR1A+272G>A and 5-HTT VNTR genotypes may be involved in responding to mirtazapine treatment in MDD patients. The response was greater for the combination than for individual genotypes. This observation should be replicated and further expanded in larger-scale studies.

33.7 Serotonin Antagonists/Inverse Agonists

33.7a Pimavanserin

JOAN M. STRIEBEL, M.D., JENNIFER A. O'DAY, M.D., NEKISA HAGHIGHAT, M.D., M.P.H., AND STEPHEN M. STAHL, M.D., PH.D., D.SC. (HON.)

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic domain	Serotonin
Mechanism of action	Receptor antagonist (5-HT_{2A})

Pimavanserin is a drug with antipsychotic actions that is a selective inverse agonist and antagonist (a partial inverse agonist) at 5-HT_{2A} and 5-HT_{2C} receptors. It is unique among drugs with antipsychotic actions in that it has negligible binding at dopamine receptors with no effect on motor function.

HISTORY

Parkinson's disease (PD) is a complex multisystem neurodegenerative disease. Patients suffer from motor symptoms—primarily bradykinesia, rigidity, and/or tremor—related to the loss of dopamine neurons in the substantia nigra pars compacta. Degeneration and/or aberrant activity of dopaminergic, cholinergic, noradrenergic, and serotonergic neurons result in non-motor symptoms. Parkinson's disease psychosis (PDP) is a non-motor symptom characterized by at least one of the following: illusions, false sense of presence, hallucinations, or delusions, which is present for at least 1 month in a PD patient after ruling out other etiologies. PDP is seen in up to 60% of PD patients and is associated with dementia, more hospitalizations, increased caregiver burden, nursing home placement, and death. With the exception of low-dose clozapine or low-dose quetiapine, treatment of PDP with other drugs that have antipsychotic actions frequently results in intolerable motor impairment due to dopamine D_2 receptor antagonism in the dorsal striatum. Clozapine's ability to treat PDP at mean doses of 25 to 36 mg daily and minute plasma levels of 4 to 6 ng/mL led to the recognition that its 5-HT_{2A} inverse agonism was the basis for its antipsychotic efficacy. Low doses of quetiapine also have anecdotal evidence of efficacy in PDP. Due to the need for mandatory hematologic monitoring, alternatives to clozapine were sought. In the late 1990s, Acadia Pharmaceuticals screened for potent, selective, and effective 5-HT_{2A} receptor inverse agonists and identified ACP-103 (pimavanserin). Subsequent safety and efficacy studies led to the FDA's approval of pimavanserin for the treatment of PDP in 2016.

Psychosis consisting of hallucinations and delusions is also a feature of other neurodegenerative disorders, including Alzheimer's disease, vascular dementia, frontotemporal dementia, and dementia with Lewy bodies. Although drugs with antipsychotic actions are prescribed off-label to treat dementia-related psychosis (DRP), efficacy is limited. Further, most drugs with antipsychotic actions demonstrate a negative effect on cognitive function and are associated with a higher risk of mortality compared with placebo. In contrast, early pimavanserin DRP studies did not demonstrate an adverse safety signal with regard to mortality risk, and pimavanserin appears not to impact cognition. These findings, along with the drug's receptor binding profile, built hopes that pimavanserin will also treat DRP.

CHEMISTRY

Pimavanserin is a member of the class of ureas in which three of four hydrogens are replaced by 4-fluorobenzyl, 1-methylpiperidin-4-yl, and 4-(isopropyloxy)benzyl groups. Pimavanserin tartrate's chemical name is urea, *N*-[(4-fluorophenyl)methyl]-*N*-(1-methyl-4-piperidinyl)-*N′*-[[4-(2-methylpropoxy)phenyl]methyl]-,(2*R*,3*R*)-2,3-dihydroxybutanedioate (2:1). It is an aromatic ether and tertiary amino compound. The molecular formula of pimavanserin tartrate is $(C_{25}H_{34}FN_3O_2)_2 \cdot C_4H_6O_6$, and its molecular weight is 1005.20. Its chemical structure is depicted in Figure 33.7a–1. Pimavanserin tartrate is water soluble.

PHARMACOLOGIC ACTION

Absorption

Pimavanserin is only available as an oral preparation. The median time to peak plasma concentration for pimavanserin and its major active *N*-desmethylated metabolite (AC-279) is 6 hours (range of 4 to 24 hours). AC-279 does not contribute to the drug's clinical effects as it does not cross the blood–brain barrier to any appreciable extent. High-fat meals do not significantly affect the rate or extent of drug exposure. The mean elimination half-life for pimavanserin and AC-279 is 57 hours and 200 hours, respectively.

Distribution

Pimavanserin is highly protein bound (~95%) in human plasma. Protein binding is dose-independent.

Metabolism and Elimination

Pimavanserin is predominantly metabolized by CYP3A4 and CYP3A5 and to a lesser extent by CYP2J2, CYP2D6, and various other CYP and flavin-containing monooxygenase enzymes. CYP3A4 is primarily responsible for the formation of AC-279. Pimavanserin and AC-279 do not cause clinically significant CYP inhibition or induction. In terms of excretion, less than 1% of the administered dose of pimavanserin or AC-279 was recovered in urine.

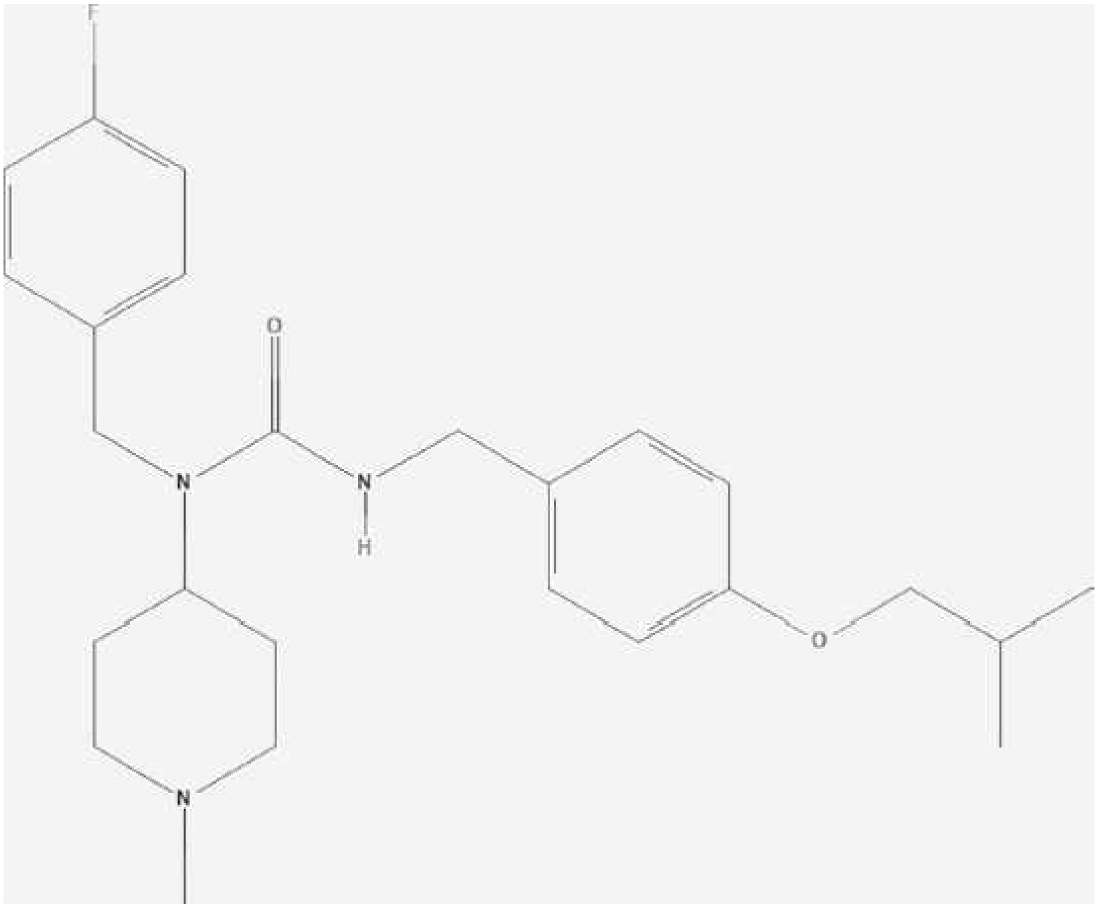

FIGURE 33.7a–1. Molecular structure of pimavanserin. (From National Center for Biotechnology Information. PubChem Compound Database; CID = 10071196, https://pubchem.ncbi.nlm.nih.gov/compound/Pimavanserin. Accessed September 15, 2021.)

Table 33.7a–1.
Binding Affinities of Pimavanserin

Receptor	Binding Affinity (K_i nM)	Binding Profile
5-HT_{2A}	0.087	Inverse agonist
5-HT_{2C}	0.44	Inverse agonist
D_2	>300	
H_1	>300	
M_1	>300	
α_1	>300	

Pharmacodynamics

Mechanism of Action. Pimavanserin is a potent, selective inverse agonist at serotonin 5-HT_{2A} receptors with lesser affinity at serotonin 5-HT_{2C} receptors. Pimavanserin has no appreciable affinity at serotonin 5-HT_{2B}, dopaminergic (including D_2), muscarinic, histaminergic, or adrenergic receptors, or calcium channels. See Table 33.7a–1 for specific binding affinities.

Pimavanserin exerts its antipsychotic effects through at least two pathways. In PDP, the loss of serotonergic neurons in the midbrain results in upregulation and increased sensitivity of postsynaptic 5-HT_{2A} receptors in the ventral visual pathway—an occipitotemporal network with projections to the ventrolateral prefrontal cortex and the orbitofrontal cortex. The stimulation of these receptors induces visual hallucinations, analogous to the visual phenomena occurring after ingestion of 5-HT_{2A} agonists such as lysergic acid diethylamide. As an inverse agonist, pimavanserin blocks the actions of serotonin and decreases the constitutive activity of the 5-HT_{2A} and 5-HT_{2C} receptors in the ventral visual pathway, reducing psychosis in patients with PDP.

The second pathway involves postsynaptic 5-HT_{2A} receptors located on a specific population of glutamatergic pyramidal neurons projecting from the prefrontal cortex. Excessive activity of these receptors leads to the downstream release of dopamine in the dopamine tract extending from the midbrain to the associative areas of the dorsal striatum and results in the positive symptoms of psychosis. Pimavanserin diminishes the excitatory tone of serotonin at these 5-HT_{2A} receptors resulting in an antipsychotic effect differing from that due to D_2 antagonism. Meltzer and colleagues (2012) provide support for this mechanism. In a population of acutely psychotic schizophrenia patients, pimavanserin added to risperidone 2 mg daily demonstrated comparable efficacy to risperidone 6 mg daily. When added to haloperidol 2 mg daily, the antipsychotic effect of pimavanserin's 5-HT_{2A} antagonism was not seen in the context of haloperidol's greater D_2 antagonism.

Table 33.7a–2.

Published Trials With Pimavanserin for Parkinson’s Disease Psychosis

Reference	Comments
Meltzer et al., 2010	**Sample:** Phase II double-blind, randomized, multicenter 28-day study of pimavanserin 20 mg daily titrating to 40–60 mg daily after 2 weeks vs. placebo in 60 patients with PDP as defined by Ravina et al. (2007). **Primary Endpoint:** Safety and tolerability as measured by the UPDRS Parts II and III. Primary efficacy measure was the SAPS total score and a UPDRS Part I psychosis score. **Results:** Pimavanserin did not separate from placebo with regard to motor function, sedation, hypotension, or other side effects. In terms of efficacy, there was a trend toward greater improvement with pimavanserin; statistical significance was not reached.
Cummings et al., 2014	**Sample:** Phase III double-blind, randomized, multicenter 6-week study of pimavanserin 40 mg daily vs. placebo, initiated after a 2-week lead-in period in 199 patients with PDP. **Primary Endpoint:** Change in total SAPS-PD score from baseline to week 6. **Results:** Pimavanserin-treated patients exhibited a significant improvement in the SAPS-PD compared to placebo (–5.79 [37% improvement] vs. –2.73 [14% improvement], respectively, effect size of 0.50, *p* = .0006. Treatment with pimavanserin resulted in significant decreases in other measures of

	psychosis, including the SAPS hallucinations and delusions score.

SAPS: Scale for the Assessment of Positive Symptoms; SAPS-PD: Scale for the Assessment of Positive Symptoms for Parkinson’s Disease Psychosis; UPDRS: Unified Parkinson’s Disease Rating Scale.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Parkinson’s Disease Psychosis

Given that there were no FDA-approved medications for the treatment of PDP, pimavanserin’s manufacturer received a Breakthrough Therapy designation in 2014, which lessened the standards required for review. Table 33.7a–2 summarizes the published placebo-controlled trials. The pivotal phase III trial was preceded by three trials that established pimavanserin’s safety and lack of effect on motor function. These early trials, including one published phase II trial, failed to reach statistical significance at the primary efficacy endpoint. When designing the phase III trial, investigators identified factors that were positively associated with effect size in failed studies, including study locations in North America, the use of centralized raters to reduce inter-rater variability, a 2-week lead-in period to minimize the placebo response, uniform pimavanserin dose of 40 mg daily, and use of a novel scale – the nine-item Scale for the Assessment of Positive Symptoms for Parkinson’s Disease Psychosis (SAPS-PD)—which measured the symptoms most relevant to PDP. The SAPS-PD was developed through posthoc analysis of questions on the Scale for the Assessment of Positive Symptoms (SAPS) that showed the most favorable change in the failed phase II trials. The original protocol for the phase III study listed the SAPS as the primary endpoint, and 16 months after data collection, the protocol was modified to include the SAPS-PD.

In the phase III trial, a 50% reduction in the SAPS-PD corresponded to a clinical presentation of much improved, was clinically meaningful, and was defined as a response. At the end of week 6, 37.2% of pimavanserin-treated patients and 27.8% of placebo-treated patients were responders. The number needed to treat (NNT) was 11; therefore, 11 patients must be treated with pimavanserin for one patient to demonstrate a 50% reduction in the SAPS-PD. Defining “harm” as any serious adverse event, including death, the number needed to harm (NNH) was 22. Since the NNH/NNT ratio was two, for every two patients with a 50% reduction in the SAPS-PD, one patient will experience a pimavanserin-related serious adverse event.

Two phase IV open-label extension studies evaluated the efficacy, safety, and tolerability of pimavanserin in 459 patients over varying lengths of treatment. In terms of safety, most adverse events were mild to moderate, and pimavanserin did not adversely affect motor function. Mortality was 6.45 deaths per 100 patient-years, which is in line with that expected for an older adult, medically fragile cohort. In terms of efficacy, response to pimavanserin was durable and was maintained for an additional 4 weeks of treatment.

Dementia-Related Psychosis

Given that pimavanserin resulted in a greater improvement in the SAPS-PD score in patients with cognitive impairment, including patients who were concomitantly treated with cognitive-enhancing medications, it was speculated that pimavanserin might treat psychosis occurring in other dementing illnesses. Pimavanserin was granted the FDA’s Breakthrough Therapy designation for the treatment of DRP in 2017. Table 33.7a–3 summarizes the published placebo-controlled trials. Based on the positive phase II study and data from the phase III HARMONY trial, the manufacturer submitted a supplemental new drug application for pimavanserin to treat hallucinations and delusions in patients with DRP. As of this writing, approval has not yet been granted.

Other Potential Indications Under Investigation

Pimavanserin had been under investigation as an adjunctive treatment for major depressive disorder. Although it demonstrated robust efficacy in a phase II trial (CLARITY), in two identical double-blind, placebo-controlled phase III trials, pimavanserin failed to achieve statistical significance on the Hamilton Depression Rating Scale, which was the primary endpoint. Case series examining the efficacy of adjunctive pimavanserin in treatment-resistant schizophrenia have yielded conflicting reports. Pimavanserin is currently under investigation as an adjunctive treatment for negative symptoms in schizophrenia and for insomnia in veterans with PTSD.

Table 33.7a–3. Published Trials With Pimavanserin for Dementia-Related Psychosis

Ballard et al., 2018	**Sample:** Phase II double-blind, randomized, 12-week study of 181 nursing home residents with possible or probable Alzheimer’s disease and psychotic symptoms who were treated with pimavanserin 34 mg daily or placebo. **Primary Endpoint:** Mean change from baseline to week 6 on NPI-NH psychosis score. **Results:** At week 6, pimavanserin-treated patients exhibited a significant improvement in the NPI-NH psychosis score compared to placebo (–3.76 [SE 0.65] vs. –1.93 [SE 0.63]) respectively, Cohen’s *d* effect size –0.32; *p* = 0.045. By week 12, no significant difference was observed between pimavanserin and placebo.
Tariot et al., 2021	**Sample:** Phase III double-blind, multicenter, randomized, discontinuation study involving 392 patients with psychosis related to Alzheimer’s disease (66.3%), Parkinson’s disease dementia (15.1%), vascular dementia (9.7%), dementia with Lewy bodies (7.1%), or frontotemporal dementia (1.8%). During the 12-week open-label lead-in phase, all patients were treated with pimavanserin 34 mg daily. Those who improved (61.8%) were randomized to pimavanserin or placebo for the double-blind treatment period of up to 26 weeks. **Primary Outcome:** Time from randomization to relapse of psychosis with a *p*-value below 0.0033. Relapse was

defined as hospitalization due to DRP, significant deterioration as measured by clinical scales, withdrawal from the study due to lack of efficacy, or the initiation of an off-label antipsychotic medication.

Results: The trial was stopped once it met the primary efficacy endpoint. A relapse occurred in 13% of the pimavanserin group and in 28% of the placebo group. There was no significant difference in mean MMSE scores between pimavanserin-treated patients and those receiving placebo.

MMSE, Mini-Mental State Examination; NPI-NH,: Neuropsychiatric Inventory-Nursing Home Version.

Therapeutic Indications

Pimavanserin is an FDA-approved treatment for patients with hallucinations and delusions associated with PDP. While studies treating patients with DRP have been positive, to date, the FDA has not approved pimavanserin for this indication.

Precautions and Adverse Reactions

Pimavanserin is contraindicated in individuals with hypersensitivity to pimavanserin or any components of the tablet or capsule.

Black Box Warning. Pimavanserin carries a black box warning regarding an increased all-cause risk of death in older adult patients with DRP. An FDA review of all postmarketing reports of deaths in patients with PDP treated with pimavanserin failed to identify new or unexpected safety findings and considered that patients with PDP have a higher mortality rate due to older age, advanced PD and other medical conditions.

QT Interval Prolongation. The effect of pimavanserin on the QT interval has been examined in patients with PDP, DRP, and healthy volunteers. The phase III PDP trial excluded subjects with QTc (Bazett correction formula) >460 msec for men or >470 msec for women, history of long QT, medical conditions that could prolong the QT interval, and medications known to prolong the QT interval. ECG data showed that pimavanserin 40 mg daily resulted in a mean QTc increase of 7.3 msec from baseline compared with no change for placebo. This increase was not associated with adverse cardiac events. In long-term safety studies, the mean maximum QTc (Fredericia correction formula) was <450 msec over the duration of the study, although individual QTc (Fredericia) values of >500 msec occurred in 2.6% of patients. In the phase III DRP trial, the mean QTc (Fridericia) increase was 5.4±0.9 msec. Five adverse events involving asymptomatic prolongation of the QT interval affected 1.3% of the study population over the trial's duration. The effect of pimavanserin at twice the maximal approved daily dose was evaluated in a randomized placebo- and positive-controlled double-blind, multiple-dose parallel QTc study in 252 healthy subjects. The maximum mean change from baseline (upper bound of the two-sided 90% CI) was 13.5 (16.6) msec.

Pimavanserin should be avoided in patients with known QT prolongation or those currently taking other medications known to prolong the QT interval. These medications include Class 1A antiarrhythmics (e.g., quinidine, procainamide), Class 3 antiarrhythmics (e.g., amiodarone, sotalol), certain antipsychotics (e.g., ziprasidone, chlorpromazine, thioridazine), and certain antibiotics (e.g., gatifloxacin, moxifloxacin). Pimavanserin should be avoided in patients with cardiac arrhythmias as well as in other circumstances that increase the risk of torsade de pointes, including symptomatic bradycardia, hypokalemia, hypomagnesemia, and the presence of congenital long QT syndrome.

Common and Drug-Related Adverse Reactions in Clinical Trials. In premarketing PDP studies, the most common adverse reactions associated with pimavanserin (defined as incidence ≥2% and greater than placebo) were nausea (7% pimavanserin vs. 4% placebo), constipation (4% pimavanserin vs. 3% placebo), peripheral edema (7% pimavanserin vs. 2% placebo), gait disturbance or fall (2% pimavanserin vs. <1% placebo), hallucinations (5% pimavanserin vs. 3% placebo), and confusional state (6% pimavanserin vs. 3% placebo). In the phase III PDP trial, 11% of pimavanserin-treated patients had a serious adverse event compared with 4% of subjects in the placebo group. Of the ten pimavanserin-treated patients who discontinued, six did so due to psychosis and of these, four discontinued within the first 10 days of the trial. The most common adverse events in the PDP open-label extension studies were falls, urinary tract infections, hallucinations, decreased weight, and confusional states. Postmarketing comparative pharmacovigilance assessment of pimavanserin versus treatment alternatives in a cohort of PD patients revealed no unforeseen adverse safety signal. When compared with other treatments, no excess mortality related to pimavanserin was identified.

In the phase II DRP study, adverse events occurred in 17% of pimavanserin-treated patients and 11% of placebo-treated patients. Specifically, agitation (19 [21%] vs. 13 [14%]), aggression (nine [10%] vs. four [4%]), and peripheral edema (seven [8%] vs. two [2%]) were more common with pimavanserin compared to placebo. There was no difference in the frequency of discontinuation due to adverse events or in the number of deaths. The most common side effects in the phase III DRP study that occurred more frequently with pimavanserin than with placebo were headache, constipation, and urinary tract infection.

Pregnancy. There is insufficient information on pimavanserin to determine if it is associated with a risk for birth defects or miscarriage. Animal data demonstrated that pimavanserin was not teratogenic. When pimavanserin was administered to pregnant or lactating rats at doses of 0.14 to 14-times the recommended dose, there was evidence of maternal toxicity as well as a decrease in pup survival, litter size, pup weight, and food consumption.

Nursing Mothers. There is insufficient information about the presence of pimavanserin in human milk, the effects on the breastfed infant, or the effects on milk production.

Drug Interactions

Concomitant use of pimavanserin with moderate CYP3A4 inducers (e.g., modafinil, nafcillin, efavirenz) or strong CYP3A4 inducers (e.g., rifampin, phenytoin, carbamazepine) is not recommended as treatment with a moderate or strong CYP3A4 inducer reduces pimavanserin exposure. Concomitant treatment with a strong CYP3A4 inhibitor (e.g., ketoconazole, clarithromycin, ritonavir) will increase pimavanserin exposure. If pimavanserin is used with a strong CYP3A4 inhibitor, the recommended dose is 10 mg once daily.

No dose adjustment of carbidopa/levodopa is required when administered with pimavanserin. Doses of P-glycoprotein substrates (e.g., digoxin, amiodarone) and other CYP3A4 substrates (e.g., clonazepam, warfarin) do not require adjustment when used with pimavanserin.

Dosage and Administration

Pimavanserin is available in 10-mg tablets and 34-mg capsules. Each capsule contains 40 mg of pimavanserin tartrate, which is equivalent to 34 mg of the pimavanserin-free base. The recommended dose is 34 mg taken orally once daily, without titration. Pimavanserin can be taken with or without food. Capsules can either be swallowed whole or opened with the contents sprinkled over a tablespoon of soft foods such as apple sauce, yogurt, or pudding.

Switching a patient with PDP from clozapine or quetiapine to pimavanserin should be commenced with attention to (1) preserving a stable level of 5-HT$_{2A}$ antagonism that allows symptomatic control throughout the switch and (2) avoiding cholinergic or histaminergic rebound effects by slowly tapering quetiapine or clozapine. The strategy developed by expert consensus involves continuing the quetiapine or clozapine while starting pimavanserin at 34 mg daily and allowing the medication to reach steady state. If tapering quetiapine, begin the taper four weeks after starting pimavanserin, reduce by 50% weekly if starting from a dose ≤100 mg/day or by 25%

weekly if starting from higher doses. Upon reaching 12.5 mg/day, discontinue the quetiapine. If tapering clozapine at doses ≤100 mg/day, begin the taper 6 weeks after starting pimavanserin, and taper clozapine by 6.25 mg weekly until discontinued.

Dosing in Special Populations

GERIATRIC USE. No dose adjustment is required for older adult patients. Of note, PDP primarily occurs in older individuals. The mean age of patients enrolled in the 6-week clinical studies was 71 years, with 49% of patients 65 to 75 years old and 31% of patients >75 years old. Neither the 6-week clinical studies nor the long-term open-label study identified significant differences in safety or effectiveness related to age.

HEPATIC IMPAIRMENT. No dose adjustment is recommended for patients with mild to severe hepatic impairment.

RENAL IMPAIRMENT. No dose adjustment is recommended for patients with mild to severe renal impairment or end-stage renal disease. However, pimavanserin should be used with caution in patients with severe renal impairment as defined as creatinine clearance <30 mL/min (Cockcroft-Gault) as the peak plasma level and total drug exposure were increased. Dialysis does not significantly affect the pimavanserin plasma concentration.

33.8 Noradrenaline Modulators

33.8a α_2-Adrenergic Receptor Agonists: Clonidine, Clonidine Extended Release, Guanfacine, and Guanfacine Extended Release

Eric Hollander, M.D., and Migena Dervishi, M.D.

Neuroscience-Based Nomenclature (NbN):	
Clonidine, guanfacine	
Pharmacologic domain	Norepinephrine
Mechanism of action	Receptor agonist (alpha-2 NE)

HISTORY

Clonidine (Catapres) was synthesized in the early 1960s and found to produce vasoconstriction mediated by α-receptors. The drug was initially developed as a topical nasal decongestant. During clinical testing, it was found to cause hypotension, sedation, and bradycardia, and it was subsequently used as a centrally active antihypertensive. Due to its effects on norepinephrine and other neurotransmitter systems and the functioning of the prefrontal cortex (PFC), clonidine has been studied in several psychiatric disorders, including tic disorders, ADHD, PTSD, and opiate, nicotine, and alcohol withdrawal. Guanfacine (Tenex) is also a α-adrenergic receptor agonist. It has a longer half-life and may have fewer side effects due to its differential affinity for certain receptor subtypes.

CHEMISTRY

Clonidine is an imidazoline derivative and exists as a mesomeric compound. Its chemical name is *N*-(2,6-Dichlorophenyl)-4,5–1H-imidazol-2-amine; the structural formula is shown in Figure 33.8a–1. Clonidine hydrochloride is an odorless, bitter, white, crystalline substance soluble in water and alcohol. Its molecular weight is 266.56.

The chemical name of guanfacine is *N*-(diaminomethylidene)-2-(2,6-dichlorophenyl)acetamide, and its molecular weight is 282.56. Guanfacine hydrochloride is a white to off-white powder sparingly soluble in water and alcohol and slightly soluble in acetone. Guanfacine's structural formula is shown in Figure 33.8a–2.

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Absorption. Clonidine immediate release (CLON-IR) is well absorbed after oral administration, and its bioavailability is nearly 100%. The plasma level peaks between 1 and 3 hours after an oral dose. Clonidine extended-release (Kapvay) (CLON-XR) is well absorbed after oral administration with a bioavailability of about 90% but is designed to be absorbed more slowly with peak plasma levels achieved at 6 to 7 hours. Due to differing pharmacokinetic characteristics, utilization of the same dose of CLON-IR and CLON-XR will result in different drug exposure. Comparisons across studies suggest peak plasma concentrations are 50% lower for CLON-XR compared with CLON-IR. The absorption of CLON-XR is not impacted by food intake. Guanfacine immediate release (GUAN-IR) is also well absorbed orally with a bioavailability of about 80%, and peak plasma levels are seen in 1 to 4 hours. Guanfacine extended-release (Intuniv) (GXR) has a relative bioavailability of 57% compared with the GUAN-IR formulation. Therefore the XR and IR formulations are not interchangeable. GXR reaches peak plasma levels in 5 to 6 hours after oral administration. Absorption of GXR is significantly affected by food intake, with a 75% increase in peak plasma levels when administered with a high-fat meal. Administration with a high-fat meal should be avoided.

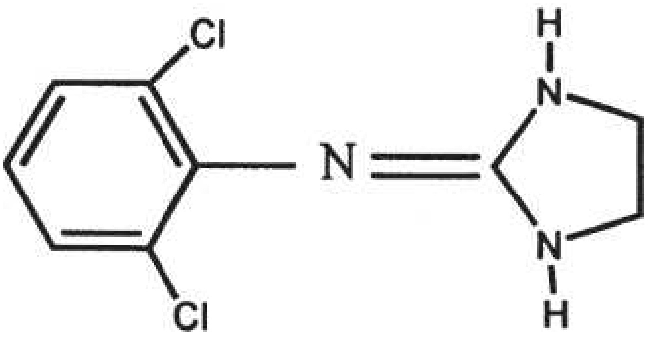

FIGURE 33.8a–1. Molecular structure of clonidine.

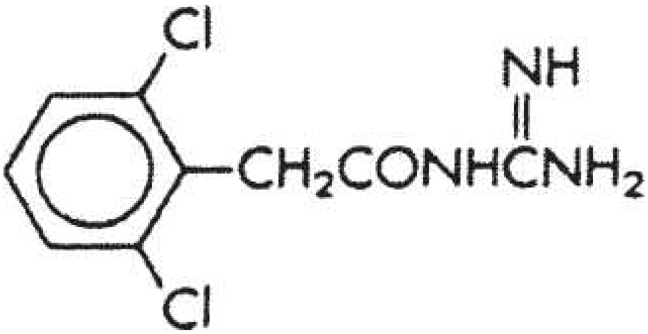

FIGURE 33.8a–2. Molecular structure of guanfacine.

Distribution. Clonidine and guanfacine formulations cross the blood–brain barrier, cross the placenta and are present in breast milk. Clonidine is between 20% and 40% protein bound and has a volume of distribution of 2.1 L/kg, whereas guanfacine is approximately 70% protein bound and has a volume of distribution of 6 L/kg. It is not known if guanfacine crosses the placenta or is excreted in breast milk, although guanfacine has been shown to cross the placenta in rats.

Metabolism and Elimination. The elimination half-life (time required for the concentration of the drug to reach half its original value) of both the immediate-release and extended-release clonidine range from 6 to 24 hours, with a mean of 12 hours. When renal function is severely impaired, the half-life can increase to approximately 41 hours. About 50% of the absorbed dose is metabolized in the liver. The elimination half-life of both guanfacine immediate release and guanfacine extended release is approximately 17 hours. Guanfacine is metabolized by hepatic cytochrome p450

(CYP) 3A4 microsomal enzymes. Exposure to guanfacine may potentially be increased by concurrent use of CYP3A4 inhibitors (clarithromycin, grapefruit juice, itraconazole) or decreased by concurrent use of CYP3A4 inducers (rifampin, St. John wort, phenytoin). If renal insufficiency clearance is reduced, drug levels are only slightly increased. Both clonidine and guanfacine are metabolized more rapidly in children and, therefore, the half-life is decreased.

Pharmacodynamics

Mechanism of Action. There are five adrenergic receptors (α_1, α_2, β_1, β_2, β_3). The α_1-receptors are located in the periphery, while the α_2-receptors are located centrally and peripherally. In the CNS, they are located both pre- and postsynaptically. The α_2-receptors have three distinct subtypes (A, B, and C) predominance. The α_2A-adrenoreceptors are concentrated in the PFC, locus ceruleus (LC), amygdala, septum, hippocampus, and hypothalamus. The α_2B-adrenoreceptor is mainly restricted to the thalamus. The α_2C-adrenoreceptor is present in the hippocampus, the olfactory system, the striatum, and the cerebral cortex. Each of these subtypes is a Gi/Go protein-coupled receptor, which, on a cellular level, when activated by endogenous agonists (epinephrine) or exogenous agonists (clonidine), suppresses adenylyl cyclase activity which then leads to decreased production of cAMP. This, in turn, decreases feedforward cAMP–calcium signaling and prevents the opening of potassium channels. Continued exposure to α_2-agonists leads to downregulation of all three receptor subtypes.

Clonidine behaves as a partial agonist at all three α_2-receptor subtypes. Guanfacine is a selective α_2A-adrenoreceptor agonist that has increased selectivity for the α_2A-receptor over α_2B- and α_2C-receptor subtypes. The majority of the pharmacologic and physiologic functions are attributed to the α_2A-adrenoreceptor subtype.

Presynaptic α_2A-adrenoreceptor activation leads to an autoinhibition of norepinephrine release with activation of presynaptic α_2-receptors in the LC and cortex and of α_2B-receptors in the thalamus, likely accounting for the sedative effects of the α_2-agonists. Guanfacine is less sedating than clonidine, which is likely due to a weaker action at α_2B- and α_2C-receptors. The majority of α_2A-receptors are postsynaptic, including receptors on the dendritic spines of pyramidal cells in the PFC. Activation of these receptors and the resulting decreases in cAMP enhances prefrontal neuronal firing and strengthens prefrontal network connectivity, allowing for greater control of behavior, including cognitive-enhancing effects. The activation of this postsynaptic receptor also has a stimulatory effect on growth hormone secretion. Less is known about the effects of agonists on the α_2B- and α_2C-adrenoreceptors.

Clonidine, an imidazoline derivative, also binds to imidazoline-binding sites (IBS) located throughout the body and in the CNS. There are three subtypes of IBS: I1, I2, and I3. Clonidine has a greater affinity for the I1 IBS, which is involved in the control of blood pressure, and there is evidence to support that the hypotensive effect of clonidine is mediated via the IBS I1. Hypotensive side effects are less common with guanfacine, likely due to its weaker affinity at the IBS I1.

Blood Concentrations and Relation to Action. Concentrations of both clonidine and guanfacine vary between individuals based on many factors, most notably age and renal function.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

The α_2-adrenergic receptor agonists have been evaluated in several psychiatric disorders with proposed underlying dysregulation of the adrenergic system or sympathetic nervous system. More recently, animal and neuroimaging research has led to further understanding of the neurobiology of PFC and the impact of the PFC and its connections on attention, emotion, and behavior. This has provided therapeutic targets to treat psychiatric disorders with a proposed underlying dysregulation of PFC. Various clinical drug trials have shown the α_2-adrenergic receptor agonists to have varying degrees of efficacy in the treatment of a variety of psychiatric disorders, including tic disorders, ADHD, PTSD, opiate, nicotine, and alcohol withdrawal. Over the past 5 years, with the development of the extended-release formulations of clonidine and guanfacine, there have been multiple larger randomized, placebo-controlled studies that have shown the extended-release α_2-agonists to be safe and efficacious for use in children and adolescents for the treatment of ADHD. In addition, the possible neuroprotective effects, especially in times of uncontrollable stress, of the α_2-adrenergic receptor agonists continue to be evaluated in humans because evidence of neuroprotective effects in animals has continued to expand.

EFFECT ON SPECIFIC ORGANS AND SYSTEMS

The α_2-agonists are active antihypertensive medications that directly affect the cardiovascular system by stimulating central α-adrenoreceptors, leading to reduced sympathetic nerve impulses from the vasomotor center to the heart and blood vessels. This results in a decrease in peripheral vascular resistance, renal vascular resistance, and a reduction in heart rate and blood pressure. Given these direct effects, measurement of heart rate and blood pressure prior to initiation, following dose increases and periodically while on therapy is recommended. Renal blood flow and glomerular filtration rate remain essentially unchanged. Normal hemodynamic responses to exercise are maintained. Both clonidine and guanfacine acutely stimulate growth hormone release in both children and adults but do not produce a chronic elevation of growth hormone with long-term use.

THERAPEUTIC INDICATIONS

Clonidine extended release and guanfacine extended release are FDA-approved in the treatment of ADHD as monotherapy and as adjunctive therapy to stimulant medication in children and adolescents. Immediate-release clonidine and guanfacine are FDA-approved only for the treatment of hypertension, as monotherapy, or in combination with other antihypertensive medications. These medications are also used in a number of off-label uses for the treatment of numerous psychiatric conditions.

Tourette Syndrome and Other Tic Disorders

A tic is a sudden, rapid, recurrent, nonrhythmic motor movement or vocalization. Tourette syndrome (TS) is a neuropsychiatric syndrome characterized by both multiple motor and one or more vocal tics that may wax and wane in frequency but have persisted for more than 1 year since first tic onset, with first tic onset before the age of 18 years.

Clonidine and guanfacine are considered by many to be the first-line treatment for tics and TS, with multiple positive double-blind, randomized placebo-controlled studies in the literature. Although haloperidol (Haldol) and pimozide (Orap) have been shown to be more effective than the α_2-agonists, concerns about their side-effect profiles, specifically NMS, tardive dyskinesia, and QTc prolongation (especially pimozide), have limited their use. Among the newer antipsychotics, the use of risperidone (Risperdal) has the strongest evidence for efficacy, yet its use is limited due to issues of weight gain, sedation, and risks of extrapyramidal symptoms and hyperprolactinemia. Preliminary data have shown clonidine and risperidone (Risperdal) to be equally efficacious. Preliminary data have also shown the clonidine transdermal patch to be an effective option for the treatment of TS and other tic disorders. When using clonidine for tics and TS, it is important to note that there can be a delayed response, sometimes taking 2 to 6 weeks to have a clinical effect.

A standard titration of clonidine for the treatment of tics is 0.05 mg before bed, increasing by 0.05 mg every 3 to 7 days until the dose is

0.05 mg in the morning and midday and 0.1 mg at bedtime. The total daily dose of clonidine for the treatment of tics is 0.1 to 0.3 mg. A standard titration of guanfacine for the treatment of tics is 0.5 mg before bed, increasing by 0.5 mg every 3 to 7 days until the dose is 1 mg twice per day. In studies of tics or TS and comorbid ADHD, the dose range was 3 to 5 µg/kg per day. Measurement of heart rate and blood pressure prior to initiation, following dose increases and periodically while on therapy is recommended.

There are no published studies on the use of the extended-release formulations of clonidine and guanfacine in TS or tic disorders.

Attention-Deficit/Hyperactivity Disorder

Dysregulation of the central noradrenergic network has long been hypothesized to be an important aspect of the pathophysiology of ADHD. Ongoing structural and functional imaging studies along with neuropsychological studies have demonstrated delayed or inadequate maturation of the PFC, particularly in the right inferior regions needed for inhibitory control and executive cognitive functioning. Moderate levels of norepinephrine are critical for proper PFC function, while high and low levels may impair function. Action at presynaptic α_2-receptors in the LC leads to decreased cell firing and release of norepinephrine modulating and optimizing catecholamine influences to remediate symptoms of ADHD. Ascending norepinephrine afferent projections from the LC to the PFC enhance functional connectivity between the PFC and other brain regions. Guanfacine mimics norepinephrine at the postsynaptic α_2A-receptors.

The α_2-agonist clonidine has been used in the treatment of ADHD for more than 20 years. Yet, the effect size for stimulant medications in ADHD is larger than that for the α_2-agonists, and clonidine and guanfacine are therefore considered second-line agents for the treatment of ADHD. The α_2-agonists are most often used for the augmentation of stimulants or when stimulant medications have been ineffective or poorly tolerated. In these patients, data have shown moderate efficacy for some symptoms of ADHD with clonidine and guanfacine monotherapy and with clonidine in combination with methylphenidate. There is increasing evidence that the addition of clonidine to ongoing psychostimulant treatment reduces symptoms of oppositional defiant disorder and conduct disorder, particularly symptoms of aggression.

A standard CLON-IR dose for the treatment of ADHD is approximately 3 to 5 µg/kg per day, with a daily dose range of 0.1 to 0.3 mg per day. It is recommended to start with low doses and increase by 0.05 mg every 3 days. A standard dose of GUAN-IR for the treatment of ADHD ranges from 0.5 to 4 mg per day. The dose can be increased by 0.5 mg every 3 to 4 days. CLON-IR is administered on a schedule of three to four times a day, while GUAN-IR, with its longer duration of action, is generally administered on a twice-a-day schedule.

For CLON-XR as monotherapy for ADHD or as adjunctive therapy to a psychostimulant, dosing should be initiated with 0.1 mg at bedtime and adjusted in increments of 0.1 mg per day at weekly intervals until the desired dose-response is achieved. Dosing should consist of twice a day with either an equal split or the higher dosage at bedtime to a maximal total dose of 0.4 mg per day. For GXR as monotherapy for ADHD or as adjunctive therapy to a psychostimulant, dosing should be initiated once daily, either morning or evening, with a dose of 1 mg per day and adjusted in increments of 1 mg per day at weekly intervals until the desired dose-response is achieved. Doses above 4 mg per day have not been systematically studied in controlled studies.

Concerns regarding the safety of the combination of stimulants and α_2-agonists remain after the sudden death of four children taking methylphenidate and clonidine was reported in 1995, although the specific contribution of clonidine in these deaths remains controversial. There have been no further reports of sudden death, and studies with children on this combination have been conducted with baseline, interval, and final visit ECGs and pulse and blood pressure monitoring. Before the initiation of an α_2-agonist, a cardiologist should evaluate patients with known cardiac problems or abnormal ECGs.

Opiate Withdrawal

Clonidine has been used for the treatment of opiate withdrawal since the 1980s and continues to be used in most detoxification protocols. Opiate withdrawal is manifested by symptoms of irritability, anxiety, sweating, sniffling, rhinorrhea, nausea, diarrhea, lacrimation, abdominal pain, headache, muscular pain, and insomnia. During withdrawal, neural activity in the LC is greatly increased, and this surge is thought to be responsible for many of the symptoms seen during withdrawal. Clonidine's ability, through its preferential action on presynaptic α_2-neurons, to inhibit noradrenergic activity has been consistently shown to be effective in decreasing these symptoms by counteracting catecholamine release and decreasing the sympathetic hyperactivity in opiate withdrawal.

Clonidine has been used as a single agent in the treatment of opiate withdrawal and in combination with methadone (Dolophine), or buprenorphine (Buprenex), a partial opiate agonist. Clonidine is also used in rapid opiate detoxification under anesthesia (RODA), which is a procedure using opiate antagonists, such as naloxone/naltrexone (Narcan/Revia), under general anesthesia to rapidly reverse opioid dependence. Preliminary evidence finds that clonidine may be particularly effective in managing the gastrointestinal (GI) side effects associated with RODA. Some authors have suggested that withdrawal-induced diarrhea may be mediated through α_2-adrenoreceptors located on intestinal smooth muscles.

Although studies have shown clonidine to be effective in the management of opiate withdrawal, in comparison to methadone and buprenorphine, the treatment retention rate of patients treated with clonidine only is markedly lower. This is believed to be because patients treated with clonidine, as compared to methadone or buprenorphine, experience the most intense symptoms of opiate withdrawal earlier in the detoxification process. In addition, these patients experience and report greater medication side effects. These side effects are sedation, lethargy, fatigue, dry mouth, and hypotension. Withholding doses or decreasing the clonidine dose according to blood pressure changes usually manages the hypotensive side effects. Although the treatment retention rates and the percentage of patients who complete detoxification is higher when methadone, buprenorphine, or RODA is used, some recent work has suggested that at 6- and 12-month follow-up, the relapse rates with these other medications are equal to or higher than, the clonidine only group.

Several standardized protocols for the use of clonidine in opiate withdrawal are commonly used. Generally, clonidine therapy is initiated at a dose of 0.1 to 0.2 mg orally up to six times per day and is titrated based on the severity of symptoms and side effects. Maximum doses of clonidine are usually approximately 1 mg per day. The maximal doses are used for 2 to 3 days during the most acute withdrawal period. When the patient is stabilized, the clonidine is tapered over a 7- to 10-day period. Some protocols involve a slower taper or transition to a transdermal patch in order to address chronic symptoms of withdrawal such as sleep disturbance.

Nicotine Withdrawal

Clonidine is considered a second-line treatment for nicotine withdrawal. Although it has been shown to be effective in promoting smoking cessation, there is a high incidence of adverse effects, such as hypotension, dry mouth, and sedation. In light of these adverse effects, clonidine is typically reserved for smokers in whom sedation would be a desirable effect, such as in a smoker who experiences extreme agitation or anxiety during nicotine withdrawal.

The recommended dose of clonidine for nicotine withdrawal from available studies is 0.1 mg twice a day with titration to 0.4 mg daily as tolerated. Clonidine should be started 48 to 72 hours prior to cessation of nicotine use to allow time to reach a steady state before the onset of nicotine withdrawal.

Autism Spectrum Disorders

In clinical practice, α_2-agonists are considered a second-line treatment for managing symptoms of hyperactivity, inattention, impulsivity, aggression, explosive outbursts, self-injury, and sleep dysfunction in autism spectrum disorders.

Overall empirical support for the use of the α-agonists in autism spectrum disorders is limited. There are three published trials of guanfacine in children with autism spectrum disorders. Preliminary evidence supports the efficacy and safety of guanfacine in the treatment of hyperactivity, inattention, and aggression in particular subsets of the autism spectrum disorders population. Clonidine has been studied as a sedative agent for autism spectrum disorder patients undergoing electroencephalogram (EEG), as a treatment for hyperactivity and inattention, and for sleep disturbance in these patients. Of note, individuals with autism spectrum disorders are generally more sensitive to the side effects of irritability and sedation when treated with α_2-agonists. There are case reports of the use of extended-release guanfacine in children with autism spectrum disorders for symptoms of inattention and hyperactivity.

Posttraumatic Stress Disorder and Other Anxiety Disorders

Increased and altered noradrenergic neurotransmission and reactivity in the CNS have been associated with a variety of hyperarousal symptoms and sleep disturbances in PTSD. Clonidine’s action at the postsynaptic α_2-adrenergic receptors in the CNS reduces sympathetic activity, possibly reducing the arousal symptoms of PTSD. Guanfacine, with the same mechanism as clonidine, has also been used for the treatment of the symptoms of PTSD, including nightmares. Clinically there are reports of effectiveness in child refugees and veterans, although there are no randomized, placebo-controlled trials of clonidine in PTSD, and there are reports that it loses its effectiveness over time.

Clonidine has also been studied in other anxiety disorders. In patients with panic disorder, clonidine appears to have an acute anxiolytic effect that is transient. Some debate exists as to whether clonidine has anxiolytic effects by proxy of its sedative side effects. The α_2-agonists do not appear to be effective in OCD.

Cognition and Neuroprotective Effects

The relationship between the noradrenergic system and executive and memory functions has been extensively investigated in animal models with positive results. Investigations of the cognitive enhancing potential of α_2-agonists via their effects on the PFC in humans have been inconclusive, and more recent studies found no significant clinical effects on healthy adult controls. There is evidence for the use of clonidine and guanfacine to enhance cognition in patients with schizophrenia and Korsakoff syndrome; however, its use remains limited by issues of tolerability.

Research on the neuroprotective effects of α_2-adrenergic receptor agonists began approximately 20 years ago after studies in rats indicated a protective effect of clonidine after cerebral ischemia. These neuroprotective effects have also been seen with the α_2-agonist brimonidine (Alphagan P) in glaucoma. At this time, despite extensive animal research, minimal investigation has been done to evaluate the neuroprotective effects of these drugs in humans.

Other Disorders

Clonidine has been used in the treatment of alcohol withdrawal to target the symptoms thought to be secondary to adrenergic hyperactivity and CNS excitation. There is no evidence suggesting that these medications are effective in reducing the incidence of seizures or delirium associated with alcohol withdrawal, thus reducing their use as an adjunctive treatment to benzodiazepines and typical antipsychotics. Animal studies have also looked at clonidine in decreasing voluntary alcohol drinking. There are also reports of using low-dose clonidine (0.025 mg three times per day) in hallucinogen persisting perception disorder, where symptoms may resolve within 2 months of initiating treatment.

There has also been a positive small double-blind, randomized placebo-controlled trial investigating the use of clonidine for hyperarousal symptoms in patients with borderline personality disorder with and without PTSD.

PRECAUTIONS AND ADVERSE REACTIONS

Adverse effects of clonidine include dry mouth (40%), drowsiness (33%), dizziness (16%), constipation (10%), and sedation (10%). There are also numerous, albeit less frequent, side effects that have been reported in which a causal relationship has not been established, including nervousness, agitation, sleep disturbance, impotence, loss of libido, weight gain, headache, nausea, and vomiting. There are isolated reports of transient abnormalities in liver function tests, urinary dysfunction, thrombocytopenia, transient elevation of blood glucose, muscle pain, and leg cramps. Abnormalities on ECG such as sinus node arrest, junctional bradycardia, high-degree AV block, and arrhythmias have also been reported. Marked bradycardia is observed in some patients. Localized contact dermatitis is an adverse reaction to the clonidine transdermal therapeutic system (TTS) for approximately 15% to 20% of patients, particularly when using the optional adhesive cover. This can be addressed by alternating the site of the patch. The clonidine TTS contains aluminum and, therefore, should be removed before undergoing magnetic resonance imaging (MRI). Adverse reactions with the use of extended-release clonidine include somnolence (30%), fatigue (15%), constipation (5%), and nightmares (3% to 9%), although there is some variability depending on the dose. For guanfacine, the adverse effects are similar to those for clonidine, although hypotension, sedation, and dry mouth are somewhat less frequent. Adverse reactions with the use of extended-release guanfacine include somnolence (35%), fatigue (14%), and hypotension (7%). For these medications, there is evidence that the severity of dose-dependent adverse effects lessens over time.

Clonidine is considered a class C drug in pregnancy, which means that the safety is uncertain and that well-controlled studies in humans do not exist. Clonidine is excreted in breast milk, and caution should be exercised when administering clonidine in pregnancy and during lactation. Studies have not found evidence to suggest carcinogenesis and mutagenesis as a result of clonidine. Guanfacine is considered a class B drug in pregnancy, meaning that studies in humans have shown no evidence of risk to the fetus, although there have been adverse findings in animal studies. The excretion of guanfacine in breast milk is unknown, but in light of the fact that most medications are eliminated in breast milk, caution is suggested.

Clonidine is known to have a withdrawal syndrome. With the sudden cessation of clonidine, there may be an associated increase in plasma and urinary catecholamines and associated symptoms such as nervousness, restlessness, insomnia, headache, increased heart rate, sweating, increased salivation, nausea, and flushing. There can also be episodes of rebound hypertension upon cessation of the medication. This syndrome is more pronounced after abrupt cessation of long-term therapy, in patients on a higher total dose, and in patients also receiving β-blockers. A taper of the clonidine is required when the duration of use has been greater than 1 week, with a reduction in dose of 0.05 mg every other day. When the duration of use has been longer than 4 weeks, the dose reduction should be every third day. If there are symptoms of withdrawal present, they can be alleviated with clonidine. There are less data regarding a withdrawal syndrome with guanfacine, and although it remains a possibility, its longer duration of action makes withdrawal less likely.

DRUG INTERACTIONS

Clonidine and guanfacine cause sedation, especially early in therapy, and when administered with other centrally active depressants, such as barbiturates, alcohol, and benzodiazepines, the potential for additive sedative effects should be considered, and dose reduction may be required. Due to the potential for additive effects, caution is required in patients receiving agents known to affect AV node and sinus node conduction, such as β-blockers, calcium channel blockers, and digitalis. This combination increases the risk of AV block and bradycardia. When utilized along with antihypertensive drugs, use caution as there is the potential for additive effects. Guanfacine is metabolized by CYP3A4 microsomal enzymes, and plasma concentrations can be affected significantly by CYP3A4 inhibitors or inducers. Guanfacine does not significantly affect exposures of methylphenidate and lisdexamfetamine when coadministered.

LABORATORY INTERFERENCE

Neither clonidine nor guanfacine is known to interfere with any laboratory tests.

DOSAGE AND ADMINISTRATION

Clonidine is supplied in 0.1-, 0.2-, and 0.3-mg tablets. It is also available in TTS that delivers 0.1, 0.2 or 0.3 mg daily (TTS-1, TTS-2, TTS-3). The dosing for the TTS is equivalent to the total oral daily dose. Multiple patches can be used at one time in order to administer the required dose. When administered for the treatment of hypertension, clonidine is initiated at 0.1 mg twice daily with increases of 0.1 mg at weekly intervals until the desired response is achieved. Therapeutic doses for the treatment of hypertension range from 0.2 to 0.6 mg per day in divided doses. The maximum effective daily dose is 2.4 mg. It is suggested to administer a larger portion of the oral daily dose at bedtime to minimize adverse effects of dry mouth and sedation. The clonidine TTS is applied once every 7 days to a clean, dry, hairless area of intact skin on the upper outer arm, chest, or back. In children, a new patch is applied every 5 days due to their more rapid hepatic metabolism. Each new application should be on a different skin site from the prior patch. If the clonidine TTS becomes loose from the skin, the adhesive cover can be placed over the system to ensure adhesion.

Clonidine extended release is available in 0.1- and 0.2-mg tablets. The tablets must be swallowed whole and never cut, crushed, or chewed.

Guanfacine is supplied in 1- and 2-mg tablets. When administered for the treatment of hypertension, guanfacine is initiated at 1 mg at bedtime to reduce sedation. The daily dose may be raised to 2 to 3 mg after 3 to 4 weeks of therapy. For the treatment of hypertension, the most clinical effect is seen in the 1- to 3-mg dose range, although the maximum recommended dose is 6 mg daily.

Guanfacine extended release is available in 1-, 2-, 3-, and 4-mg tablets. The tablets must be swallowed whole and never cut, crushed, or chewed.

33.8b β-Adrenergic Receptor Antagonists

Migena Dervishi, M.D., and Eric Hollander, M.D.

HISTORY

The first nontoxic β-adrenergic receptor antagonist, propranolol, was isolated by the Scottish pharmacologist James W. Black, earning him the Nobel Prize in Medicine in 1988. β-Adrenergic receptors are ubiquitously distributed throughout the body, including the heart, lung, autonomic, and CNS. The five β-adrenergic receptor antagonists most frequently studied for psychiatric application are propranolol (Inderal), metoprolol (Lopressor, Toprol XL), atenolol (Tenormin), nadolol (Corgard), and pindolol (Visken).

CHEMISTRY

Propranolol is chemically described as 1-(isopropylamino)-3-(naphthalene-1-yloxy) propan-2-ol. Its molecular formula is $C_{16}H_{21}NO_2$. Propranolol is a stable, white, crystalline solid that is readily soluble in water and ethanol. Its molecular mass is 295.34. Its molecular structure is shown in Figure 33.8b–1.

Metoprolol tartrate is chemically described as (1-[4-(2-methoxyethyl) phenoxy]-3-propan-2-ylamino-propan-2-ol). It is a white, practically odorless, crystalline powder with a molecular mass of [267.36] 684.82. Its molecular formula is $C_{15}H_{25}NO_3$. It is very soluble in water, freely soluble in methylene chloride, chloroform, and alcohol; slightly soluble in acetone; and insoluble in ether. The molecular structure is shown in Figure 33.8b–1.

Atenolol may be chemically described as benzeneacetamide, 2-[4-[2-hydroxy-3-(1-methylethylamine)propoxy]phenyl]ethanamide. The molecular formula is $C_{14}H_{22}N_2O_3$. Atenolol has a molecular weight of 266.34. It is a relatively polar hydrophilic compound with a water solubility of 26.5 mg/mL at 37°C and a log partition coefficient (octanol/water) of 0.23. It is freely soluble in 1N hydrochloric acid (300 mg/mL at 25°C) and less soluble in chloroform (3 mg/mL at 25°C). The molecular structure is given in Figure 33.8b–1.

Nadolol is chemically described as 2R,3S 5-[2-hydroxy-3-3(tert-butylamino)-propoxy]tetralin-2,3-diol. Its molecular formula is $C_{17}H_{27}NO_4$. Nadolol has a molecular weight of 309.40. It is a white, crystalline powder that is freely soluble in alcohol, propylene glycol, and ethanol; slightly soluble in chloroform and water; very slightly soluble in sodium hydroxide; and insoluble in acetone, benzene, ether, and hexane. The molecular structure is shown in Figure 33.8b–1.

Pindolol is chemically described as 1-(1H-indol-4-ylox)-3-(1-methylethylamino)propan-2-ol. Its molecular formula is $C_{14}H_{20}N_2O_2$. Pindolol has a molecular mass of 248.32. Pindolol is a white to off-white crystalline powder with a faint odor. It is practically insoluble in water, slightly soluble in methanol, and very slightly soluble in chloroform. The molecular structure is shown in Figure 33.8b–1.

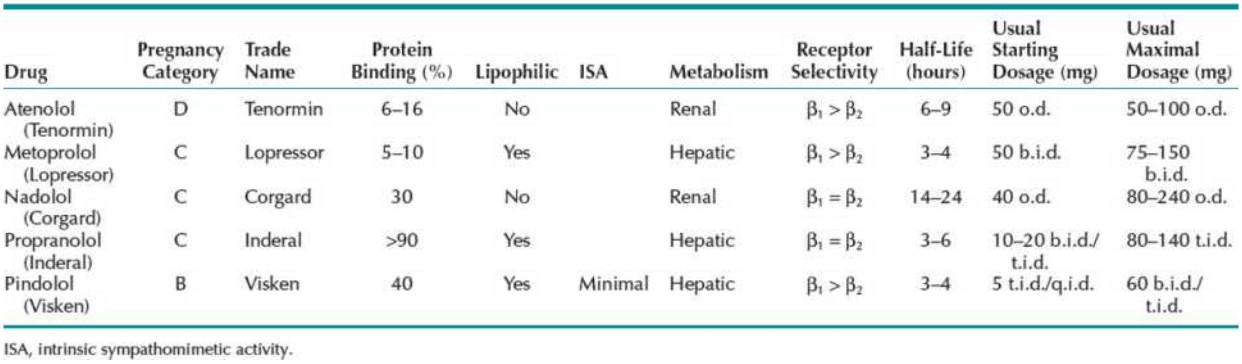
PHARMACOLOGIC ACTIONS

Pharmacokinetics

The pharmacokinetics of atenolol, metoprolol, nadolol, propranolol, and pindolol are listed in Table 33.8b–1.

Absorption. Absorption of propranolol (>95%) and pindolol (~95%) is extensive. Atenolol (~50%) and metoprolol (~50%) are intermediate, while absorption for nadolol is variable, averaging approximately 30%.

Table 33.8b–1. Pharmacokinetics



Drug	Pregnancy Category	Trade Name	Protein Binding (%)	Lipophilic	ISA	Metabolism	Receptor Selectivity	Half-Life (hours)	Usual Starting Dosage (mg)	Usual Maximal Dosage (mg)
Atenolol (Tenormin)	D	Tenormin	6–16	No		Renal	$\beta_1 > \beta_2$	6–9	50 o.d.	50–100 o.d.
Metoprolol (Lopressor)	C	Lopressor	5–10	Yes		Hepatic	$\beta_1 > \beta_2$	3–4	50 b.i.d.	75–150 b.i.d.
Nadolol (Corgard)	C	Corgard	30	No		Renal	$\beta_1 = \beta_2$	14–24	40 o.d.	80–240 o.d.
Propranolol (Inderal)	C	Inderal	>90	Yes		Hepatic	$\beta_1 = \beta_2$	3–6	10–20 b.i.d./t.i.d.	80–140 t.i.d.
Pindolol (Visken)	B	Visken	40	Yes	Minimal	Hepatic	$\beta_1 > \beta_2$	3–4	5 t.i.d./q.i.d.	60 b.i.d./t.i.d.

ISA, intrinsic sympathomimetic activity.

Distribution. β-Adrenergic receptor antagonists are categorized based on their lipophilicity. Propranolol and metoprolol are highly lipophilic and, as a result, have both potent central and peripheral effects. Pindolol is of intermediate lipophilicity; nadolol and atenolol are the least lipophilic and have minimal central effects.

Propranolol exhibits extensive first-pass metabolism, with approximately 25% of an orally administered dose reaching the systemic circulation. Metoprolol is extensively metabolized by cytochrome P450 enzymes of the liver. With repeated oral administration, it increases in a dose-dependent fashion. Metoprolol exhibits approximately 50% first-pass metabolism and relatively low protein binding (10% to 15%).

Atenolol plasma levels are proportional to the dose over the range of 50 to 400 mg with relatively low protein binding (5% to 16%).

Pindolol exhibits substantial interindividual variation in plasma concentrations. Pindolol has relatively low protein binding (~40%). In man, 35% to 40% is excreted unchanged in the urine and 60% to

65% is metabolized primarily to hydroxy-metabolites, which are excreted as glucuronides and ethereal sulfates. Approximately 30% of nadolol in serum is reversibly bound to plasma protein and is not metabolized by the liver but is excreted unchanged principally by the kidneys.

Elimination. The β-adrenergic receptor antagonists exhibit considerable variation in elimination half-life (see Table 33.8b–1).

PHARMACODYNAMICS

Mechanism of Action

β-Adrenergic receptor antagonists block the action of endogenous catecholamines (primarily norepinephrine, as well as epinephrine) on β-adrenergic receptors. There are three types of β-adrenergic receptors, each of which exhibits tissue selectivity. β_1-Adrenergic receptors are localized in the myocardium and kidney; β_2-adrenergic receptors are located in the gastrointestinal tract, lung, liver, uterus, and vascular smooth muscles; and β_3-adrenergic receptors are located in fat cells. Norepinephrine is produced in the CNS by neurons in the locus ceruleus, a phylogenetically old monoamine system located in the dorsal pons with diffuse projections to subcortical and cortical regions.

There are also three types of α_1- and α_2-adrenoreceptors. Both α- and β-adrenergic receptors are G-protein–coupled receptors. β-Adrenergic receptor antagonists are categorized as selective or nonselective on the basis of their affinity for β_1 and β_2 receptors, respectively. For example, propranolol and nadolol are nonselective, whereas atenolol, pindolol, and metoprolol exhibit differential affinity for the β_1-adrenergic receptor.

The β-adrenergic system participates in the formation and consolidation of emotional memories in humans. Pre- and postlearning stimulation of the β-adrenergic system enhances memory for the events that trigger stressful experiences, whereas β-adrenergic receptor antagonists administered prior to learning may inhibit declarative stressful memories. Propranolol affects context conditioning but has less impact on the acquisition or retention of cued fear conditioning.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

β-Adrenergic receptor antagonists are used in psychiatry to treat a variety of conditions. They are most frequently used as a treatment for performance anxiety, lithium-induced postural tremor, and neuroleptic-induced akathisia. β-Adrenergic receptor antagonists are also used occasionally as adjunctive agents for the treatment of major depressive episodes, anxiety disorders, notably performance-based anxiety and panic attacks, aggression, behavioral disorders in the older adults, posttraumatic stress, and alcohol and cocaine withdrawal.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

The ubiquity of β-adrenergic receptors throughout the body implies a panoply of physiologic effects on organs and systems (Tables 33.8b–2 and 33.8b–3). The systems most pertinent are cardiovascular, respiratory, and metabolic. Psychiatric populations commonly treated with β-adrenergic receptor antagonists (e.g., individuals with mood, anxiety, and psychotic disorders) are differentially affected by disorders in each of these systems. For individuals without pre-existing cardiovascular disease (e.g., hypertension), β-adrenergic receptor antagonists rarely cause hypotension at doses prescribed. Individuals with pre-existing hypertension, however, exhibit an increased propensity to the hypotensive effects of β-adrenergic receptor antagonists.

β-Adrenergic receptor antagonists minimally affect pulmonary function in healthy persons, but they may result in severe life-threatening bronchoconstriction in patients with chronic obstructive pulmonary disease and asthma. As β-adrenergic receptor antagonists may alter the metabolism of carbohydrates and lipids and mask the premonitory signs of hypoglycemia, they should be used with caution in individuals with diabetes mellitus.

TERATOGENIC EFFECTS

None of the available β-adrenergic receptor antagonists has been adequately tested with controlled trials in pregnant women. Perinatal complications (e.g., placental insufficiency and intrauterine growth retardation) are reported with propranolol. Some infants born to mothers administered propranolol during pregnancy exhibited hypoglycemia and/or bradycardia, hypotonia and intrauterine growth retardation.

Table 33.8b–2.

Side Effects and Toxicity of β-Adrenergic Receptor Antagonists

- Cardiovascular
  - Hypotension
  - Bradycardia
  - Congestive heart failure (in patients with compromised myocardial function)
- Gastrointestinal
  - Anorexia
  - Nausea
  - Vomiting
  - Diarrhea
  - Abdominal pain
- Metabolic
  - Weight gain
  - Worsened hypoglycemia in diabetic patients on insulin or oral agents
- Respiratory
  - Asthma (less risk with β_1-selective drugs)
  - Shortness of breath
  - Wheezing
- Sleep disturbances
  - Vivid dreams and nightmares with or without insomnia
- Central nervous system
  - Dizziness
  - Drowsiness
  - Lassitude
  - Fatigue
  - Dysphoria
  - Bronchospasm
  - Lethargy
  - Depression
  - Psychosis (rare)
- Dermatologic
  - Rashes
  - Urticaria
  - Sweating

Sexual function
    Impotence
Other (rare)
    Raynaud phenomenon
    Peyronie disease
Withdrawal syndrome
    Rebound worsening of pre-existing angina pectoris when β-adrenergic receptor antagonists are discontinued

---

β_1-Selective adrenergic antagonists such as atenolol or metoprolol may be preferred as they interfere less with β_2-receptor–mediated uterine relaxation.

Both metoprolol and pindolol cross the placental barrier; they are excreted in breast milk in small amounts. Transplacental passage of atenolol also occurs in pregnant women; fetal drug serum levels equal to the mother have been reported. Patients administered atenolol in the third trimester of pregnancy are at risk for low–birth-weight newborns and placental insufficiency. Nadolol crosses the placenta and is distributed into breast milk.

Table 33.8b–3.
β-Adrenergic Receptor Antagonist Preparations

	Tablets (mg)	Extended Release (mg)	Solution	Parenteral
Atenolol	25, 50, 100			
Metoprolol	50, 100	200		1 mg/mL
Nadolol	20, 40, 80, 120, 160			
Propranolol	10, 20, 40, 80, 120	60, 80, 120, 160		1 mg/mL
Pindolol	5, 10, 15

Table 33.8b–4.
Indications for β-Adrenergic Receptor Antagonists in Psychiatric Practice

- Effective
  - Social phobia (performance type)
  - Obsessive-compulsive disorder
  - Lithium-induced postural tremor
  - Neuroleptic-induced acute akathisia
  - Accelerate antidepressant action
- Probably effective
  - Control of impulsive aggression or violence
  - Adjunct to benzodiazepines in treatment of alcohol withdrawal
  - Adjunct in treatment of cocaine and benzodiazepine withdrawal
- Possibly effective
  - Generalized anxiety disorder
  - Schizophrenia
  - Treatment-resistant depression
  - Panic disorder
  - Posttraumatic stress disorder

THERAPEUTIC INDICATIONS

Indications for β-adrenergic receptor antagonists are listed in Table 33.8b–4.

Lithium Tremor

Lithium may result in an action tremor at nontoxic therapeutic levels. A stable lithium tremor in the absence of toxicity may, however, be distressing and impairing to the individual and require intervention. Therapeutic guiding principles are to ensure adequate blood levels necessary to achieve efficacy and to ensure that no other concomitant agents are contributory. If tremor persists, propranolol is most often used at a dose of 20 to 160 mg per day given in b.i.d. or t.i.d. dosing.

Major Depressive Disorder

Pharmacologic blockade of 5-HT_{1A} autoreceptors is thought to mimic the effect of autoreceptor desensitization and hasten the antidepressant effect of SSRIs. Results from open and randomized controlled clinical trials indicate that pindolol may accelerate the onset of antidepressant action in individuals with major depressive disorder. Pindolol’s efficacy in treatment-resistant major depressive disorder, however, is less consistent. One possible explanation for inconsistent efficacy with pindolol may relate to drug–drug interactions as a consequence of a patient’s pharmacokinetic profile (i.e., slow vs. fast metabolizer).

The possibility that pindolol dosing in resistant populations was suboptimal (i.e., at 2.5 mg t.i.d.) has not been excluded. It is presumed that pindolol’s mechanism of action relates to its affinity for somatic 5-HT_{1A} autoreceptors. When combined with SSRIs, pindolol also increases rapid eye movement (REM) suppression, notably an increase in REM onset latency and reduction in slow-wave sleep.

Substance Use Disorders

Available data suggest that blockade of β-adrenergic receptors potentiates cocaine-induced elevation of dopamine transmission in the nucleus accumbens, which is associated with an increase in cocaine-induced motor activity and a decrease in cocaine self-administration. Propranolol may attenuate the responsivity of noradrenergic neurons, resulting in decreased anxiety from abstinence from cocaine, alcohol, and benzodiazepines. Propranolol may also selectively block memories associated with arousal in humans, which is salient to cue-triggered relapses in substance use disorders. Propranolol is superior to a placebo in reducing cocaine withdrawal symptoms but is not reliably efficacious in promoting abstinence from cocaine.

β-Adrenergic receptor antagonists have been used adjunctively for alcohol withdrawal and relapse prevention. β-Adrenergic receptor antagonists do not replace benzodiazepines for alcohol withdrawal. β-Adrenergic receptor antagonists are not administered during alcohol withdrawal in individuals with a heart rate of fewer than 50 beats per minute.

Violence

Results from case reports and randomized, placebo-controlled trials indicate that β-adrenergic receptor antagonists are modestly effective and well tolerated for individuals with impulsive violence and disruptive behaviors associated with impulsive control disorders, brain injury, neurodegenerative disorder, and general medical conditions affecting the CNS. In individuals with psychological impairment and severe aggression, propranolol 40 to 600 mg per day in divided doses has frequently been used as an adjuvant to antipsychotics, anticonvulsants, and lithium.

Performance Anxiety

The use of propranolol for performance anxiety as part of social phobia is the most familiar application of β-adrenergic receptor antagonists in anxiety disorders. Performance anxiety includes symptoms of dry mouth, coarse voice, increased heart rate, difficulty breathing, tremor, weakness, and dizziness. Single dosing of propranolol 10 to 40 mg per day given approximately 20 to 30 minutes before the performance is most frequently employed. It is generally recommended to consider a test dose prior to the performance event. The mechanism of action of β-adrenergic receptor antagonists relates to their effect on the peripheral sympathetic nervous system. In keeping with that view, less lipophilic agents may also be effective.

Anxiety

It has been postulated that disturbances in β-adrenergic receptor activity are associated with several anxiety disorders, notably panic disorder. Moreover, the anxiety behaviors are subserved by neural structures and circuits that involve the locus ceruleus. Several randomized, controlled trials have established the efficacy of β-adrenergic receptor antagonists in the treatment of disparate anxiety disorders. Pindolol 2.5 mg per day t.i.d. has been used successfully as an adjunct to SSRIs in the treatment of OCD. For generalized anxiety disorder and panic attacks, propranolol doses of 40 to 320 mg per day have been employed.

Neuroleptic-Induced Akathisia

β-Adrenergic receptor antagonists may be more efficacious than anticholinergics and benzodiazepines for medication-induced movement disorders such as akathisia. β-Adrenergic receptor antagonists are not considered efficacious for other neuroleptic-induced movement disorders such as acute dystonia and parkinsonism. In some resistant cases, β-adrenergic receptor antagonists may be combined with benzodiazepines and anticholinergics.

Precautions and Adverse Reactions

Symptoms of propranolol overdose include bradycardia, cardiac failure, hypotension, and bronchospasm. For patients with asthma or chronic obstructive pulmonary disease, selective β_1-adrenergic receptor antagonists should be used. Depression of the myocardium leading to cardiac failure has also been described. Abrupt discontinuation of propranolol therapy has been associated with severe exacerbation of angina and the occurrence of myocardial infarction. Skin rashes and conjunctival xerosis are rarely associated with β-adrenergic receptor antagonists. β-Adrenergic receptor antagonists may mask clinical signs of developing or continuing hyperthyroidism, as well as block premonitory signs and symptoms of acute hypoglycemia.

Other adverse events include CNS depression, fatigue, nightmares, insomnia, vivid dreaming, and hallucinations. β-Adrenergic receptor antagonists do not adversely affect cognitive function and may enhance performance in measures of memory, learning, and psychomotor speed. The incidence of CNS side effects is lowest with the most hydrophilic agents (e.g., atenolol) and highest with pindolol and propranolol, while metoprolol is intermediate. Other side effects attributable to β-adrenergic receptor antagonists are sexual dysfunction and gastrointestinal disturbances; hypersensitivity reactions are rare. Incident depressive symptoms are hypothesized to be due to the inhibitory actions of β-adrenergic receptor antagonists on β-adrenergic and serotonin receptors in the CNS. Individuals with sinus bradycardia, congestive heart failure, greater than first-degree atrioventricular block, severe chronic obstructive pulmonary disease, and bronchial asthma should not be prescribed, β-adrenergic receptor antagonists.

Drug Interactions

Coadministered drugs that induce hepatic oxidative enzymes may increase the clearance of propranolol and metoprolol. Individuals coadministered metoprolol with a cytochrome P450 2D6-inhibiting SSRIs, or those who are slow metabolizers of debrisoquine hydroxylase may exhibit elevated plasma concentrations of metoprolol.

Coadministered agents that alter hepatic blood flow are also predicted to increase plasma concentrations of orally administered metoprolol and propranolol. Agents that inhibit hepatic enzymes and/or reduce hepatic blood flow will exert an opposite effect.

β-Adrenergic receptor antagonists may alter the pharmacokinetics of other agents by reducing hepatic blood flow and inhibiting hepatic oxidative metabolism. Propranolol may increase the blood concentration of chlorpromazine by inhibiting its metabolism. Propranolol may also inhibit the metabolism of coumarin anticoagulants.

Pharmacodynamic interactions with β-adrenergic receptor antagonists include cardiac depression effects and potentiation of postural hypotension with coadministered antiarrhythmics and vasodilators.

Laboratory Interference

Pindolol may elevate liver transaminases, alkaline phosphatase, lactate dehydrogenase, and serum uric acid; pindolol rarely reduces bilirubin. Cases of thrombocytopenia and leucopenia have been described with β-adrenergic receptor antagonists.

DOSAGE AND ADMINISTRATION

For disorders in which a central effect is desired (e.g., violence), a more lipophilic agent (e.g., propranolol) should be considered. For peripheral side effects associated with psychotropic medication use, less lipophilic agents should be considered.

Propranolol is usually initiated orally at 10 mg t.i.d. or 20 mg b.i.d. increasing by approximately 20 to 30 mg per day until the desired effect is achieved. The patient's pulse and blood pressure readings should be taken regularly, and the agent should be withheld if the pulse is less than 50 beats per minute, the systolic blood pressure is less than 90 mm Hg, or the patient manifests CNS symptomatology. Propranolol should be tapered by approximately 40 to 60 mg daily until 60 mg per day is reached, after which time the drug should be tapered 10 to 20 mg per day every 3 to 4 days. β-Adrenergic receptor antagonists should not be discontinued abruptly as severe exacerbation of angina and the occurrence of myocardial infarction have been reported in patients with pre-existing cardiovascular disease following abrupt discontinuation of propranolol therapy.

Pindolol is initiated at 2.5 mg t.i.d., and increases are tolerated up to a maximum of 60 mg per day. Nadolol is initiated at 40 mg per day, increasing to 80 mg per day as tolerated. Atenolol is initiated at 50 mg per day and can be increased to 100 mg per day. Rarely an atenolol dose of up to 200 mg per day is used. The effective dosing range of metoprolol is 100 to 450 mg. The initiation dose is 100 mg; dosing beyond 450 mg has not been studied.

33.9 GABA Enhancers

33.9a Barbiturates and Similarly Acting Substances

Steven L. Dubovsky, M.D., and Dori Marshall, M.D.

Stories of substances that depress consciousness date back to antiquity. The first commercially available sedative-hypnotics were the bromides, which were introduced in 1853. These substances had unpredictable effects and were frequently taken in overdose. In 1864, Adolf Johann Friedrich von Baeyer (who eventually won the Nobel Prize for his contributions to the development of organic chemistry) synthesized barbituric acid. The name barbituric acid comes from a combination of uric acid, which Bayer had been studying, and the name Barbara. The name Barbara was apparently chosen because it was the name of a close friend of von Baeyer or because he celebrated the new compound by visiting a tavern on St. Barbara's Day. Barbituric acid had no sedative or hypnotic properties, but diethylbarbituric acid or barbital was introduced in 1903 by Fisher and Von Mering as the first sedative barbiturate. Barbital was marketed as Veronal, after Mt. Verona, where Fisher had been traveling. Many other barbituric acid derivatives (barbiturates) were subsequently developed, beginning with phenobarbital in 1912, followed by a number of related compounds such as chloral hydrate and paraldehyde.

Barbiturates were the first effective antiepileptic medications and the first injectable anesthetics. Barbiturates were widely used as sedative-hypnotic agents in the first half of the 20th century. However, by the 1950s and 1960s, these medications had become a common means of suicide, as was publicized in the deaths of celebrities such as Marilyn Monroe and Judy Garland. After additional problems such as high addiction potential, significant risk of respiratory depression, and a narrow therapeutic index became apparent, allegedly "safer" alternatives such as methyprylon, glutethimide, ethchlorvynol, and methaqualone were introduced. These drugs turned out to have the same problems, however, and the entire group of agents was eventually supplanted by the benzodiazepines, the first one of which (chlordiazepoxide) was synthesized in 1955 and marketed in 1960. Glutethimide, methaqualone, and other derivatives were withdrawn from the market because of significant toxicity and risks of misuse. Barbiturates are still used clinically, most frequently in anesthesia, including for ECT, for detoxification from alcohol or other sedative-hypnotics, as anticonvulsants and for promoting recovery from a cerebral hemorrhage.

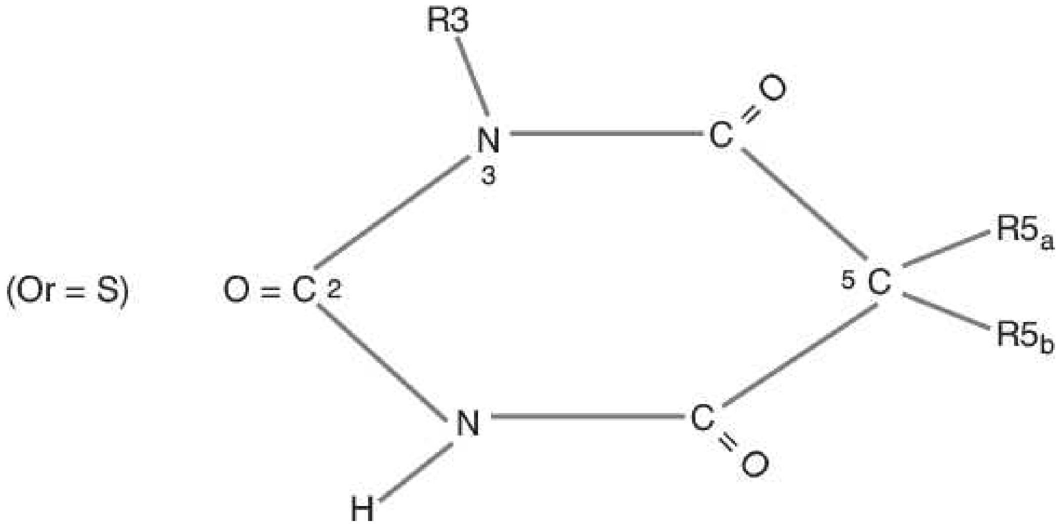

FIGURE 33.9a–1. Basic barbiturate molecular structure.

CHEMISTRY

Modern barbiturates (Fig. 33.9a–1) are derivatives of barbituric acid (2,4,6-trioxo-hexahydropyrimidine). Barbituric acid itself has no CNS depressant properties, but the presence of an alkyl or aryl group at position 5 confers sedative-hypnotic and anticonvulsant activity and various side chains alter lipophilicity, potency, and elimination. For example, a sulfur group at position 2 (Fig. 33.9a–1) produces thiobarbiturates, which have different lipid solubility and, therefore, different duration of action, latency of action, metabolism, and potency compared with other barbiturates.

PHARMACOLOGIC ACTIONS

Pharmacokinetics

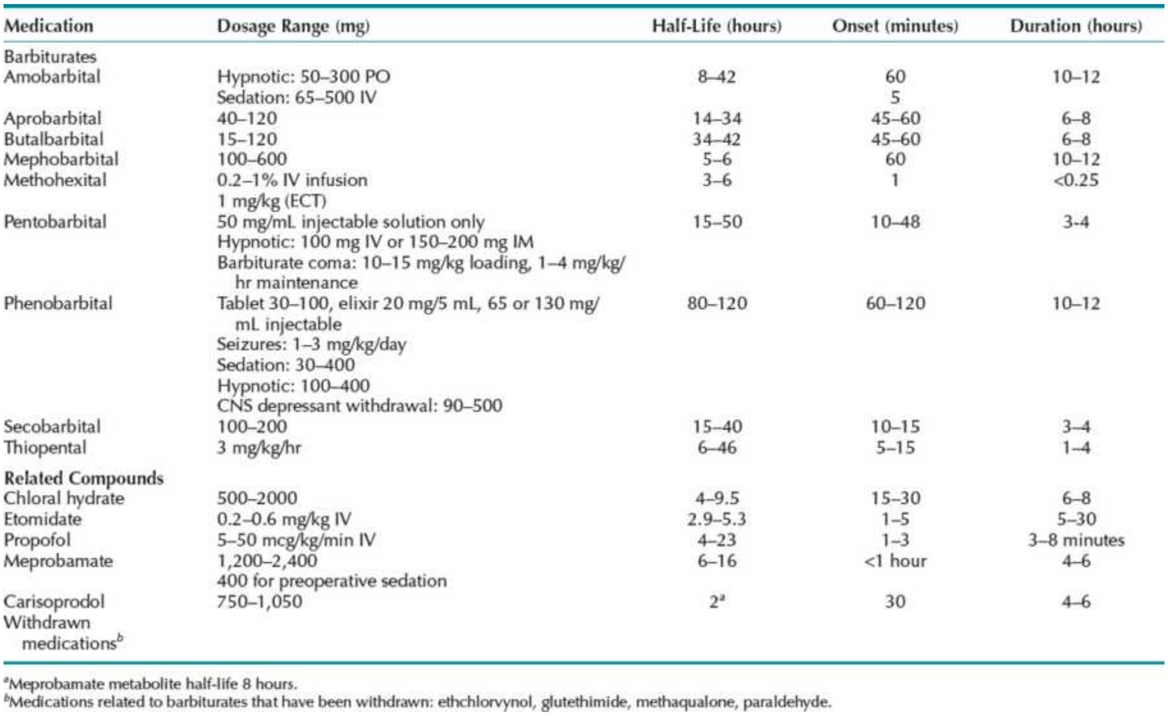
Absorption. The barbiturates are administered orally when used as sedative-hypnotics and chronic anticonvulsants and parenterally when used for anesthesia and for the treatment of status epilepticus. The intramuscular route is sometimes used for the diagnosis and early treatment of CNS depressant withdrawal in agitated patients. Oral doses of barbiturates are rapidly and completely absorbed from the small intestine. The onset of action after oral administration ranges from 10 to 60 minutes, depending on the preparation and stomach contents. Barbiturates with greater lipid solubility and protein binding and a high pKa, have a more rapid onset and a shorter duration of action. When administered intravenously (IV), the onset of action is immediate.

Distribution. Barbiturates are widely distributed and readily cross the blood–brain barrier. Barbiturates vary in their lipid solubility and their binding to plasma proteins. More lipophilic compounds such as thiopental and methohexital are 80% protein-bound, whereas less lipophilic compounds (such as phenobarbital) are only 20% to 40% protein bound. More lipid-soluble barbiturates are more rapidly distributed to the brain, resulting in a rapid onset of action. Rapid efflux from the brain along a concentration gradient then leads to a short duration of action. Some weak acids, such as warfarin or aspirin, can displace barbiturates from plasma proteins, augmenting their CNS effects.

Metabolism and Elimination. Most barbiturates are metabolized almost completely in the liver by cytochrome P450 microsomal enzymes. However, a significant amount of phenobarbital is excreted unchanged by the kidney. Urinary excretion of phenobarbital, which has a low pKa, can be increased five- to tenfold by alkalinization of the urine. This approach will not work for short-acting barbiturates because they have higher pKas, more protein binding, and more metabolism to inactive products in the liver. The biotransformation that is largely responsible for the termination of barbiturate activity is the oxidation of radicals at C5. N-glycosylation is also an important metabolic pathway that, in some instances, yields active metabolites. Metabolism and elimination are more rapid in young people than in the older adults, infants, and pregnant women. Metabolism is slowed, increasing the elimination half-life, in chronic liver disease. Elimination half-lives for some barbiturates are summarized in Table 33.9a–1.

Many barbiturates induce their own metabolism as well as the metabolism of other drugs. One consequence of this phenomenon is decreased elimination half-life and declining serum levels, and effect with repeated administration. Phenobarbital induces CYP2- and 3A isoenzymes, resulting in substantially increased metabolism and decreased effect of beta-blockers, corticosteroids, doxycycline, estrogen, phenothiazines, tricyclic and a number of newer antidepressants (e.g., fluoxetine, paroxetine, bupropion), quinidine, and other anticonvulsants.

Table 33.9a–1.
Dose Range, Elimination Half-Life, and Onset and Duration of Action of Some Barbiturates and Related Compounds



Medication	Dosage Range (mg)	Half-Life (hours)	Onset (minutes)	Duration (hours)
Barbiturates				
Amobarbital	Hypnotic: 50–300 PO Sedation: 65–500 IV	8–42	60 5	10–12
Aprobarbital	40–120	14–34	45–60	6–8
Butalbarbital	15–120	34–42	45–60	6–8
Mephobarbital	100–600	5–6	60	10–12
Methohexital	0.2–1% IV infusion 1 mg/kg (ECT)	3–6	1	<0.25
Pentobarbital	50 mg/mL injectable solution only Hypnotic: 100 mg IV or 150–200 mg IM Barbiturate coma: 10–15 mg/kg loading, 1–4 mg/kg/hr maintenance	15–50	10–48	3-4
Phenobarbital	Tablet 30–100, elixir 20 mg/5 mL, 65 or 130 mg/mL injectable Seizures: 1–3 mg/kg/day Sedation: 30–400 Hypnotic: 100–400 CNS depressant withdrawal: 90–500	80–120	60–120	10–12
Secobarbital	100–200	15–40	10–15	3–4
Thiopental	3 mg/kg/hr	6–46	5–15	1–4
Related Compounds				
Chloral hydrate	500–2000	4–9.5	15–30	6–8
Etomidate	0.2–0.6 mg/kg IV	2.9–5.3	1–5	5–30
Propofol	5–50 mcg/kg/min IV	4–23	1–3	3–8 minutes
Meprobamate	1,200–2,400 400 for preoperative sedation	6–16	<1 hour	4–6
Carisoprodol	750–1,050	2[a]	30	4–6
Withdrawn medications[b]				

[a] Meprobamate metabolite half-life 8 hours.

[b] Medications related to barbiturates that have been withdrawn: ethchlorvynol, glutethimide, methaqualone, paraldehyde.

Pharmacodynamics

Mechanism of Action. Barbiturate-binding sites are allosterically linked to other binding sites that comprise the GABAA–benzodiazepine complex on the anionic chloride ion channel on postsynaptic neuronal membranes. Whereas benzodiazepines alter GABA receptor affinity to increase the frequency of chloride ion channel openings, barbiturates increase the duration of openings of the chloride ion channel.

Most barbiturate sedative-hypnotics bind to GABAA receptors containing the alpha1 subunit, but etomidate produces sedation at the beta2 subunit and anesthesia at the beta3 subunit. In addition to binding to P- and Q-type calcium channels to inhibit the influx of depolarizing positive charges, barbiturates, along with etomidate, and propofol, inhibit NMDA and amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA)/kainate receptors as well as reducing glutamate release and increasing presynaptic glutamate reuptake. Barbiturates and related drugs inhibit pentameric ligand-gated excitatory cation channels such as those linked to nicotinic cholinergic receptors by acting at binding sites in the closed state of the cation channel, stabilizing the closed state and reducing neuronal excitability. At higher concentrations used for anesthesia, barbiturates appear to reduce the repetitive firing of neurons by inhibiting voltage-dependent sodium and possibly potassium channels. Barbiturates and related drugs may also affect the binding of other drugs to their binding sites. For example, propofol potentiates the binding of pentobarbital to its receptor on the GABAA–benzodiazepine complex.

Blood Concentrations. Although barbiturates have greater acute effects at higher plasma concentrations, tolerance is common; therefore, the same plasma level may produce drastically different actions at different times in the same individual and from one individual to another. Tolerance to barbiturates, which may not have a linear relationship to dose, is associated with downregulation and desensitization of receptors, structural changes in receptors, and uncoupling of the drug from the receptor, in addition to declining serum levels due to autoinduction of metabolism. Tolerance to anesthetics such as thiopental may occur within minutes. The Mellanby effect refers to acute tolerance that results in more clinical effects when serum levels are increasing than when they are decreasing. Cross-tolerance of barbiturates and all other drugs acting on the GABAA receptor is common. One mechanism of cross-tolerance is the reduced affinity of barbiturate-binding sites induced by tolerance to benzodiazepines.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Because barbiturates were introduced as hypnotics before the advent of validated instruments of assessment of insomnia and treatment response, there are few reliable controlled studies of this application. Although extensive clinical experience indicates that barbiturates are effective as sedative-hypnotics, the rapid development of tolerance, a frequent rebound of insomnia and REM sleep, multiple drug interactions, and a narrow therapeutic index make these drugs poor initial choices for insomnia. Barbiturates and related compounds are only approved for short-term treatment of insomnia and are at best second- or third-line treatment for severe acute insomnia after benzodiazepines, nonbenzodiazepine GABAA agonists, and sedating antidepressants or antipsychotic drugs.

Although the sedative and antiarousal actions of barbiturates may secondarily moderate anxiety, there is little evidence from any controlled studies of reliable benefit for any specific anxiety disorder. Benzodiazepines and antidepressants, especially SSRIs, are generally recommended as first-line agents in the treatment of anxiety disorders.

There is variable evidence supporting the use of barbiturates in the treatment of a number of neurologic conditions. Phenobarbital is considered a safe, economical, and effective treatment for generalized tonic–clonic seizures and simple and complex partial seizures. Because barbiturates reduce intracranial pressure (ICP), they are sometimes used as adjunctive acute treatments following head injury. Use of barbiturate infusion, usually pentobarbital, is sometimes used—along with various neurosurgical approaches—to manage increased ICP in pediatric severe traumatic brain injury (TBI) after first-line therapies have failed. However, a systematic review found no evidence that the reduction of ICP by barbiturates is associated with a reduction in morbidity or mortality. In addition, hypotension caused by the barbiturate can reduce cerebral perfusion pressure. Barbiturate-containing analgesic products are often prescribed for headaches (including vascular, tension, and mixed migraines) as well as premenstrual and postpartum pain. A Canadian review of the literature found that there was no evidence of a clinically important enhancement of analgesia by adding a barbiturate to an established analgesic, and the risks of dependence, misuse and withdrawal outweigh any benefit from sedation caused by the barbiturate. In addition, the use of barbiturates 5 days or more per month is associated with rebound headaches and the progression of headache disorders.

Barbiturates are still routinely used to induce anesthesia. Methohexital is the most frequently utilized anesthetic agent for ECT. Propofol, etomidate, and thiopental have also been found to be effective for this indication. Propofol has increasingly been used for outpatient anesthesia (e.g., for colonoscopy), but this application requires careful monitoring and benzodiazepines such as midazolam may be safer. Fentanyl appears to be an equivalent anesthetic agent to propofol, but it is associated with better postoperative pain control.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Barbiturates depress the activity of all excitable tissues. The CNS is more sensitive to these effects than are peripheral tissues. Barbiturates produce varying degrees of CNS depression, from mild sedation to general anesthesia. Although all barbiturates have anticonvulsant properties at anesthetic doses, only phenobarbital and mephobarbital have anticonvulsant properties at subhypnotic doses. Barbiturates depress the sensory cortex, decrease motor activity, alter cerebellar function, and produce drowsiness, sedation, and sleep. At subanesthetic doses, barbiturates may increase the reaction to painful stimuli by suppressing inhibitory pain centers.

Barbiturates decrease sleep latency and the number of awakenings, and they increase total sleep time, but they also suppress REM sleep as well as stages III and IV sleep. As a result, any increase in sleep is not necessarily restorative. Tolerance develops to the hypnotic effect, often within a few days. Within 2 weeks of continued use, the effects of barbiturates on prolonging sleep are virtually eliminated, and doses must be increased to obtain the same effect. Abrupt discontinuation of barbiturates results in rebound insomnia and REM rebound with nightmares.

In the peripheral nervous system, barbiturates selectively inhibit transmission in autonomic ganglia and reduce nicotinic excitation. This results in a reduction of blood pressure, at times with clinically significant hypotension.

Respiratory drive and sleep–wake rhythms are depressed by barbiturates. At therapeutic barbiturate doses, the neurogenic drive for wakefulness is reduced to the level that promotes normal sleep. However, at three times the hypnotic dose, the wakefulness drive is virtually eliminated. These doses also appear to reduce the hypoxic drive for breathing, exacerbating sleep apnea. Protective reflexes are not depressed until sedation produces severe respiratory depression, causing one of the most serious complications of barbiturate anesthesia, namely laryngospasm. These factors may have contributed to the death of the entertainer Michael Jackson after he was administered escalating doses of propofol in an attempt to suppress tolerance, rebound insomnia, and withdrawal.

Barbiturate effects on the cardiovascular system are generally mild. At sedative-hypnotic doses, barbiturates produce a slight decrease in blood pressure and heart rate but usually no more than that seen during normal sleep. This reduction in blood pressure and heart rate can be exaggerated in patients with congestive heart failure or hypovolemic shock. IV barbiturate administration may cause ventricular arrhythmias.

The primary effect of barbiturates on the liver is the induction of microsomal enzymes. The induction of cytochrome P450 isoenzymes increases the metabolism of a number of medications and other substances, including many anticonvulsants, antidepressants, antipsychotic drugs, and steroid hormones. In addition, the autoinduction of P450 enzymes accelerates the metabolism of barbiturates themselves.

THERAPEUTIC INDICATIONS

Many barbiturates, including amobarbital, butabarbital, aprobarbital, pentobarbital, and secobarbital, are indicated for oral use as sedatives or hypnotics (Table 33.9a–1). However, their use in insomnia should be limited to 2 weeks or less because they lose much of their effectiveness after this period of time, followed by frequent tolerance, rebound and misuse.

Seizure Disorders

Barbiturates are standard anticonvulsants used for prophylaxis of seizures and treatment of status epilepticus. These medications inhibit epileptic foci and reduce the spread of seizure activity. Phenobarbital, the most commonly used barbiturate, is often administered along with other anticonvulsant classes. Phenobarbital is effective for simple and complex partial seizures, as well as generalized tonic-clonic seizures. For status epilepticus, intravenous benzodiazepines (e.g., diazepam) and phenytoin are first-line treatments. However, if seizure activity continues, IV phenobarbital (20 mg/kg) at a rate no faster than 100 mg/min may be administered. A systematic review and meta-analysis concluded that propofol is superior to barbiturates in controlling refractory status epilepticus and shortening the average duration of tracheal intubation. Because it raises the seizure threshold, ECT has been used for refractory status epilepticus.

Anesthesia

The first barbiturate to be used intravenously was a combination of barbital and diallylbarbituric acid known as Somnifen, which was synthesized in 1920 for obstetrical use and introduced as an agent for surgical anesthesia in 1924. Some surgeons administered the barbiturate intravenously as preanesthesia prior to inhalational anesthesia. This and similar agents were limited by slow onset of action and long recovery times. The first short-acting barbiturate was hexobarbital (Evipan), which was introduced as an induction agent in 1932. Amobarbital (sodium amytal) was introduced into American anesthesia practice in the late 1920s. Thiopental came into widespread use in the 1930s, establishing barbiturates as popular anesthetic agents. The addition of a methyl group to the barbituric acid substrate led to the development of methohexital, which proved to be shorter acting than other barbiturates and therefore preferable for briefer procedures, including dental procedures and ECT.

In general, the brief duration of ECT requires shorter-acting agents. Methohexital is still the first-line agent for anesthesia during ECT. The rapid onset and offset of action of etomidate make it an appropriate choice. Thiopental is longer acting, and its anticonvulsant properties can interfere with the induction of therapeutic seizures. Propofol may also shorten seizure duration. The proconvulsant action of ketamine could make it useful when seizures are difficult to induce. Multiple reports of an acute antidepressant effect of ketamine led to the expectation that it might augment ECT, but an additive effect of ketamine and ECT has not been confirmed empirically, and side effects such as dissociation, psychosis and possibly excitotoxicity with ongoing use are precautions in its use in psychiatry. A randomized comparison of etomidate, propofol, and thiopental found all to be relatively free of important cardiovascular effects in otherwise healthy patients undergoing ECT. Etomidate raises the seizure threshold less than propofol, and its use is associated with the need for a lower stimulus dose to produce adequate seizures.

Cerebral Lateralization

The intracarotid amobarbital procedure (IAP or Wada Test) is used to determine the lateralization of memory and language in order to predict the risks of amnesia and aphasia following epilepsy surgery. First, amobarbital (100 to 200 mg) is administered directly into the internal carotid artery contralateral to the epileptic focus, and the next day it is administered ipsilateral to the focus. Temporarily anesthetizing each hemisphere separately interrupts all functions localized to that hemisphere, such as naming, repetition, following commands and remembering. By comparing the impact of injections on the two sides, it is possible to predict whether surgery on that side is likely to interrupt the functions tested. Methohexital is not as reliable as amobarbital for this purpose.

Narcoanalysis

Since the 1930s, interviews with amobarbital have been performed to help to distinguish between psychogenic and neurologic symptoms when symptoms disappear during the amobarbital session and to elicit a history from a mute patient. The amobarbital interview has been used as a diagnostic tool in cases of mutism, stupor, unexplained confusion, and suspected malingering and conversion disorder. The procedure involves administering IV amobarbital slowly in doses up to a maximum of 500 mg. Initial responses include dizziness, blurred vision, and fatigue, followed by drowsiness and mild euphoria. It is during this phase that the interview may be most fruitful. If the dose is increased further, the patient is likely to fall asleep. Controlled studies of the amobarbital interview are difficult to conduct, but clinical experience suggests that it may reduce inhibitions, help an uncommunicative patient has about communicating with the clinician, and clarify confusing psychogenic symptoms. The amobarbital interview should only be performed if personnel and equipment for resuscitation are present and increased intracranial pressure is not suspected.

Diagnosing Withdrawal From Sedative-Hypnotics

Because CNS depressants are cross-reactive through actions at different sites on the GABAA receptor complex, the barbiturate tolerance test can be used to determine the degree to which tolerance exists to barbiturates, related drugs, benzodiazepines and alcohol, alone or in combination. In the presence of signs and symptoms of CNS depressant withdrawal, a test dose is administered of 200 mg of pentobarbital or 30 to 100 mg of phenobarbital. If the patient is grossly intoxicated an hour later, tolerance is not significant, and a withdrawal syndrome is unlikely. For less marked intoxication after the test dose (e.g., dysarthria and ataxia without evidence of obtundation), further doses are administered every 1 to 2 hours for pentobarbital or every 1 to 4 hours for phenobarbital until signs and symptoms of withdrawal are completely suppressed, distinct intoxication emerges, or until a maximum dose (e.g., 480 mg of phenobarbital or 500 mg of pentobarbital) is reached. The barbiturate is then administered in a divided dose, and the dose is decreased by about 10 percent per day as determined each day by the emergence of signs of toxicity (e.g., gross sedation, nystagmus) or withdrawal (e.g., hypertension, hyperreflexia) charted before and after each dose of barbiturate. Such determinations can be difficult because features such as confusion, dysarthria and hypotension can occur with intoxication or withdrawal, although nystagmus is usually specific to intoxication. Prospective charting of specific features facilitates making the distinction. Because it is available in an injectable form and it has a longer duration of action, phenobarbital is preferred as the withdrawal agent (with 30 mg of phenobarbital being roughly equivalent to 100 mg of pentobarbital), whereas either drug can be used to diagnose tolerance.

Delirium Tremens

Oral or IV phenobarbital, sometimes in doses as high as 1,500 to 2,000 mg on the first day, has been used as alternatives to benzodiazepines in the treatment of alcohol withdrawal delirium. Propofol in doses up to 4 mg/kg/hr has been used for severe, intractable withdrawal delirium, especially if the patient is intubated. In such severe cases, ECT might also be considered since it is an effective treatment for delirium of any cause.

Neuroprotection

Because they reduce neuronal electrical activity and energy demands and antagonize NMDA and AMPA receptors, barbiturates alone or with hypothermia have been used for years to protect the brain during surgery and sometimes following severe CNS injury, especially intraoperative stroke. If damage is not severe, brain oxygen levels are increased by pentobarbital. However, any protective action is short-term because these medications also have systemic immunosuppressive properties related to inhibition of T-cell calcineurin/ calmodulin function, and their use for this purpose has been supplanted by newer anesthetic agents such as isoflurane. Barbiturates have been used in some settings to reduce intracranial pressure following TBI, but these medications can also cause hemodynamic instability that reduces cerebral perfusion. Despite some positive in vitro data, no compelling evidence has emerged of an actual clinical benefit of barbiturates following intraoperative stroke. Data on improved outcomes after barbiturate treatment following TBI have not been robust. Animal studies suggest that propofol and related medications may reduce beta amyloid-induced mitochondrial dysfunction and improve cognition. However, demented patients may be more susceptible to adverse cognitive effects, although they appear not to have increased vulnerability to respiratory depression after anesthesia. By combining nucleic acid bases, heterocyclic amines, and barbiturate derivatives, a group of nucleobase-based barbiturates have been developed that appear to have antioxidant properties that protect against DNA damage in laboratory studies. Magnesium has also been shown to have some promise in providing neuroprotection after surgical procedures associated with ischemia and also among patients treated within 12 hours of acute ischemic stroke, but there is conflicting evidence of clinical benefit of this effect.

PRECAUTIONS AND ADVERSE REACTIONS

Barbiturate overdoses can be dangerous: 1 g (10 pills) causes serious toxicity, and 2 g or more may be fatal. Acute overdose is manifested by dysarthria, ataxia, incoordination, CNS depression, respiratory depression, respiratory acidosis, tachycardia, hypotension, hypothermia, and oliguria. Overdoses of specific drugs are associated with additional features. For example, chloral hydrate and ethchlorvynol produce unique odors; meprobamate and chloral hydrate cause cardiac arrhythmias; methaqualone, propofol, and etomidate induce myoclonus; chloral hydrate and methaqualone can cause GI bleeding, and glutethimide produces anticholinergic signs. Intravenous overdoses can produce additional toxicity associated with the material in which the drug is diluted. Propylene glycol in intravenous formulations of etomidate (and lorazepam) can cause hypotension, hyperosmolar states, and metabolic acidosis.

Because death from barbiturate overdose is caused by cardiorespiratory collapse, treatment involves supporting the airway, oxygenation, and cardiovascular functions. Volume expansion is used to treat severe hypotension, with vasopressors only added when this approach does not work or causes volume overload. Beta-adrenergic antagonists may be helpful for tachyarrhythmias. Activated charcoal with a protected airway can be helpful, although controlled research has not confirmed the benefit of this practice. The benzodiazepine receptor antagonist flumazenil, which can reverse benzodiazepine overdoses, is not useful for overdoses of barbiturates because they act on a different receptor on the GABA receptor chloride ion channel complex. Severe barbiturate overdose can be successfully treated with hemodialysis, which is used earlier in the course of chloral hydrate overdoses with lifethreatening arrhythmias and prolonged intubation after ingestion of large quantities of phenobarbital.

The older adutls, children and those with brain damage may develop paradoxical excitation in response to barbiturates and other CNS depressants. Cases have been reported in which phenobarbital caused or exacerbated hyperactivity when used chronically in younger children, and the hyperactivity did not remit when the medication was withdrawn.

As noted earlier, barbiturates are often prescribed in combination with analgesics (Table 33.9a–2). However, they may exacerbate pain in some patients, and there is no evidence that they have analgesic properties. On the other hand, headache preparations containing butalbital are clearly implicated in medication overuse headaches. In this syndrome, which usually involves migraine headaches, continued use of the medication results in rebound headaches, which are then treated with more self-administered medication. Discontinuing the medication can be a challenge since rebound headaches may persist for some time after detoxification, and relapse of medication use is common.

Table 33.9a–2.
Barbiturate and Related Substance Containing Analgesics

Product Brand Name	Barbiturate Component	Other Constituents
Fiorinal with codeine	Butalbital 50 mg	Aspirin 325 mg, caffeine 40 mg, codeine 30 mg
Fioricet with codeine	Butalbital 50 mg	Acetaminophen 325 mg, caffeine 40 mg, codeine 30 mg
Esgic	Butalbital 50 mg	Acetaminophen 325 mg, caffeine 40 mg
Donnatal	Phenobarbital 16.2 mg	Atropine 0.02 mg, hyoscyamine 1 mg, scopolamine 6.5 mcg
Soma with codeine	Carisoprodol 200 mg	Aspirin 325 mg, codeine 16 mg

Hypersensitivity to barbiturates is not uncommon. Allergic reactions are most likely to occur in patients with asthma, urticaria, and other autoimmune disorders and range from local swelling to exfoliative dermatitis. Bullous lesions have occasionally been caused by phenobarbital, more frequently but not exclusively in comatose patients.

Barbiturates are contraindicated in patients with porphyria variegata or acute intermittent porphyria because they enhance porphyrin synthesis and aggravate the illness.

Barbiturate Dependence

Barbiturates rapidly induce tolerance and dependence. Dependence is most common with shorter-acting agents such as pentobarbital and secobarbital. Pre-existing substance use increases the risk of barbiturate dependence. The risk of dependence on barbiturates increases with higher doses taken for longer periods of time (e.g., 400 mg per day of secobarbital equivalent taken for 90 days or more). Patients who have become dependent on barbiturates take on average 1,500 mg per day.

As is true of benzodiazepines and other CNS depressants, rapid discontinuation of barbiturates induces withdrawal syndromes that include anxiety, tremor, myoclonus, unstable blood pressure, dizziness, nausea, vomiting, agitation, and insomnia. Seizures, delirium, coma, and death may occur in more severe cases. Signs and symptoms of barbiturate withdrawal begin sooner and abate more rapidly after discontinuation of shorter-acting agents. As noted earlier, withdrawal from barbiturates with or without other CNS depressants that act on the GABA receptor complex can be diagnosed with the barbiturate tolerance test and treated with a gradual taper of phenobarbital.

Teratogenicity

Barbiturates inhibit progesterone synthesis by inhibiting cholesterol transport, which can impair the maintenance of pregnancy. In addition, barbiturates readily cross the placental barrier, and there is some evidence that maternal consumption of barbiturates is associated with fetal abnormalities, especially cardiac anomalies. Newborns of mothers who use barbiturates in the third trimester may develop neonatal abstinence syndromes. Barbiturates are excreted in breast milk and may produce sedation and withdrawal syndromes in nursing infants. Concerns have been expressed about potential adverse effects of barbiturate and related anesthetics during pregnancy, but exposure is brief, and any minimal risk is balanced by the adverse impact on the pregnancy of the condition for which anesthesia is administered, including depression if anesthesia for ECT is planned. Otherwise, ongoing use of barbiturates should be avoided during pregnancy unless a compelling indication such as intractable epilepsy is present.

Psychomotor Impairment

As is true of benzodiazepines, barbiturates can impair driving in addition to causing sedation and an intoxicated feeling. The degree of impairment is similar to that of alcohol.

DRUG INTERACTIONS

Complications from the concomitant use of barbiturates and other medications most often result from additive CNS depressant effects or from induction by the barbiturate of hepatic microsomal enzymes. Additive

CNS depression occurs with alcohol, antihistamines, benzodiazepines, and other sedative-hypnotics. Metabolism of vitamins D and K are accelerated by barbiturates, which may reduce dietary calcium absorption. Induction of hepatic metabolism may decrease the effectiveness of oral anticoagulants such as warfarin, corticosteroids, and estrogen. The latter effect may result in the failure of oral contraceptives. Phenobarbital interferes with oral absorption of griseofulvin, thereby decreasing blood levels and possibly reducing therapeutic response. Phenobarbital induces metabolizing enzymes for doxycycline, phenytoin, TCAs, and some antipsychotic drugs. Valproate may decrease barbiturate metabolism, thus reducing the dose of barbiturate needed, while monoamine oxidase inhibitors may prolong the effects of barbiturates by inhibiting their metabolism. In view of the frequent induction of CYP450 enzymes by barbiturates, it is important to look for an altered efficacy of any P450 substrate to which barbiturates are added.

LABORATORY INTERFERENCES

Routine toxicology screening does not identify barbiturates. Barbiturates have been reported to produce a false-positive phentolamine test result. Acceleration of dexamethasone metabolism by phenobarbital results in a false-positive dexamethasone suppression test. Induction of metabolism by barbiturates of metyrapone, a cortisol synthesis inhibitor that normally increases the production of corticotropin-releasing hormone and corticotropin (ACTH) and is used to assess Cushing disease and other forms of hypercortisolism, can lead to false-negative tests due to reduced metyrapone levels and inadequate suppression of cortisol production.

DOSAGE AND ADMINISTRATION

Dosages and routes of administration are given in Table 33.9a–1. Table 33.9a–2 lists doses of some preparations that contain barbiturates in combination with other medications.

NONBARBITURATE, NONBENZODIAZEPINE SEDATIVE-HYPNOTIC AGENTS

Chloral Hydrate

Chloral hydrate was introduced in 1832. It was widely used in the late 19th century as a sedative and hypnotic. Chloral hydrate was also used to treat many psychiatric illnesses, such as anxiety, psychosis, and mania until more effective treatments were introduced. As reports of overdose deaths accumulated, by 1910, it was considered to be more dangerous than heroin or opium. The routine use of chloral hydrate as a sedative-hypnotic has mostly been replaced by benzodiazepines and related medications, but it is still used regularly to sedate children for medical procedures. In addition, some clinicians prefer to prescribe it because it is relatively inexpensive and it is a schedule IV medication. Probably as a matter of tradition, chloral hydrate is often used as a hypnotic agent during industry-sponsored clinical trials of novel psychotropic drugs.

Chemistry. Chloral hydrate is synthesized by adding a molecule of H_2O to the carbonyl group of chloral, 2,2,2-trichloroacetaldehyde. The hypnotic effect of chloral hydrate is attributable to an active metabolite (trichloroethanol).

Pharmacologic Actions

PHARMACOKINETICS. Chloral hydrate is quickly and completely absorbed from the GI tract after oral administration. It is rapidly converted by a hepatic dehydrogenase to trichloroethanol, which has an elimination half-life of 4 to 12 hours and is metabolized by alcohol and aldehyde dehydrogenases to the inactive trichloroacetic acid; it is also conjugated with glucuronide to urochloralic acid, which is excreted by the kidney. About 10% of the total chloral hydrate dose is excreted unchanged. Plasma concentrations reach their peak in 30 to 60 minutes. Chloral hydrate and trichloroethanol are highly lipid-soluble, readily penetrate the blood–brain barrier and the placenta, and are excreted in breast milk. In newborns, the elimination half-life of trichloroethanol is around 28 hours; it decreases to 10 hours in toddlers. Repetitive dosing in infants causes drug accumulation, and trichloroacetic acid has been detected 6 days after exposure of infants to the drug is discontinued.

PHARMACODYNAMICS. Most of the pharmacologic action of chloral hydrate is attributable to its major metabolite, tricholoroethanol, which increases GABAA receptor affinity in a manner similar to barbiturates, increasing chloride ion influx and reducing neuronal excitability.

Design and Interpretation of Clinical Drug Studies. Chloral hydrate was used at one time to treat alcohol withdrawal, but the effectiveness of this application was never supported by controlled trials. Comparisons of chloral hydrate and benzodiazepines suggested equivalent efficacy for short-term treatment of insomnia, but the benefits of chloral hydrate diminished after 2 weeks due to tolerance. Concerns about genotoxicity, carcinogenesis, and lethality in overdose have led to recommendations that chloral hydrate not be used routinely as a hypnotic, especially in older people.

Chloral hydrate is often used as a sedative during pediatric procedures such as echocardiography, MRI, and other radiologic examinations. A randomized study found that chloral hydrate was as effective as midazolam in producing adequate sedation during pediatric echocardiography.

Effects on Specific Organs and Systems

CENTRAL NERVOUS SYSTEM. The CNS depressant action of chloral hydrate produces drowsiness, sedation, lightheadedness, malaise, ataxia, and nightmares. Hangover effects seen with other hypnotics are rare with chloral hydrate. Chloral hydrate has few analgesic properties and occasionally associated causes agitation when taken by patients with pain. CNS effects of an overdose of chloral hydrate are similar to an overdose of other CNS depressants. However, the lethal dose (5 to 10 g) is only 2.5 to 10 times greater than the hypnotic dose (500 mg to 2 g).

CARDIOVASCULAR SYSTEM. Chloral hydrate and trichloroethanol reduce myocardial contractility, shorten the refractory period, and increase the sensitivity of the myocardium to endogenous catecholamines. As a result, most deaths from chloral hydrate poisoning are caused by cardiac dysrhythmias that are refractory to standard antiarrhythmics. Adrenergic-blocking agents may be helpful in this setting.

RESPIRATORY SYSTEM. In typical clinical doses, there is little effect of chloral hydrate on respiration. However, an overdose may cause respiratory depression.

GASTROINTESTINAL SYSTEM. Chloral hydrate may cause GI irritation, resulting in nausea and vomiting. Because GI toxicity is more likely when the medication is ingested on an empty stomach, the medication is usually taken with meals. Overdoses can cause hemorrhagic gastritis and occasionally gastric or intestinal necrosis with perforation, as well as esophagitis with stricture.

Therapeutic Indications

INSOMNIA. Chloral hydrate is indicated for the short-term treatment of insomnia. Most patients respond to a dose of 500 to 1,500 mg, with sleep taking place within 1 hour. Chloral hydrate may be helpful for some medically ill and younger patients and for some older adult patients who become agitated or confused with a benzodiazepine, but alternative treatments with a lower risk of toxicity such as suvorexant, ramelteon, sedating antidepressants and sedating antipsychotics should be considered first.

SEDATION FOR PEDIATRIC PROCEDURES. Chloral hydrate is often used to sedate children undergoing diagnostic and minor surgical procedures. In this population, it has a rapid onset of action when administered orally or rectally. Children younger than 2 do not respond as reliably. The usual dose in older children is 25 to 100 mg/kg, with a maximum dose of 1 g. Careful monitoring is necessary until the child has completely regained consciousness, especially if the dose of chloral hydrate is repeated.

PREOPERATIVE USE. Chloral hydrate can be used in low doses preoperatively to reduce anxiety associated with surgery and to induce sleep without excessively depressing respiration or the cough reflex, although close monitoring of respiratory status is important. There is no evidence that chloral hydrate is superior to benzodiazepines or z-drugs for this purpose.

Precautions and Adverse Reactions

CENTRAL NERVOUS SYSTEM. Chloral hydrate can cause sedation, dizziness, lightheadedness, confusion, and, occasionally, paradoxical excitement. The CNS depressant effect of chloral hydrate is additive to that of other CNS depressants, especially barbiturates and alcohol.

ABUSE AND DEPENDENCE. Similar to many other CNS depressants, chloral hydrate may be habit-forming, particularly in those who have a history of alcohol or other drug dependence. Tolerance and physiologic dependence may develop if chloral hydrate is used for long periods of time on a regular basis. Sudden withdrawal of chloral hydrate can precipitate a syndrome that is similar to barbiturate withdrawal and can be diagnosed and treated using the barbiturate tolerance test described above.

OVERDOSE. Signs and symptoms of overdose of chloral hydrate are similar to those of barbiturate overdose. Initial features are ataxia and lethargy, followed by stupor or coma. Pupils are initially constricted but then become dilated as the coma deepens. Toxic doses for adults are approximately 5 to 10 g. Treatment of overdose includes gastric lavage and supportive measures. Hemodialysis may be effective in promoting the clearance of trichloroethanol.

ALLERGIC REACTIONS. Allergic skin reactions have been reported with chloral hydrate, including hives, eczematoid dermatitis, and urticaria. Occasionally, its use has been associated with leukopenia and eosinophilia.

GASTROINTESTINAL SYSTEM. Chloral hydrate causes GI irritation, especially when taken on an empty stomach. Common symptoms include nausea, vomiting, diarrhea, and an unpleasant taste.

PORPHYRIA. Like the barbiturates, chloral hydrate may precipitate attacks of acute intermittent porphyria.

CARCINOGENICITY. Animal studies suggest carcinogenicity of trichloroethylene, which appears to increase the risk of hepatic and renal cancer. Research suggesting no compelling association between chloral hydrate and cancer in humans has been underpowered and has involved only short-term use of chloral hydrate.

Given these considerations, chloral hydrate is contraindicated in the presence of gastric ulcers, hepatic insufficiency, porphyria, respiratory insufficiency, use of anticoagulants, and hypersensitivity to the medication, and caution is necessary for patients who are prone to cancer.

Drug Interactions. Chloral hydrate competes with ethanol for alcohol dehydrogenase, resulting in an increase in the half-life of ethanol by concurrent chloral hydrate administration. At the same time, ethanol inhibits the conversion of chloral hydrate to trichloroethanol as well as the conjugation of trichloroethanol. The combination of ethanol and chloral hydrate (Mickey Finn or knockout drops) produces rapid unconsciousness and has been notorious for surreptitious use for criminal purposes. Chloral hydrate has an unpredictable effect on warfarin levels and may cause hypoprothrombinemia. Combining chloral hydrate with furosemide can lead to vasomotor instability due to displacement of furosemide from protein-binding sites resulting in increased free drug, resulting in vasodilation, flushing, tachycardia, sweating, and hypotension.

Laboratory Interference. Because they are radioopaque, chloral hydrate capsules may be detected on abdominal X-ray. Chloral hydrate may interfere with copper sulfate tests for glycosuria. It may also interfere with tests for urine catecholamines or 17-hydroxycorticosteroid.

Dosage and Administration. Chloral hydrate is available as a capsule, a liquid, and a suppository. Chloral hydrate capsules are formulated in 250- or 500-mg strengths. Chloral hydrate syrup is available in a 500 mg per 5 mL concentration. The oral syrup should be mixed with 4 to 8 oz of water or juice to reduce GI distress. Suppositories are formulated in 325- and 650-mg strengths. The usual adult dose for insomnia is 500 to 1,000 mg, taken 15 to 30 minutes before bedtime. Daily adult doses should not exceed 2 g. Pediatric doses vary from 25 to 100 mg/kg per dose, with a maximum dose of 1 g/day.

OTHER SEDATIVE-HYPNOTICS

Over the years, a number of medications with varying structures with actions similar to barbiturates have been used as sedative-hypnotics.

Glutethimide was introduced as an alternative to barbiturates. However, its absorption was erratic, and it had more than 14 metabolites, some contributing to toxicity. In addition, recirculation in the enterohepatic circulation contributed to fluctuating, prolonged toxicity alternating with withdrawal following overdose. Glutethimide was unique in causing anticholinergic side effects, leading to thick bronchial secretions that further compromised respiration after overdose. Psychosis, seizures, peripheral neuropathy, and ataxia occur with prolonged use. These problems led to the withdrawal of glutethimide in the United States.

Meprobamate was introduced in 1950 as a muscle relaxant. Carisoprodol (Soma), which was introduced 5 years later, is metabolized to meprobamate. Both of these propanediol carbamates have actions on the GABAA receptor and on NMDA receptors similar to the barbiturates and are used as muscle relaxants. Meprobamate can cause dysrhythmias, and it is more likely than other drugs in the group to cause euphoria. Meprobamate pills can agglutinate in the stomach to form concretions, leading to recurrent toxicity after overdose. Both meprobamate and carisoprodol can precipitate acute episodes of porphyria.

Paraldehyde was used parenterally for agitation in alcohol withdrawal, but it caused sterile abscesses, and the drug was withdrawn.

Ethchlorvynol was removed from the market because it caused severe withdrawal syndromes and was particularly lethal after overdose.

Anesthetic Agents

Propofol. Propofol is a GABAA that also induces the presynaptic release of GABA and dopamine (the latter possibly through action on GABAB heteroreceptors on dopaminergic neurons); it is also a partial agonist at NMDA and dopamine D2 receptors. Because it is very lipid-soluble, it readily crosses the blood–brain barrier, inducing anesthesia in less than 1 minute. Rapid redistribution out of the CNS terminates propofol action within 3 to 8 minutes of discontinuing the infusion. Propofol is well tolerated in conscious sedation, but it can cause acute adverse effects that include respiratory depression, apnea, and bradyarrhythmias. Prolonged infusion can cause acidosis and myopathies. The infusion liquid contains a soybean emulsion carrier that can serve as a culture medium for multiple organisms and that can impair macrophage function and cause anaphylactic reactions and hematologic and lipid abnormalities. As mentioned earlier, unmonitored use of propofol, especially for off-label indications such as insomnia, can be extremely dangerous.

Etomidate. Etomidate is a carboxylated imidazole that acts at the beta-2 and beta-3 subunits of the GABAA receptor. Etomidate has a rapid onset (1 minute) and short duration (less than 5 minutes) of action. As is true of parenteral lorazepam preparations, the propylene glycol vehicle used in etomidate infusions can cause hyperosmolar metabolic acidosis. Proconvulsant and anticonvulsant properties of etomidate can have unpredictable effects, and inhibition of cortisol release can alter hypothalamic–pituitary–adrenal axis function after long-term use.

Dexmedetomidine. Dexmedetomidine is an intravenous selective alpha-2 agonist, similar to clonidine but far more selective. While it does not act at the GABA receptor complex, it is often used as an adjunct or alternative to barbiturates and related medications. It is used for sedation in the ICU and for procedures because of sedative and analgesic actions. The former is mediated by dose-dependent postsynaptic alpha 2 receptor binding in the locus ceruleus, and the latter by alpha 2 receptor binding in the spinal cord. An open randomized controlled comparison of dexmedetomidine, superficial cervical plexus blockade or placebo prior to induction of anesthesia for thyroidectomy found both active treatments to be equivalently superior to placebo in reducing postoperative pain. Unlike agents acting on the GABA complex, dexmedetomidine does not produce respiratory depression. Low-dose intravenous dexmedetomidine can decrease mean arterial pressure; higher-dose intravenous dexmedetomidine loses alpha-2 selectivity and can cause hypertension. Common adverse effects include hypotension, hypertension, dry mouth, dizziness, and nausea; less common adverse effects include fever, cyanosis, and muscle weakness. More serious adverse involve cardiac arrhythmias. Dosage for premedication is 0.33 to 0.67 mg/kg/iv or 2.5 ug/kg IM given 15 minutes prior to surgery.

Although the safety and efficacy of dexmedetomidine in children are not established, moderately reliable evidence suggests that perioperative administration may reduce postoperative pain and agitation in juvenile patients. The mechanism of such benefits is not clear. Concerns remain with regard to bradycardia and hypotension among pediatric patients.

33.9b Benzodiazepine Receptor Agonists and Antagonists

STEVEN L. DUBOVSKY, M.D., AND DORI MARSHALL, M.D.

Alcohol has been used as a sedative since biblical times. Bromides were introduced as hypnotics in the mid-19th century. Barbital, the first barbiturate, was introduced in 1903, and phenobarbital was synthesized in 1912. In the mid-1940s, mephenesin was found to have calming properties without sedation in rodents, but it was not effective in humans; its shortcomings were overcome by the development of meprobamate, which became a blockbuster in the mid-1950s even though it did not outperform placebo in clinical trials. Because it produced tranquil feelings, barbital was called a “tranquilizer” and later a “minor tranquilizer.” In the mid-1950s, competitive pressure facilitated the synthesis of the first benzodiazepine, chlordiazepoxide. Chlordiazepoxide was approved by the FDA in 1960, followed by the approval of diazepam in 1963. By 2020, all benzodiazepines currently marketed in the United States were available as generics.

Benzodiazepines were originally introduced in the 1960s as safe alternatives to barbiturates and related drugs as anxiolytics and hypnotics. In 1975, 60 million retail prescriptions were written in the United States, or 0.38 prescriptions per person, and by 1977, benzodiazepines were the most prescribed medications worldwide for anxiety, insomnia, agitation, seizures, muscle spasm, and anesthesia premedication. Subsequently, concerns about risks, particularly of misuse, led to the view of benzodiazepines as being potentially too dangerous for anything but short-term use, an attitude that in some settings led to extensive regulation and declining use for chronic anxiety. The year after a requirement for triplicate prescribing of benzodiazepines was introduced in New York State in 1989, benzodiazepine prescriptions decreased by 60%, with the largest reduction being for the treatment of seizure disorders, while prescriptions for the more dangerous meprobamate, chloral hydrate, and butabarbital increased by 1.25%, 136%, and 30%, respectively. As benzodiazepine discontinuation syndromes due to abrupt withdrawal increased, so did overdoses of the more dangerous alternative drugs.

At about the same time, an American Psychiatric Association task force review of over 2,000 studies concluded that benzodiazepines are rarely abused, and when they are, it is usually by people who abuse other substances. Although the task force concluded that most benzodiazepine prescriptions are for appropriate indications, many practitioners abandoned benzodiazepines in favor of antidepressants. As the use of SSRIs increased for anxiety and depression, prescriptions for benzodiazepines continued to decline even though there was no evidence for the superiority of SSRIs. The preferential use of SSRIs was also driven by studies of effectiveness in the new anxiety disorders that were introduced in DSM-III, whereas benzodiazepines were generally not studied for these indications because they were off patent by the time the nomenclature changed.

Despite these developments, clinicians have continued to prescribe benzodiazepines. A national cross-sectional survey of U.S. adults (*N* = 154,171) found that the self-reported rate of filling more than 2 benzodiazepine prescriptions in a year (i.e., repeated use) increased from 1.8% in 2002 to 2003 to 2.4% in 2015 to 2016. The increase in benzodiazepine prescriptions was largely attributable to an increase in repeated rather than single prescriptions, the latter remaining essentially the same at 1% to 1.8%. The implication is that the number of people chronically taking benzodiazepines increased, not that the use of benzodiazepines increased in the general population. Another serial cross-sectional national representative survey of 386,457 office-based physician visits between 2003 and 2015 found that visits for a benzodiazepine prescription essentially doubled (from 3.8% to 7.4%) over that time. Visits to psychiatrists stayed the same, the increase being attributable to visits to primary care physicians, who prescribed benzodiazepines slightly more frequently for anxiety, depression, and neurologic indications and much more for back pain and chronic pain, and who co-prescribed benzodiazepines with narcotics and other CNS depressants (nonbenzodiazepine sedative hypnotics, muscle relaxants, and antipsychotic drugs). In 2015 to 2016, 30.6 million persons reported past-year use of benzodiazepines. Not counting the “Z-drugs” (zolpidem, zaleplon, and eszopiclone), in 2017, there were 69.8 million prescriptions or 0.215 per person. In 2019, 92 million benzodiazepine prescriptions were filled, half of them for people taking a benzodiazepine for at least 2 months. Somewhere between 25% and 76% of patients who are prescribed benzodiazepines, or 2% to 7.5% of the general population, use benzodiazepines long-term. As many as half of chronic benzodiazepine users list insomnia as the primary reason for taking the medication.

Studies of the actions of the benzodiazepines and barbiturates have led to the elucidation of the structure and function of their primary target, the GABA–benzodiazepine receptor complex. This research has led to the development of other medications that act on this complex as agonists, antagonists, and inverse agonists. Understanding benzodiazepine receptors and their interaction with linked receptors makes it straightforward to predict the actions of a diverse group of medications.

GABA–BENZODIAZEPINE RECEPTOR COMPLEX

Gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the central nervous system (CNS), interacts with ionotropic GABA heteroreceptors. The pentameric GABA receptor complex is a member of the nicotinicoid superfamily and includes 6 subunit families (α, β, γ, ρ, δ, θ) and 16 specific subunits that are encoded by separate genes and are allosterically linked to form a chloride ion channel (Fig. 33.9b–1). Several GABA receptor subtypes have been identified.

GABA_A receptor activity is regulated by a number of transmembrane proteins, some of which are linked to other receptors such as the AMPA receptor. A GABA_B receptor, which is linked by a G protein to calcium and potassium channels, is a presynaptic autoreceptor that modulates the release of GABA, glutamate, and monoamines. A structurally and functionally distinct oligomeric GABA$_C$ (also called GABA$_P$) receptor composed of five subunits in a pentameric arrangement has been identified in the retina, spinal cord, superior colliculus, pituitary, and gut. These receptors appear to be involved in the regulation of vision, memory, and the sleep–wake cycle. Drugs targeting this receptor may be useful for visual, sleep, and cognitive disorders. The balance between inhibitory GABAergic, inhibitory glycinergic, and excitatory glutaminergic systems is fine-tuned to set the responsiveness of the CNS to a host of neurotransmitters and neuromodulators.

FIGURE 33.9b–1. Components of the benzodiazepine–GABA receptor complex.

The benzodiazepine receptor complex (Fig. 33.9b–1) consists of two α, two β, and one γ subunit from a pool of α, β, γ, δ, ε, π, and θ subunits allosterically linked to the GABA receptor to form a pentameric, GABA-gated chloride ion channel. Benzodiazepines bind to an extracellular site at the α/γ interface; there is also a low-affinity benzodiazepine-binding site in the transmembrane region of the β/α interface, which is also a binding site for propofol and etomidate. Many benzodiazepines bind at multiple sites. In addition to a receptor for GABA and for benzodiazepines, the

GABA receptor complex contains receptors for a number of ligands that influence the conformation of the central anion pore (Fig. 33.9b–2A).

Interaction of the postsynaptic $GABA_A$ receptor with GABA alters the conformation of the GABA receptor, increasing chloride channel openings and allowing more negative charges into the cytosol (Fig. 33.9b–2B), hyperpolarizing it and decreasing the excitability of neurons that regulate vigilance, emotions, cognition, arousal, and muscle activity.

Occupancy of the benzodiazepine receptor does not affect the chloride ion channel directly but changes the conformation of the GABA receptor to increase its affinity for GABA, resulting in more chloride ion influx per GABA molecule (Fig. 33.9b–2C). Benzodiazepine receptor agonists, therefore, have the effect of hyperpolarizing neurons on which the receptor complex is located. A picrotoxin site associated with the benzodiazepine–GABA receptor complex reduces GABA receptor affinity, reducing chloride ion influx and tending to depolarize the same neuron. A number of other substances, including inhaled and intravenous (IV) anesthetics, barbiturates, neurosteroids and alcohol, alter $GABA_A$ receptor affinity at various binding sites, not all of which have been identified.

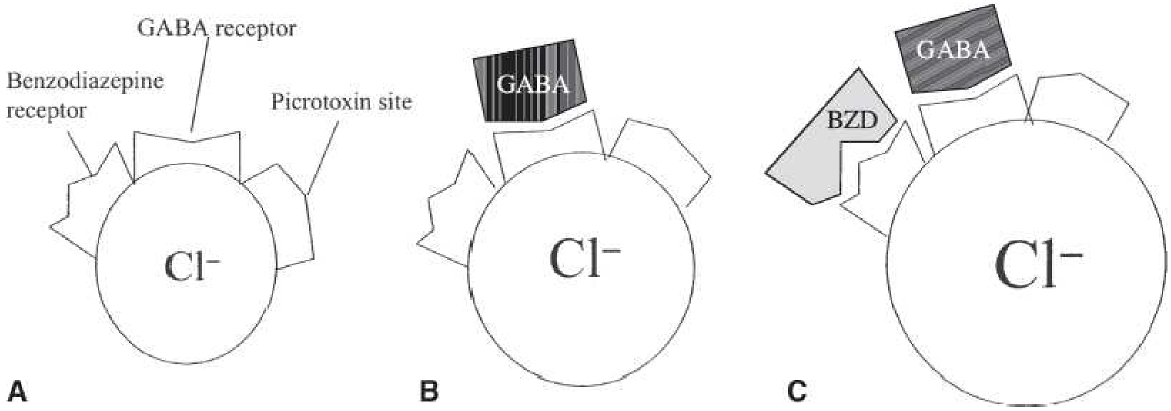

FIGURE 33.9b–2. The GABA–benzodiazepine receptor complex is comprised of multiple allosterically linked receptors that alter the conformation of the central chloride ion channel directly, or indirectly by modifying GABA receptor affinity (**A**). Occupancy of the GABA receptor increases chloride ion channel openings, hyperpolarizing the neuron (**B**). Benzodiazepine receptor occupancy increases the affinity of the GABA receptor, resulting in more chloride ion channel openings and more hyperpolarization, per molecule of GABA (**C**). The picrotoxin site has the opposite effect, reducing GABA receptor affinity and depolarizing the neuron.

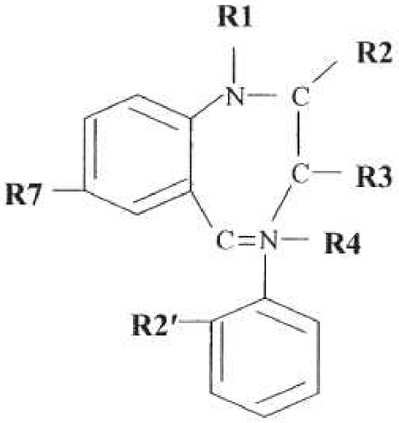
Three major benzodiazepine receptor subtypes have been described, two of them called central benzodiazepine receptors, and one called a peripheral benzodiazepine receptor (PBR). Benzodiazepine-1 (Ω-1) receptors contain the α1 subunit and are located throughout the CNS, particularly the reticular activating system, cerebellum and cerebral cortex, mediating sleep and anti-anxiety effects. Benzodiazepine-2 receptors, which are a heterogeneous group of receptors containing α2, α3, or α5 subunits, are located in the cortex, hippocampus, striatum, and spinal cord and on pyramidal neurons and mediate anxiolysis, muscle relaxation, CNS depression, sedation, and psychomotor impairment and contribute to the anticonvulsant effect. Type 3 receptors in peripheral tissues may mediate dependence.

Benzodiazepine-3 (Ω-3) receptors (PBRs, also known as translocator proteins [TSPOs]) are 18-kDa proteins with a structure and function distinct from that of the central (i.e., benzodiazepine-1 and benzodiazepine-2) receptors. PBRs are found on glial and other brain cells as well as throughout the body. These receptors, which bind benzodiazepines and the endogenous inverse agonist, are primarily located in the outer mitochondrial membrane and may contribute to tolerance and withdrawal. They are also involved in a number of complicated processes, including the synthesis of neurosteroids implicated in some psychiatric disorders and the regulation of apoptosis. The mitochondrial PBR is linked to a mitochondrial permeability transition pore (MPTP) consisting of a nonselective ion channel, which alters the transmembrane potential, leading to the release of proapoptotic proteins from the mitochondrion and other actions. The PBR plays an important role in protecting neurons from oxidative damage, which is implicated in Parkinson disease, Alzheimer disease, and negative schizophrenia. At micromolar concentrations at the receptor, PBR ligands may promote apoptosis, whereas nanomolar concentrations may, under some circumstances, interfere with it. An agonist effect at this receptor could protect against oxidative damage, whereas an inverse agonist effect (described below) could play a role in cancer chemotherapy, which enhances apoptosis. Carbamazepine binds to PBRs in lymphocytes, which may contribute to altered chemotaxis by these cells in carbamazepine-treated patients.

BENZODIAZEPINE RECEPTOR LIGANDS

Compounds that bind to the benzodiazepine receptor can have five different kinds of action. Nonselective full agonists (e.g., benzodiazepines) cause all benzodiazepine receptors to increase the affinity of GABA receptors, which increases the frequency of chloride channel openings and hyperpolarizes neurons. Selective full agonists (e.g., zolpidem) have the same effect, but this action is selective for the benzodiazepine-1 receptor. Avoiding actions on benzodiazepine-2 receptors and PBRs reduces the risk of adverse effects such as psychomotor impairment, tolerance and withdrawal, although these still occur. Dobazam is the only benzodiazepine with more affinity for benzodiazepine-2 than for benzodiazepine-1 receptors. Partial agonists bind to all benzodiazepine receptors, but they are less effective than full agonists. If low levels of an endogenous agonist for a receptor are present, partial agonists occupy the receptor and stimulate it, although less so than the full agonist. If levels of the endogenous agonist are high, a partial agonist competes for receptors but is less effective than the full agonist, essentially reducing activity at the receptor. In the case of the benzodiazepine receptor, partial agonists have a less pronounced therapeutic effect at the receptor than full agonists, but they also have less severe adverse effects. Inverse agonists occupy receptors in the same manner as full agonists, but they have the opposite effect. An inverse agonist of the benzodiazepine receptor binds to the same site as the benzodiazepines but reduces GABA receptor affinity, decreasing the frequency of chloride channel openings and depolarizing neurons. Inverse agonists produce arousal and anxiety and sometimes cause seizures and psychosis. Antagonists occupy a receptor without affecting its activity, thereby blocking the action of agonists and inverse agonists. Flumazenil is an intravenous (IV) benzodiazepine receptor antagonist used to treat benzodiazepine overdose. It has a brain half-life of 30 minutes and a terminal half-life of 1 hour, necessitating repeated doses for treatment of overdose with longer-acting benzodiazepines.

The existence of benzodiazepine receptors would appear to imply the existence of an endogenous ligand for them. In fact, there are endogenous benzodiazepine receptor ligands called endozepines that act on central and peripheral benzodiazepine receptors to participate in the regulation of arousal, neurosteroid biosynthesis, neuropeptide expression, neurogenesis, and pro-inflammatory cytokine secretion. An 86-amino acid endozepine, the gene for which is found in astroglial cells and peripheral organs, has been identified that is called diazepam-binding inhibitor (DBI) because it displaces labeled diazepam from brain-binding sites. DBI, also called acyl-CoA-binding protein (ACBP), acts as a benzodiazepine inverse agonist, promoting arousal. The function of DBI/ACBP appears to fine-tune the set point of arousal in conjunction with other endogenous substances acting on different points on the benzodiazepine–GABA receptor complex to depress or activate the CNS.



Benzodiazepine	R1	R2	R3	R7	R2′
Alprazolam	Fused triazolo ring		-H	-Cl	-H
Chlordiazepoxide	-	-$NHCH_3$	-H	-Cl	-H
Clonazepam	-H	=O	-H	NO_2	-Cl
Diazepam	-CH_3	=O	-H	-Cl	-H

FIGURE 33.9b–3. Basic benzodiazepine structure.

A number of medications and substances directly or indirectly alter the activity of the GABA–benzodiazepine receptor complex. For example, picrotoxin binds to the GABA receptor at a site distinct from the benzodiazepine receptor and reduces chloride channel openings to induce seizures. Alcohol and barbiturates have direct effects on GABA receptors and chloride channels and possibly on the picrotoxin site, reducing cortical and limbic neuronal activity. Valproate enhances GABA release, and gabapentin has unclear actions on GABAergic neurotransmission. Propofol, an IV anesthetic discussed in a separate chapter, acts at a site other than the benzodiazepine receptor to increase GABA affinity in a manner similar to benzodiazepines. Unidentified constituents of valerian, an herbal preparation used for centuries as a hypnotic and anxiolytic, seem to be GABA receptor agonists. The anticonvulsant tiagabine inhibits GABA reuptake, increasing GABA action at all GABA receptors, and the anticonvulsant vigabatrin reduces GABA breakdown. Baclofen is a $GABA_B$ agonist that reduces spasticity via an action on presynaptic receptors on excitatory spinal cord neurons. This chapter reviews medications that act primarily on the benzodiazepine-$GABA_A$ receptor complex.

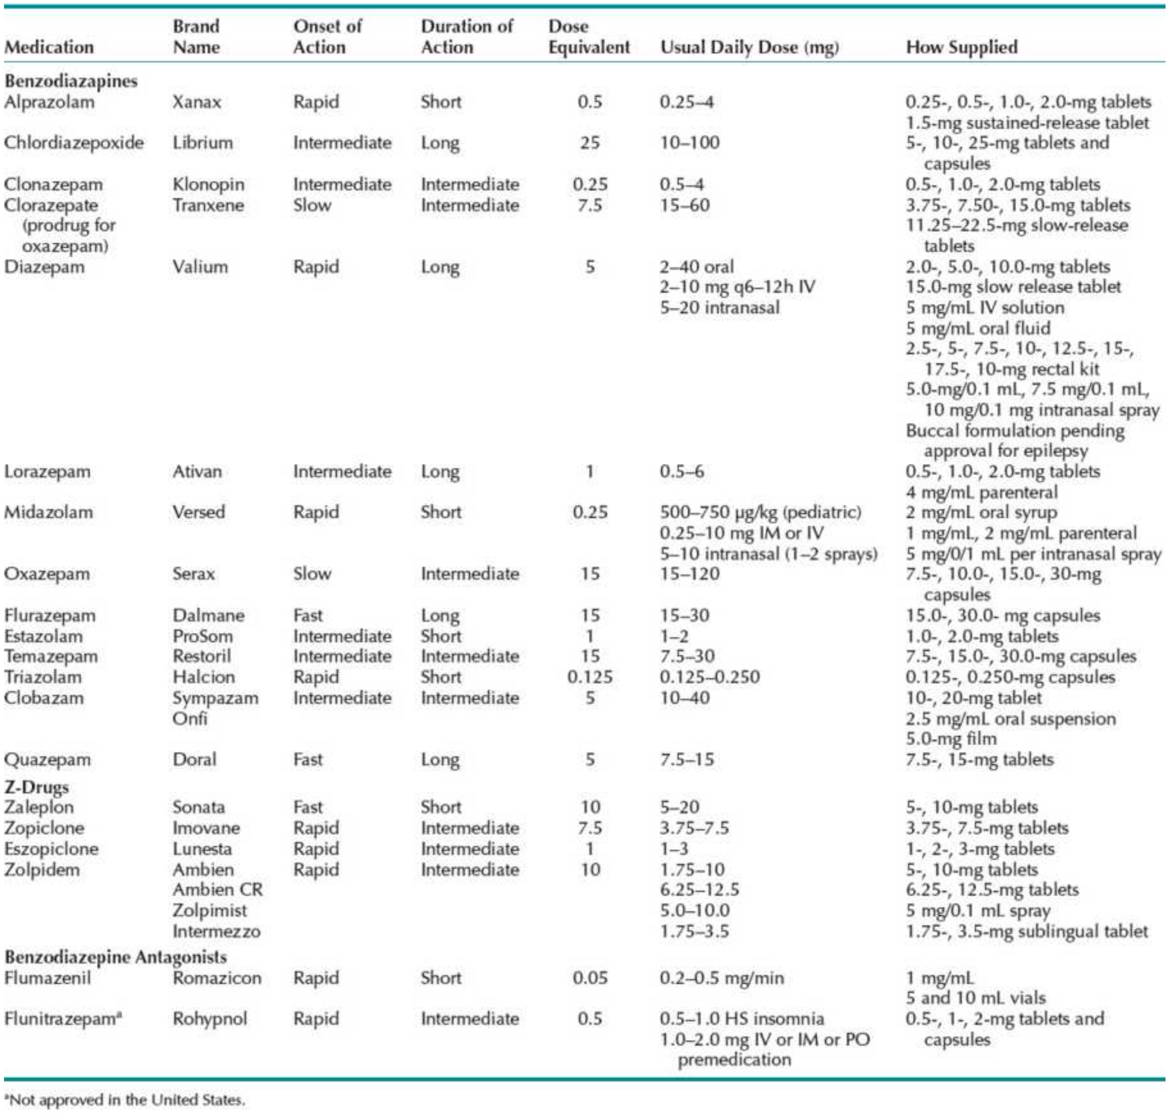
BENZODIAZEPINES

Neuroscience-Based Nomenclature (NbN)	
Alprazolam, chlordiazepoxide, clonazepam, clorazepate, diazepam, estazolam, flurazepam, flunitrazepam, lorazepam, midazolam, oxazepam, temazepam, triazolam, quazepam	
Pharmacologic Domain	GABA
Mechanism of Action	Positive Allosteric Modulator (GABA-A receptor, benzodiazepine site)

Chemistry

Benzodiazepines contain two benzene rings and a seven-member diazepine ring. Most benzodiazepines in current clinical use contain a 5-aryl substituent ring and a 1,4-diazepine ring and therefore are 5-aryl-1,4-benzodiazepines (Fig. 33.9b–3). A fused triazolo ring at positions RI and R2 on the diazepine ring in triazolobenzodiazepines such as alprazolam, triazolam, and estazolam, increases potency; the same is true of a fused imidazole ring at these positions in midazolam. Replacement of ring C with a keto substituent in position 5 and a methyl substituent in position 4 in flumazenil confers benzodiazepine antagonist properties. Clobazam, the only 1-5-benzodiazepine, is approved for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome. Benzodiazepines and other medications acting on the GABA–benzodiazepine receptor complex are listed in Table 33.9b–1.

Table 33.9b–1.
Benzodiazepines, Z-Drugs, and Benzodiazepine Antagonists



Medication	Brand Name	Onset of Action	Duration of Action	Dose Equivalent	Usual Daily Dose (mg)	How Supplied
Benzodiazepines						
Alprazolam	Xanax	Rapid	Short	0.5	0.25–4	0.25-, 0.5-, 1.0-, 2.0-mg tablets 1.5-mg sustained-release tablet
Chlordiazepoxide	Librium	Intermediate	Long	25	10–100	5-, 10-, 25-mg tablets and capsules
Clonazepam	Klonopin	Intermediate	Intermediate	0.25	0.5–4	0.5-, 1.0-, 2.0-mg tablets
Clorazepate (prodrug for oxazepam)	Tranxene	Slow	Intermediate	7.5	15–60	3.75-, 7.50-, 15.0-mg tablets 11.25–22.5-mg slow-release tablets
Diazepam	Valium	Rapid	Long	5	2–40 oral 2–10 mg q6–12h IV 5–20 intranasal	2.0-, 5.0-, 10.0-mg tablets 15.0-mg slow release tablet 5 mg/mL IV solution 5 mg/mL oral fluid 2.5-, 5-, 7.5-, 10-, 12.5-, 15-, 17.5-, 10-mg rectal kit 5.0-mg/0.1 mL, 7.5 mg/0.1 mL, 10 mg/0.1 mg intranasal spray Buccal formulation pending approval for epilepsy
Lorazepam	Ativan	Intermediate	Long	1	0.5–6	0.5-, 1.0-, 2.0-mg tablets 4 mg/mL parenteral
Midazolam	Versed	Rapid	Short	0.25	500–750 µg/kg (pediatric) 0.25–10 mg IM or IV 5–10 intranasal (1–2 sprays)	2 mg/mL oral syrup 1 mg/mL, 2 mg/mL parenteral 5 mg/0/1 mL per intranasal spray
Oxazepam	Serax	Slow	Intermediate	15	15–120	7.5-, 10.0-, 15.0-, 30-mg capsules
Flurazepam	Dalmane	Fast	Long	15	15–30	15.0-, 30.0- mg capsules
Estazolam	ProSom	Intermediate	Short	1	1–2	1.0-, 2.0-mg tablets
Temazepam	Restoril	Intermediate	Intermediate	15	7.5–30	7.5-, 15.0-, 30.0-mg capsules
Triazolam	Halcion	Rapid	Short	0.125	0.125–0.250	0.125-, 0.250-mg capsules
Clobazam	Sympazam Onfi	Intermediate	Intermediate	5	10–40	10-, 20-mg tablet 2.5 mg/mL oral suspension 5.0-mg film
Quazepam	Doral	Fast	Long	5	7.5–15	7.5-, 15-mg tablets
Z-Drugs						
Zaleplon	Sonata	Fast	Short	10	5–20	5-, 10-mg tablets
Zopiclone	Imovane	Rapid	Intermediate	7.5	3.75–7.5	3.75-, 7.5-mg tablets
Eszopiclone	Lunesta	Rapid	Intermediate	1	1–3	1-, 2-, 3-mg tablets
Zolpidem	Ambien	Rapid	Intermediate	10	1.75–10	5-, 10-mg tablets
	Ambien CR				6.25–12.5	6.25-, 12.5-mg tablets
	Zolpimist				5.0–10.0	5 mg/0.1 mL spray
	Intermezzo				1.75–3.5	1.75-, 3.5-mg sublingual tablet
Benzodiazepine Antagonists						
Flumazenil	Romazicon	Rapid	Short	0.05	0.2–0.5 mg/min	1 mg/mL 5 and 10 mL vials
Flunitrazepam[a]	Rohypnol	Rapid	Intermediate	0.5	0.5–1.0 HS insomnia 1.0–2.0 mg IV or IM or PO premedication	0.5-, 1-, 2-mg tablets and capsules

[a] Not approved in the United States.

Pharmacologic Actions

Absorption. All benzodiazepines except clorazepate are completely absorbed after oral administration and reach peak serum levels within 30 minutes to 2 hours. Metabolism of clorazepate in the stomach converts it to desmethyldiazepam, which is then completely absorbed. Intramuscular (IM) absorption of benzodiazepines other than lorazepam (Ativan) is slower than oral absorption. The onset of action is nearly immediate with intravenous administration of high-potency benzodiazepines such as midazolam.

Distribution. All benzodiazepines are lipid-soluble, but the degree of lipid solubility varies considerably between drugs. Benzodiazepines and their active metabolites are 70% to 99% protein bound, the extent of the binding being proportional to their lipid solubility. Benzodiazepines follow a two-compartment distribution, which involves a rapid central compartment phase followed by a redistribution phase to adipose tissue that ultimately determines the duration of action. As a result, a component of the long half-life of some highly lipophilic benzodiazepines such as diazepam is attributable to extensive storage in adipose tissue. At the same time, a single dose of a very lipophilic benzodiazepine (e.g., midazolam) redistributes rapidly to adipose tissue from CNS receptors, leading to a short duration of action while less lipophilic benzodiazepines like lorazepam remain at therapeutic concentrations at $GABA_A$ receptors longer because they do not redistribute as quickly. Reminazolam, a carboxylate benzodiazepine derivative with a high affinity for benzodiazepine receptors in the cerebral cortex, limbic system, midbrain and spinal cord, was developed as an alternative to midazolam for conscious sedation because it has a longer-acting metabolite that may reduce the risk of withdrawal and rebound seen with midazolam. This medication has not yet received regulatory approval. Because of high lipid solubility, high potency, and a short elimination half-life, alprazolam has a rapid onset and offset of action, with frequent interdose rebound and withdrawal that leads to increasing the dose which only intensifies symptoms when brain levels of the next dose fall.

Metabolism. Benzodiazepine pharmacokinetics vary. Oxazepam and lorazepam are conjugated directly by glucuronidation to a water-soluble form and are excreted without any intermediate metabolites. Most other benzodiazepines are oxidized by cytochrome P450 (CYP) 3A4 and 2C19, frequently to active metabolites. These metabolites may then be hydroxylated to another active metabolite (Fig. 33.9b–4). For example, diazepam is oxidized to desmethyldiazepam, which, in tum, is hydroxylated to oxazepam. These products undergo glucuronidation to water-soluble inactive metabolites that can be excreted in the urine. A number of benzodiazepines (e.g., diazepam, chlordiazepoxide, clorazepate) have the same active metabolite (desmethyldiazepam), which has an elimination half-life of more than 120 hours. Flurazepam, a lipid-soluble benzodiazepine used as a hypnotic that has a short elimination half-life, has an active metabolite (desalkylflurazepam) with a half-life greater than 100 hours. The hypnotic drug quazepam is selective for the benzodiazepine-1 receptor, but it is metabolized to desalkylflurazepam, a nonselective benzodiazepine metabolite of flurazepam that accounts for 40% of total drug activity. With chronic dosing, this medication, therefore, is similar to other longacting benzodiazepine hypnotics.

FIGURE 33.9b–4. Simplified benzodiazepine metabolism.

The duration of action of a benzodiazepine, therefore, may not correspond to the half-life of the parent drug. Many benzodiazepines are substrates for CYP3A4 and CYP2C19. CYP3A inhibitors such as ketoconazole, nefazodone, and the antiretroviral lopinavir can substantially increase levels of CYP3A substrate benzodiazepines such as midazolam, diazepam and triazolam. Conversely, grapefruit juice, which induces CYP3A4, lowers levels of these benzodiazepines; however, even though alprazolam is a CYP3A4 substrate, it does not seem to be affected by grapefruit juice because of its high bioavailability.

Because administration of medications at shorter intervals than the elimination half-life leads to drug accumulation, medications such as diazepam and flurazepam accumulate with more than one daily dose, eventually resulting in increased daytime sedation. Clorazepate is not pharmacologically active but is a prodrug for desmethyldiazepam (nordiazepam), the primary active metabolite of diazepam and chlordiazepoxide. In contrast, temazepam, oxazepam, and lorazepam are conjugated directly and do not have active metabolites. Unlike barbiturates, benzodiazepines do not induce their own metabolism.

The combination of lipid solubility, potency, and elimination half-life of benzodiazepines (Fig. 33.9b–5) can be used to predict the onset and duration of action in clinical settings as well as the optimal frequency of drug administration. Benzodiazepines that are high in lipid solubility and potency and have a short half-life have a rapid onset but a brief duration of action and produce more intense and abrupt discontinuation syndromes. For example, midazolam, a high-potency and highly lipid-soluble nonselective full benzodiazepine receptor agonist with a short elimination halflife has an almost immediate onset of action when used intravenously for conscious sedation or anesthesia. As the medication leaves the CNS quickly, sedation diminishes rapidly, and after a single dose is followed by withdrawal symptoms (most frequently amnesia) in approximately 70% of patients. This profile makes midazolam useful for anesthesia and emergency treatment of agitation but impractical for chronic treatment. Alprazolam, which is high in lipid solubility and potency, reduces anxiety rapidly but can produce interdose withdrawal when it is administered in accordance with its intermediate half-life (three to four times per day) because it leaves the brain more rapidly than it is eliminated from the body. In contrast, chlordiazepoxide is low in lipid solubility and potency and has a long elimination half-life. This medication has a slow onset of action after a single dose and is administered less frequently in chronic treatment. Discontinuation of long half-life, low-potency, low lipidsoluble benzodiazepines such as chlordiazepoxide causes syndromes that are less intense but more prolonged than those associated with shorter-acting medications such as alprazolam.

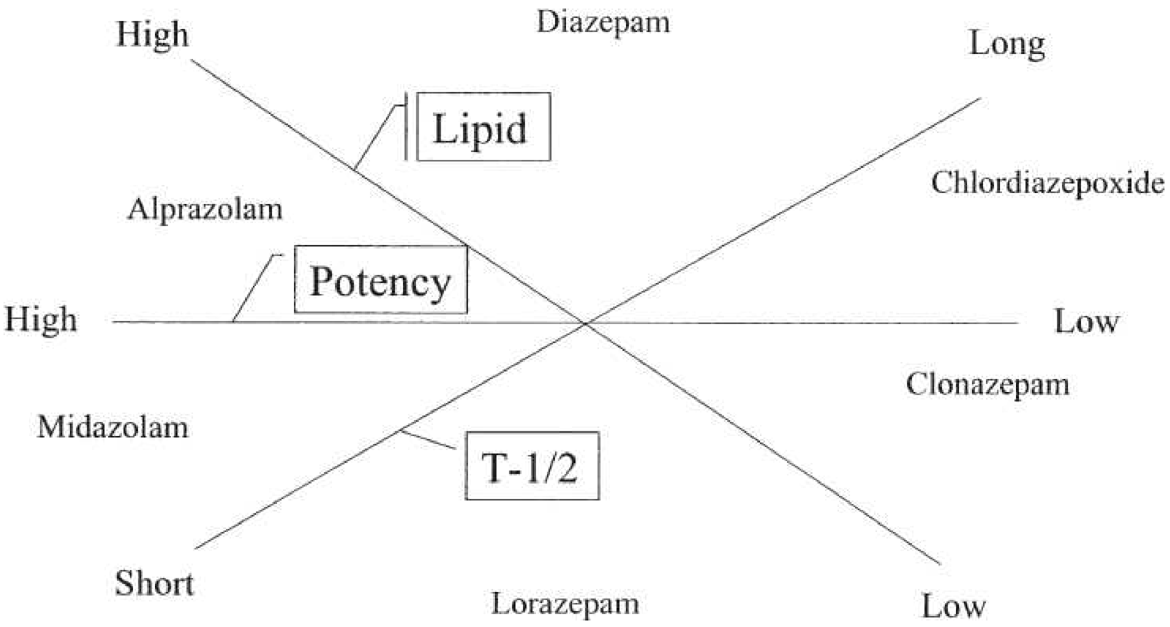

FIGURE 33.9b–5. Potency, lipid solubility, and half-life of some benzodiazepines.

Pharmacodynamics

Mechanism of Action. As noted earlier, the endogenous inverse agonist DBI may serve to upregulate the gain on the CNS by lowering the threshold for depolarization in arousal systems. DBI levels are increased in refractory epilepsy, suggesting that elevated DBI activity could be a mechanism of uncontrolled gross neuronal activation in this and other disorders associated with an excessive stress response. One cause of chronic anxiety, therefore, may be the excessive activity of DBI, which is antagonized when benzodiazepines compete for benzodiazepine receptor occupancy, a shift toward greater chloride ion influx hyperpolarizing neurons of arousal (Fig. 33.9b–2). Even if anxiety is linked to excessive excitability of arousal systems that is primary or secondary to some other influence, such as a hyperactive suffocation response (as in panic disorder), benzodiazepines can reduce anxiety by enhancing hyperpolarization of systems that underlie arousal.

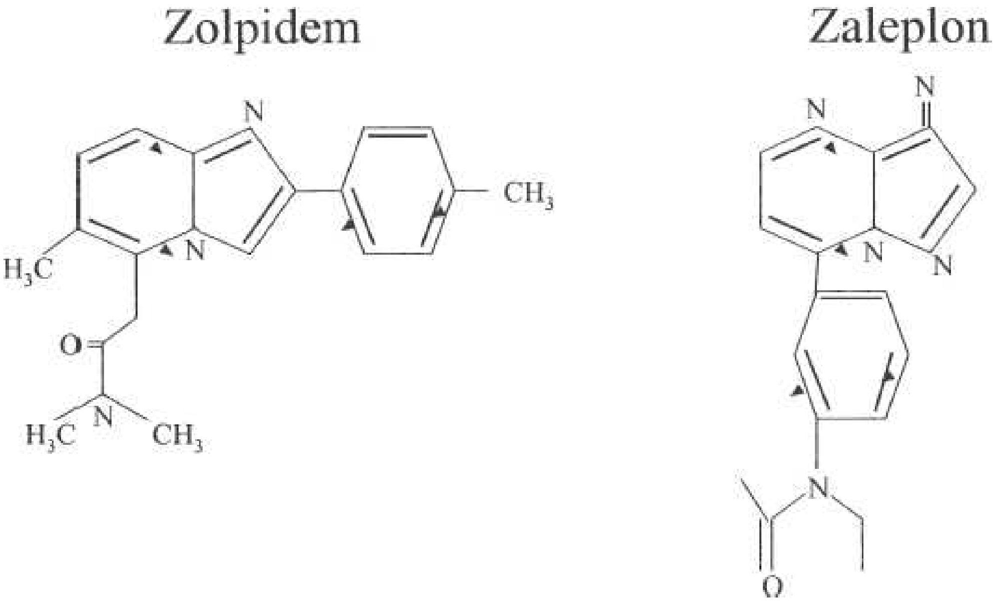
The same action that results in the therapeutic action of benzodiazepines on benzodiazepine receptors in relevant locations can cause adverse effects. For example, the actions of benzodiazepines on benzodiazepine receptors in the cortex can cause cognitive and psychomotor impairment. Actions on pyramidal benzodiazepine receptors have an anticonvulsant effect and can also cause muscle relaxation and incoordination. Benzodiazepine hypnotics act on receptors in the reticular activating system, but if suppression of this system is prolonged, daytime sedation results. Suppression of the reticular activating system can induce delirium in demented patients and aggravate delirium if it is already present.

Blood Concentration and Relation to Action. Concentrations of benzodiazepines in the CSF are equal to plasma concentrations of the free drug. Because of the complex metabolism of long-acting benzodiazepines, serum levels vary considerably between individuals. Levels of parent compounds have not been correlated with therapeutic response, and because many of these medications have active metabolites, it is unlikely that such a correlation exists. Although many shorter-acting benzodiazepines do not have active metabolites, a correlation between blood levels and clinical response has not been demonstrated for these preparations either. There may be a correlation between levels of alprazolam and both adverse effects and efficacy for panic attacks, with a response more likely at plasma concentrations around 20 to 40 ng/mL, which correspond to doses of 1.5 to 6.0 mg per day. However, such levels are rarely measured in clinical practice, and levels would be expected to fluctuate substantially between doses, making the optimal time to measure the trough level difficult to identify. On the other hand, undetectable levels in an agitated patient who has been taking benzodiazepines raise the suspicion of a discontinuation syndrome. The primary uses of serum levels, therefore, are for toxicology screening and the identification of abstinence syndromes.

NONBENZODIAZEPINE AGONISTS OF THE BENZODIAZEPINE RECEPTOR

Neuroscience-Based Nomenclature (NbN)	
Zolpidem, zaleplon, zopiclone, eszopiclone	
Pharmacologic Domain	GABA
Mechanism of Action	Positive Allosteric Modulator (GABA-A receptor, benzodiazepine site)

Zolpidem, an imidazopyridine, and zaleplon, a pyrazolopyrimidine, are not benzodiazepines in that they lack a diazepine ring (Fig. 33.9b–6). Although it is technically accurate to describe these medications as nonbenzodiazepines, they act on benzodiazepine receptors, and their clinical effect can be blocked by the benzodiazepine receptor antagonist flumazenil. They are selective for the benzodiazepine-1 receptor and have no significant effect on other benzodiazepine receptor subtypes at usual doses; at higher doses, they are less selective. Alpidem is a selective benzodiazepine-1 agonist approved as an anxiolytic in some countries other than the United States. Selectivity for the benzodiazepine-1 receptor results in hypnotic and some anxiolytic action without muscle relaxant or anticonvulsant effects for zolpidem and zaleplon. Lack of effects on benzodiazepine-3 receptors appears to result in a lower incidence of withdrawal and rebound symptoms, although these may occur, especially at higher doses and with more chronic treatment. Zopiclone is a nonbenzodiazepine nonselective benzodiazepine receptor partial agonist that is in widespread use in Europe but is not available in the United States. Its S-enantiomer, eszopiclone, is approved in the United States. Zolpidem, zaleplon, and zopiclone/eszopiclone are collectively often referred to as Z-drugs. Currently available benzodiazepines and Z-drugs are listed in Table 33.9b–1, along with the benzodiazepine antagonist discussed below.



Zolpidem

Zaleplon

FIGURE 33.9b–6. Selective benzodiazepine-1 receptor agonists.

Zolpidem is rapidly absorbed after oral administration and reaches peak plasma levels in 2 to 3 hours, with 70% bioavailability; ingestion with food slows absorption. Zolpidem has an elimination half-life of approximately 2 hours and is oxidized to inactive metabolites. As a result, in most cases, a bedtime dose is completely eliminated during the night, and there is no daytime hangover, predicting greater usefulness for difficulty falling asleep than for interrupted sleep or early morning awakening. Zaleplon, which is rapidly absorbed and reaches peak plasma levels 1 to 2 hours after dosing with only 30% bioavailability due to extensive presystemic metabolism, has an elimination half-life of approximately 1.5 hours. Zaleplon is almost entirely metabolized to inactive metabolites. It, therefore, is primarily useful for difficulty falling asleep and usually does not cause a hangover. Eszopiclone is rapidly absorbed from the GI tract, with an elimination half-life of 5 to 7 hours. About 50% to 60% is weakly bound to plasma protein. Eszopiclone is extensively metabolized by CYP3A4 and CYP2E1; less than 10% of an orally administered dose is excreted in the urine, mainly as racemic zopiclone. It does not appear to stimulate or inhibit any CYP450 enzymes.

BREXANOLONE

Neuroscience-Based Nomenclature (NbN)	
Brexanolone	
Pharmacologic Domain	GABA
Mechanism of Action	Positive Allosteric Modulator (GABA-A receptor, neurosteroid site)

Approval has been granted to brexanolone (SAGE-547), a synthetic analog of the neuroactive steroid allopregnanolone that is a positive allosteric modulator of the GABA_A receptor. Used as an intravenous infusion to treat postpartum depression, brexanolone has been reported to produce rapid improvement of depressive symptoms. Phase III studies demonstrated superiority to placebo during a 60-hour infusion, with effect sizes as high as 1.2 and improvement lasting 7 to 30 days post-infusion. Brexanolone has not been compared with a benzodiazepine or any other benzodiazepine–GABA receptor complex agonist. It remains to be determined which features of postpartum depression would indicate the need for a 2.5-day continuous stay in an infusion center to receive an expensive drug but not hospitalization or electroconvulsive therapy (ECT). In addition, no data have been reported on appropriate maintenance treatment.

Zuranolone (SAGE-217) is an oral neuroactive steroid $GABA_A$ positive allosteric modulator that was granted breakthrough therapy designation for depression by the FDA. Zuranolone was well tolerated in Phase I studies for depression. In 2-week Phase II studies and a Phase III study comparing zuranolone to placebo and reference antidepressants, zuranolone was superior to placebo within a few days, with an NNT of 3 for response and remission at day 15, as well as superiority to SSRIs and SNRIs, with NNTs of 4 to 5. Zuranolone had a small negative NNH, suggesting few acute adverse effects. Some benefit was retained in studies at the last measurement on day 42. A 2-week industry-sponsored multicenter RCT of 150 women with postpartum depression (mean age 27 to 29) noted a significantly greater reduction at day 15 in HRSD-17 scores with zuranolone than placebo (–17.8 vs. –13.6 points, effect size 0.53), as well as a significantly greater reduction in anxiety. A difference in depression rating scale scores was still present at day 45. In all studies, the total sample size was small, the trial was short, and there was no comparison with a benzodiazepine, making superiority to cheaper and easier-to-use benzodiazepine–GABA agonists unclear. With these limitations, early experience suggests a rapid reduction of depressive symptoms. Long-term studies have not been performed. In an open-label study, zuranolone in the same doses used in depression studies (30 mg) improved tremor in Parkinson disease when added to a dopaminergic agent.

NONPRESCRIPTION, DESIGNER AND OTHER ILLICIT BENZODIAZEPINES

A number of substances with a 1,4-benzodiazepine/triazolo structure referred to as “designer benzodiazepines” have recently been synthesized but have never been licensed for medical use. These compounds have been designed to circumvent controlled substance regulations and are often sold on the internet. Examples include diclazepam, clonazolam, nitrazolam, adinazolam, cloniprazepam, diclazepam, etizolam, flubromazepam, flubromazolam, meclonazepam, nifoxipam, norflurazepam, pyrazolam metizolam, estazolam, bromazepam, deschloroetiozolam, ketazolam, phenazepam, and 3-hydroxyphenazepam. Many of these compounds are used illicitly in association with other substances.

Designer benzodiazepines all produce CNS depression that responds to the benzodiazepine antagonist flumazenil. Between 2014 and 2017, exposures to these substances, especially etizolam and clonazolam, increased by 330% in 40 U.S. states that were studied. Surveillance reports indicated that 36% of cases required hospitalization (22% to the ICU), and 3% needed intubation; one person died. The capacity of low concentrations of these drugs to produce pharmacologic effects allows them to escape detection by routine toxicology.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Placebo-controlled trials have clearly established the efficacy of benzodiazepines in the treatment of generalized anxiety disorder. Multicenter, double-blind studies have also demonstrated that alprazolam is effective for panic disorder. Smaller studies indicate that, in equivalent doses, other benzodiazepines can also reduce the frequency of panic attacks, although such doses are much higher than ordinary doses for generalized anxiety. For example, 60 mg of diazepam would be equivalent to the reported antipanic dose of alprazolam of around 6 mg per day in a pivotal multicenter trial. Although patients report substantially prolonged sleep with benzodiazepine hypnotics, and these medications shorten sleep onset in the sleep laboratory compared to placebo, total sleep time is increased by an average of only 30 minutes or so with these drugs. No recent therapeutic studies have been conducted in the absence of any potential return on investment for the industry to study medications that are all off-patent and prospective studies of preferential response to one or another benzodiazepine despite substantial differences in their pharmacology. In general, clinical experience suggests that factors listed in Table 33.9b–2 predict a good response to benzodiazepines in the treatment of acute anxiety.

Table 33.9b–2.
Predictors of a Good Response to a Benzodiazepine

Acute anxiety
Clear precipitant
Previous good response to a benzodiazepine
Patient awareness that symptoms are psychological
Patient desire for a benzodiazepine
Absence of history of substance misuse

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

The primary action of benzodiazepines is on the CNS, where they have anticonvulsant, anxiolytic, muscle relaxant, and CNS depressant effects. Hyperpolarization of brainstem neurons at high benzodiazepine doses can cause respiratory depression. Diazepam increases coronary blood flow and has negative inotropic effects. Benzodiazepines used as preanesthetics reduce peripheral vascular resistance, thereby decreasing blood pressure and increasing heart rate. As discussed below, benzodiazepines cross the placenta and enter breast milk.

Benzodiazepines such as diazepam bind to PBRs. The therapeutic potential of these interactions has not been extensively explored, but it is possible that stabilizing the mitochondrial ion channel could reduce neurotoxicity in some degenerative disorders.

THERAPEUTIC INDICATIONS

The primary advantages of benzodiazepines and Z-drugs are their effectiveness, ease of use, tolerability, and relative safety in the treatment of most forms of anxiety, and their rapid onset of action in acute anxiety. They can also facilitate exposure to phobic and other anxiety-provoking situations, promoting desensitization to such stimuli. However, like any medication, they have the potential to reinforce a passive approach to symptom relief that can reinforce relying on something outside oneself for symptom relief and undermine acquiring an internal sense of mastery of stressful situations.

Anxiety Disorders

Benzodiazepines have primarily been used to treat situational anxiety and anxiety disorders. Higher doses may be necessary for panic disorder more than other anxiety disorders. In recent years, prescribing trends and treatment guidelines have shifted from the use of benzodiazepines to SSRIs and SNRIs for anxiety disorders, and most treatment guidelines favor antidepressants over benzodiazepines for anxiety disorders. However, benzodiazepines and antidepressants have been found to have similar efficacy, side effects and withdrawal syndromes. A review and meta-analysis of randomized controlled trials (RCTs) of treatment for anxiety disorders, and maintenance studies lasting at least 13 weeks after RCTs, found no significant differences between antidepressants and benzodiazepines in any outcome after the initial 8 weeks of treatment, except that benzodiazepines had lower discontinuation rates than placebo. In the limited number of continuation studies of patients who responded to an initial 8-week RCT, continued treatment with benzodiazepines and antidepressants was equivalent in efficacy and safety. Another systematic review and meta-analysis examined comparisons between antidepressants and benzodiazepines. The authors identified 18 studies of tricyclic antidepressants (TCAs), phenelzine, and newer antidepressants. Due to the small number of studies in each category, a meta-analysis could only be performed on the 11 comparisons of TCAs to benzodiazepines in the treatment of panic disorder with or without agoraphobia. Panic disorder studies included 2,624 patients assigned to a benzodiazepine or a TCA. Heterogeneity of studies limited the finding of a slight advantage with benzodiazepines, especially for comparisons of a benzodiazepine with a newer antidepressant such as venlafaxine. However, benzodiazepines had significantly fewer adverse effects than TCAs. Overall, the authors found no support for the superiority of antidepressants for anxiety disorders.

A Cochrane review of 24 double-blind RCTs comparing benzodiazepines to placebo or other treatments in panic disorder in adults with or without agoraphobia (*N* = 4,233) concluded that most studies were of poor methodologic quality and 20 were at high risk of bias in at least one domain. The overall likelihood of response was 65% higher with benzodiazepines (RR 1.65; NNT = 4). Half as many benzodiazepine-treated patients withdrew (RR = 0.50), although dropouts because of adverse effects were higher with benzodiazepines. Benzodiazepines were superior for remission and social functioning, although the quality of evidence was low for all outcomes because of the likelihood of unblinding. A systematic review and meta-analysis of randomized controlled studies 4 to 12 weeks in duration of acute treatment of panic disorder with a benzodiazepine or an SSRI versus placebo found that benzodiazepines and SSRIs both caused somnolence; benzodiazepines were associated with more memory problems, decreased libido, constipation and dry mouth, and SSRIs caused more diaphoresis, abnormal ejaculation, fatigue, nausea, diarrhea, and insomnia. Benzodiazepines were protective against tachycardia, diaphoresis, fatigue, and insomnia. The small number of randomized trials directly comparing benzodiazepines and SSRIs made it impossible to draw definitive conclusions.

Benzodiazepines are used as adjuncts to reduce arousal in PTSD and are sometimes used intermittently to reduce social anxiety, although ongoing treatment, especially with antidepressants, is often preferred. β-Blockers can be more useful than benzodiazepines for performance anxiety because they are less likely to impair psychomotor function, and they directly reduce autonomic arousal that interferes with performance. Conversely, rapid reduction of anxiety and the arrhythmogenic effects of increased circulating levels of catecholamines on a damaged myocardium can be especially useful to patients with acute myocardial infarction in the coronary care unit.

Insomnia

As many as half of chronic benzodiazepine users list insomnia as the primary reason for taking the medication. Benzodiazepines promote sleep by a variety of mechanisms, including alteration of arousal systems in the ventrolateral preoptic area and inhibition of the orexin arousal-promoting system. Benzodiazepines increase sleep duration and perceived quality of sleep, decrease sleep latency, slightly reduce REM sleep, and suppress slow-wave sleep. Tolerance develops to the hypnotic effect after 1 to 2 months; after 24 weeks of continuous treatment, subjective sleep quality decreases below baseline, but efficacy can be retained by intermittent use. Rebound insomnia after discontinuing benzodiazepines has been noted in up to 71% of patients. Gaboxadol, an experimental neuroactive steroid that is a nonselective extrasynaptic $GABA_A$ agonist, reduces sleep latency and increases slow-wave sleep; however, it was withdrawn from further study because of a narrow therapeutic index. Benzodiazepines are particularly useful for insomnia caused by acute stress, such as hospitalization.

The benzodiazepine hypnotic flurazepam has a short elimination half-life, but its major active metabolite, desalkylflurazepam, has a half-life longer than 1 day. While high lipid solubility can lead to a rapid onset of action for people who have trouble falling asleep, the persistence of a drug effect the next day makes this medication most useful for patients with daytime anxiety. On the other hand, accumulation with repeated dosing often leads to daytime sedation. The relatively slow onset of action of temazepam, which is related to its lower lipid solubility, combined with an intermediate half-life, make it most appropriate for patients with middle or terminal but not initial insomnia. Triazolam, on the other hand, has a rapid onset of action and a short elimination half-life, making it useful for patients who have difficulty falling asleep and who want to avoid daytime impairment. However, the same features lead to a high frequency of discontinuation phenomena the next morning, especially amnesia. In addition, concerns have been raised about the efficacy of lower doses (0.125 mg) and the safety of higher doses (0.5 mg). Compared with placebo, 15 mg of temazepam decreased objective sleep latency by 37 minutes, while it increased objective total sleep time by 99 minutes; triazolam improved subjective sleep latency and total sleep time to clinically insignificant degrees.

Zolpidem accounts for approximately one-third of all hypnotic prescriptions, having eclipsed benzodiazepines because of its perceived more favorable side-effect profile, although psychomotor impairment has been noted with repeated dosing. Zolpidem improves sleep latency and total sleep time to an extent similar to benzodiazepines, without reduction of REM or delta sleep or other changes in sleep architecture. An extended-release form (Ambien CR) and a slow-release formulation (Intermezzo) were developed for the treatment of difficulty remaining asleep. A sublingual tablet (Edluar) and an oral spray (Zolpimist) are also available. As is true of most other hypnotics, it is usually recommended that zolpidem not be administered for more than 2 to 8 weeks. However, one study showed no loss of efficacy over 6 months of treatment with extended-release oral zolpidem. Zaleplon in a 10-mg dose reduces sleep latency to an extent similar to 0.25 mg of triazolam. Usual doses increase total sleep time by approximately 42 minutes. At higher doses (40 to 60 mg), slow-wave sleep increases, and REM percentage decreases.

Eszopiclone improves sleep efficiency, sleep latency, number of awakenings, total sleep time, and quality and depth of sleep in adults and elderly patients, in whom it also decreases the number of daytime naps. Because the manufacturer chose to conduct 6-month studies, eszopiclone is approved for long-term treatment of insomnia. Sales increased as a result of extensive advertising of this indication. From a pharmacologic standpoint, there is no reason to think that nonselective benzodiazepines that have been marketed for anxiety, such as lorazepam and oxazepam, would not be as effective as hypnotics as similarly acting benzodiazepines and Z-drugs such as temazepam and zolpidem.

A randomized, controlled trial assigned 63 patients with sleep-onset insomnia (mean age 49) to cognitive-behavioral therapy (CBT), zolpidem, the combination, or placebo. Subjects were blinded to the medication condition but not psychotherapy. CBT was more effective than other interventions in improving sleep-onset latency ($P = .003$), with effect sizes at the conclusion of treatment compared with placebo of 1.22 for CBT, 1.12 for combination treatment, and –0.1 for pharmacotherapy. CBT produced significantly greater increases in sleep efficiency than pharmacotherapy and produced the greatest number of normal sleepers (≥85% sleep efficiency), although the difference was not statistically significant. All treatments produced similar increases in total sleep time. The combination of CBT and zolpidem was no more effective than CBT alone.

Gamma-hydroxybutyrate (GHB), a $GABA_A$ receptor co-agonist that binds to GHB receptors on the benzodiazepine–GABA receptor complex, is approved for the treatment of narcolepsy. Prior to its approval in the United States, it was in increasing use as a “club drug” and for other recreational and illicit purposes. GHB has the capacity to induce absence seizures, dependence, abuse, severe withdrawal syndromes, dangerous intoxication, and amnesia as a result of complex actions on tegmental dopaminergic systems; the latter effects have led to its use as a date rape drug. GHB, therefore, is not recommended as a treatment for insomnia or any other purpose.

The “Z-drugs” and some short-acting benzodiazepines have been used to treat jet lag and to facilitate adjustment to work shift changes. However, while all hypnotics induce sleep, they have no effect on the sleep–wake cycle, which is determined more by the time of waking up, especially with exposure to bright light, than the time of going to sleep. Therefore, the best approach to preventing jet lag and sleep disruption associated with changes in work shift is to take melatonin or the melatonin agonist ramelteon at the desired time of going to sleep and have 30 minutes of exposure to daylight or artificial bright light at an intensity of 10,000 lux at the desired time of waking up.

Sedating antidepressants, especially trazodone, and sedating atypical antipsychotic drugs such as quetiapine and olanzapine are currently used frequently to treat chronic insomnia. Additional alternatives to benzodiazepines for insomnia include orexin antagonists (e.g., suvorexant, lemborexant), melatonin agonists (e.g., ramelteon), and other sedating antidepressants (e.g., low dose doxepin). A summary of 64 systematic reviews (35 with meta-analyses) found consistent evidence in more than one high or medium-quality study of effectiveness in multiple outcome domains for zolpidem, suvorexant, doxepin, melatonin, and CBT, and evidence of effectiveness across multiple outcomes based on one high-quality review with meta-analysis each for temazepam, triazolam, zopiclone, trazodone, and behavioral interventions; most studies were short-term.

In developing guidelines for the treatment of insomnia, the American Academy of Sleep Medicine regarded all of their recommendations as “weak,” which they defined as reflecting “a lower degree of certainty in the outcome and appropriateness of the patient-care strategy for all patients, but [also]… not… an indication of ineffectiveness.” These recommendations included zaleplon, triazolam, or ramelteon for initial insomnia, eszopiclone, zolpidem, or temazepam for initial and sleep maintenance insomnia and ramelteon or suvorexant for sleep maintenance insomnia. The Academy recommended against using trazodone, tiagabine, diphenhydramine, melatonin, tryptophan, or valerian for sleep onset or sleep maintenance insomnia. The Academy did not recommend quazepam, estazolam, or flurazepam because of a lack of sufficient data. CBT is considered by most sleep specialists to be the best first-line treatment for chronic insomnia.

Given these considerations, benzodiazepine and Z-drug hypnotics should probably be considered first for acute insomnia associated with hospitalization, acute illness, or other acute stress. The choice of agent would depend on whether medications with longer durations of action would be desirable to ameliorate acute daytime anxiety or whether daytime or psychomotor impairment would be problematic. CBT should be considered for more persistent insomnia. The choice of medication would depend on associated disorders. For example, insomnia associated with depression might be an indication for a sedating antidepressant, whereas insomnia associated with a chronic anxiety disorder could be treated with an antidepressant, benzodiazepine receptor agonist, or alternative agent recommended by the American Academy of Sleep Medicine.

Depressive Disorders

A systematic review and, where possible, meta-analysis of 38 RCTs of benzodiazepines in depression addressed the common assumption that benzodiazepines are not appropriate treatments for depression. The review included studies of a benzodiazepine versus a TCA and placebo, and studies of a benzodiazepine versus placebo, for depression with or without anxiety. All studies were conducted prior to the 1990s, and only one involved a newer antidepressant (fluvoxamine). The meta-analysis involved 22 RCTs of a benzodiazepine versus placebo and 20 separate analyses of a benzodiazepine versus a TCA. In about half the studies comparing a benzodiazepine to a TCA and/or placebo, benzodiazepines were significantly more effective than placebo and as effective as a TCA. In the review of 11 studies, TCAs were more effective than benzodiazepines, while benzodiazepines were more effective than TCAs in only one study. In 12 studies, benzodiazepines had a faster onset of action than TCAs. There were no significant differences in response to benzodiazepines between anxious depression and nonanxious depression. In the meta-analysis, there were no significant differences in response rates between benzodiazepines and TCAs or between benzodiazepines and placebo.

A Cochrane review evaluated 10 RCTs (*N* = 731) conducted through May 2019 of an antidepressant plus a benzodiazepine versus antidepressant monotherapy for patients with major depression. During the first 4 weeks but not after 5 weeks, the combination was more effective for reduction of depressive symptoms and for response and remission of major depression, but not for the reduction of anxiety. Dropouts for adverse effects were about half as frequent in the combination group. An advantage of early co-administration of a benzodiazepine with an antidepressant may be that it reduces the initial jitteriness that can occur with the initiation of antidepressant therapy, even in depressed patients without comorbid anxiety, reducing the risk of patients discontinuing the antidepressant before the therapeutic effect begins. Such benefits must be weighed against potential risks of the benzodiazepine, reports of which could be confounded by the more frequent use of benzodiazepine-antidepressant combinations in patients with more severe, complex, comorbid, and treatment-refractory depression that does not respond well to an antidepressant alone and is associated with more adverse events of treatment.

While the benefit of most benzodiazepines in the treatment of depression probably involves reduction of early antidepressant-induced jitteriness associated with initial increased noradrenergic neurotransmission and/or reduction of anxiety or insomnia, alprazolam has antidepressant properties, although it is not as effective as antidepressants as monotherapy for more severe depression. Alprazolam might be considered for patients with mild–moderate depression who cannot tolerate or do not respond to any antidepressant or psychotherapy. The long-term goal would be to transition to an antidepressant.

Bipolar Disorder

For many years, benzodiazepines, especially clonazepam and lorazepam, were frequently used to treat mania, alone or in combination with an antipsychotic drug or a mood stabilizer. In recent years, the use of benzodiazepines has declined, concomitant with the increased use of atypical antipsychotic drugs. However, because they can ameliorate agitation and promote sleep rapidly, with fewer adverse effects than antipsychotic drugs, benzodiazepines are still appropriate adjuncts in the treatment of mania. In longer-term treatment, nonspecific anxiety occurring in the context of an affective episode often remits with remission of the episode; for persistent anxiety or insomnia and for comorbid anxiety disorders, valproate or a benzodiazepine would be appropriate choices. One exception would be alprazolam, which has been reported to destabilize bipolar disorder, probably because of its antidepressant properties.

A secondary analysis of 482 patients with bipolar I or bipolar II disorder enrolled in a 6-month controlled comparison of lithium- versus quetiapine-based treatment suggested that the addition of a benzodiazepine did not improve clinical outcome over 6 months. As with other disorders, the need for continued use of benzodiazepines (and other forms of adjunctive treatment) may be a marker of more severe and refractory bipolar illness requiring more definitive treatment rather than promiscuous use of anxiolytics.

Schizophrenia

A Cochrane review of 34 short-term studies involving 2,657 schizophrenia patients, 8 of the studies comparing a benzodiazepine to placebo and 14 comparing benzodiazepine to antipsychotic monotherapy, found small sample sizes and incomplete data reporting. The only evidence that emerged for benzodiazepines alone or added to antipsychotic drugs was for short-term sedation (generally 30 to 60 minutes) of agitation in schizophrenia patients. A follow-up Cochrane report supported the impression that although they are well-tolerated, benzodiazepines do not augment antipsychotic drugs or improve overall outcomes in the treatment of schizophrenia, their only appropriate use being for very short-term treatment of agitation. In addition, although the quality of studies is limited, benzodiazepines reduce acute akathisia caused by antipsychotic drugs.

A meta-analysis of studies reported through 2017 found no difference in the outcome of schizophrenia between the benzodiazepine-1 agonist alpidem, eszopiclone, and placebo. However, one individual study reported superiority of alpidem to placebo in overall improvement of schizophrenia, and one study found that short-term treatment with eszopiclone was effective for insomnia in schizophrenia patients.

Catatonia

In case series, the remission rate of catatonia has been reported to range from 60% to 80% with benzodiazepines, the most commonly reported of which has been lorazepam. A common protocol begins with a lorazepam challenge test of 1 to 2 mg in adults and 0.5 to 1 mg in children and geriatric patients, administered orally (including via nasogastric tube) or parenterally. Following a response (≥50% improvement), the dose is increased to 6 mg/day in divided dose. The dose is further increased to 6 to 16 mg/day, and sometimes as much as 30 mg/day. Oral is less effective than sublingual or IM administration. At five times the lorazepam dose, diazepam has also been found to be effective. A zolpidem challenge test of 10 mg orally or via nasogastric tube has also been utilized. If the patient responds, lorazepam is substituted, although zolpidem up to 40 mg/day has been used for ongoing treatment.

Another benzodiazepine protocol begins with a 2-mg intravenous dose of lorazepam, repeated 3 to 5 times per day. The dose is increased to 10 to 12 mg/day if the initial doses are partially effective. A combined lorazepam/diazepam approach begins with 2 mg of IM lorazepam. If there is no effect within 2 hours, a second 2-mg dose is administered, followed by an intravenous infusion of 10-mg diazepam in 500 mL of normal saline at 1.25 mg/hr until catatonia remits.

Several studies suggest that a more robust response of catatonia to lorazepam, at least in lower doses, is more likely with a shorter duration of catatonia and waxy flexibility. Factors predicting a poorer response include passivity, mutism, auditory hallucinations describing the patient in the third person and marked retardation and mutism complicating schizophrenia, especially with chronic negative symptoms. Maintenance lorazepam can be effective in reducing relapse and recurrence. There are no controlled studies of maintenance treatment with benzodiazepines, but clinical reports suggest that lorazepam doses in the range of 4 to 10 mg/day are effective.

Gastrointestinal Disorders

Patients with unexplained gastrointestinal (GI) symptoms have an increased rate of panic disorder, agoraphobia, and major depression, while many GI disorders are aggravated by anxiety. A number of studies of benzodiazepines in GI disorders published in the 1970s and 1980s reported improvement of symptoms, as well as physical signs such as peptic ulcer. Benzodiazepines are better tolerated than antidepressants by some patients with GI disorders in that they do not cause constipation (like TCAs) or diarrhea (like SSRIs), and they can decrease gastric secretion and induce smooth muscle relaxation.

Cardiovascular Disorders

There is an increased prevalence of anxiety disorders and depression in patients with cardiovascular disease. Reduction by benzodiazepines of autonomic hyperactivity associated with anxiety and depression can attenuate myocardial ischemia and hypertension in these individuals. As noted earlier, reduction of arousal by benzodiazepines can be particularly helpful in the coronary care unit in decreasing high levels of circulating benzodiazepines that are arrhythmogenic in the presence of a damaged cardiac conduction system.

Treatment of Alcohol Withdrawal

Uncomplicated alcohol withdrawal symptoms begin within 4 to 12 hours after stopping or significantly reducing alcohol intake. Symptoms normally reach peak intensity on the second day and improve by the 4th or 5th day. Delirium tremens (DTs) usually has an onset 3 to 5 days after alcohol discontinuation and persists for about a week. The mortality rate in DTs remains about 8%.

The standard treatment of alcohol withdrawal syndromes is with benzodiazepines, most frequently lorazepam, diazepam, chlordiazepoxide, or clorazepate. Some protocols use standardized protocols with a progressively decreasing dose, while others adjust each dose based on the response to the previous dose. Alcohol withdrawal syndromes refractory to benzodiazepines are often treated with the addition of phenobarbital, propofol, or dexmedetomidine. The latter medication is an α_2-agonist that is more potent than clonidine, with an onset of action of 15 minutes and an elimination half-life of 2 hours, the antiadrenergic effect of which decreases sympathetic tone without causing respiratory depression.

A retrospective chart review comparing phenobarbital (N = 143) and benzodiazepines (N = 419) in treating alcohol withdrawal found equal outcomes in both, although 16 patients who did not respond to benzodiazepines did well when switched to phenobarbital. Amplifying this finding, a Cochrane review of 64 RCTs involving 4,309 subjects comparing benzodiazepines to placebo, other treatments, and each other in the treatment of alcohol withdrawal found benzodiazepines to be significantly superior to placebo for seizures and suggested superiority of benzodiazepines for many other outcomes, but the studies were too heterogeneous to draw definitive conclusions about comparative effectiveness and safety.

Agitation

Since the antimanic and antipsychotic effects of antipsychotic drugs are delayed, treatment of agitation associated with mania and schizophrenia with these medications relies on their sedative side effects. Adding or substituting a benzodiazepine has the advantage of rapid sedation without the risks of high or repeated doses of antipsychotics. In the treatment of mania, improvement of sleep with a benzodiazepine may contribute to a reduction of manic symptoms. The addition of a benzodiazepine to an antipsychotic drug may also ameliorate akathisia, which can be mistaken for agitation. IM lorazepam has been used most frequently for agitation in acutely ill psychiatric patients, but midazolam is also available in an IM formulation. High lipid solubility and potency and a very short elimination half-life make midazolam an appealing choice when a rapid onset of action without drug accumulation with repeated dosing is desired. Recent experience suggests that midazolam is rapidly effective and well tolerated in the prehospital treatment of agitation.

In one study, oral risperidone plus lorazepam was effective in the emergency treatment of acutely psychotic patients. Similarly, a multicenter controlled trial in acute psychosis reported that risperidone plus lorazepam more rapidly reduced aggression, produced more sedation, and was better tolerated than risperidone alone. Anticipating that an antipsychotic drug will be necessary anyway, most clinicians add a benzodiazepine as an adjunct. However, particularly in the treatment of mania, it may be reasonable to treat agitation and insomnia with a benzodiazepine with or without an antipsychotic drug and gradually transition to lithium or another mood stabilizing medication that does not have prominent sedative properties.

The treatment of agitation in unselected acutely ill patients in the hospital or emergency department who may be experiencing an acute psychiatric disorder, delirium, or a substance-induced condition frequently involves an antipsychotic drug alone or in combination with a benzodiazepine, especially lorazepam. A commonly used IM combination consists of 5-mg haloperidol and 2-mg lorazepam. This tradition is based on a randomized uncontrolled trial that found that the combination of 5 mg of haloperidol and 2 mg of lorazepam produced more rapid sedation than either medication alone, although hospitalization and the need for additional medication doses did not differ between the three conditions. Following a systematic review and consensus discussion, the American College of Emergency Physicians found no class I RCTs, prospective cohort studies or meta-analyses of RCTs supporting this or any other pharmacologic treatment for agitation. The consensus statement noted that multiple class II observational reports, case-controlled studies, and meta-analyses found equivalence of 2- to 4-mg lorazepam to 5-mg haloperidol, equivalence of clonazepam and flunitrazepam to haloperidol, and a shorter time to sedation with 5 mg of IM midazolam than with lorazepam or haloperidol; 15 mg of IM midazolam was found to be more effective than haloperidol plus promethazine for rapid sedation and sleep. Class III cross-sectional and case studies and consensus panels determined 2.5 to 3 mg of midazolam to be rapidly effective for agitation in acutely ill psychiatric patients, while there was no clear benefit of adding haloperidol to a benzodiazepine. The group had no level A recommendations. Their level B recommendation (moderate clinical certainty based on observational studies, decision analysis or strong consensus) suggested the use of monotherapy with lorazepam, midazolam, droperidol, or haloperidol, followed by benzodiazepine-antipsychotic drug combinations if the first approach was ineffective.

Delirium

Benzodiazepines are often used for agitation secondary to delirium; however, CNS depression from the benzodiazepine can aggravate delirium. A Cochrane attempt to review studies of the effectiveness and tolerability of benzodiazepines for non–alcohol-related delirium found only one study meeting the selection criteria. A study comparing lorazepam with the α_2-agonist dexmedetomidine for delirium in mechanically ventilated ICU patients found that dexmedetomidine was associated with 7 delirium- and coma-free days compared with 3 days for lorazepam ($P = .01$). One partially controlled study showed no advantage of alprazolam over neuroleptics for agitation associated with delirium, and another partially controlled study found that lorazepam was not as effective as haloperidol or chlorpromazine for acute confusion and had more adverse effects. The authors concluded that there are insufficient blinded, controlled studies of benzodiazepines for delirium and no support at this point for the use of benzodiazepines for delirium. In a later Cochrane review that addressed RCTs of benzodiazepines to treat delirium in adults not associated with alcohol or benzodiazepine withdrawal in settings other than an ICU, including hospitals, nursing homes, and long-term care settings, only two trials qualified for review. The Cochrane authors' review of a study of 58 delirious advanced cancer patients in an acute palliative care unit treated with haloperidol and then randomized to the addition of lorazepam or placebo for delirium of similar severity and duration, and a study of 30 AIDS patients (mean age 39) randomized to lorazepam, haloperidol, or chlorpromazine, revealed no superiority of one treatment over another. The authors concluded that there is still insufficient evidence to determine whether benzodiazepines are useful in the treatment of delirium.

Substance Use Disorders

In animal studies, pretreatment with experimental positive allosteric modulators of the GABAB receptor blocked neuroplasticity in the ventral tegmental area induced by alcohol and cocaine and attenuated self-administration of these substances. A review of human studies of alcohol dependence found that in lower doses, baclofen, an orthosteric $GABA_B$ agonist, was significantly superior to placebo in prolonging the time to relapse of drinking. However, the tolerability of baclofen was low.

Use With Electroconvulsive Therapy

The anticonvulsant action of benzodiazepines leads most clinicians to avoid benzodiazepines during ECT for several reasons. ECT increases diazepam binding in preclinical studies and shortens seizure duration in clinical series. Despite not taking benzodiazepines, pretreatment with flumazenil improved seizure duration and clinical response after declining benefit in a small study, possibly implicating a shift of the benzodiazepine receptor toward inverse agonism as a mechanism of ECT. For several reasons, the assumption that the anticonvulsant action of benzodiazepines increases seizure threshold has not always been supported by clinical experience.

Many studies suggesting that benzodiazepines impair the response to ECT have not used stimulus titration according to seizure threshold. In contrast, a retrospective chart review of 70 major depressive disorder patients (22 taking benzodiazepines) undergoing the dose titration method for ECT found significantly greater remission rates and decreases in MADRS scores in patients taking benzodiazepines; there were no differences between benzodiazepine and nonbenzodiazepine patients in seizure duration or seizure threshold. Changes in anxiety and cognitive function were not assessed. A retrospective review of records of 90 patients with major depressive disorder treated with bitemporal ECT found no impact of benzodiazepines on the efficacy of ECT. This finding was limited by the retrospective method, lack of information about seizure threshold, lack of randomization, absence of control for the number of ECTs, use of Hamilton Depression Rating Scale (HDRS) scores completed openly by treating clinicians, and use of a single approach to ECT.

If benzodiazepines increase the seizure threshold, interference with the therapeutic action of ECT should be more likely with unilateral electrode placement, for which stimulus intensity must exceed the seizure threshold to a greater degree than bilateral placement. Indeed, a review of the literature concluded that benzodiazepines may impair the response to unilateral more than bilateral ECT. This possibility was supported by a French retrospective study of 70 patients receiving biweekly ECT for major depressive disorder that compared outcomes in 22 patients (mean age 61) taking benzodiazepines (mean diazepam equivalent dose 17 mg) with outcomes for 48 patients (mean age 62) not taking benzodiazepines. All benzodiazepine patients and 88% of nonbenzodiazepine patients received bitemporal electrode placement. Stimulus intensity was titrated to twice the seizure threshold in bilateral and six times the seizure threshold in unilateral ECT. There were no significant differences between groups in the number of ECTs (mean 13 to 14), seizure threshold, or seizure duration. However, the benzodiazepine group had a significantly greater reduction in Montgomery-Asberg Depression Rating Scale (MADRS) scores (–28.9 vs. –21.9; $P < .02$) and significantly more remissions (MADRS score <10), but not responses (decrease in MADRS score ≥50%), than the nonbenzodiazepine group. The authors concluded that with appropriate stimulus titration and use of bilateral ECT, benzodiazepines may not impair and may even enhance the response to ECT, perhaps by treatment of comorbid anxiety or additive increases in seizure threshold to the effect of artificial seizures. A double-blind comparison of midazolam versus methohexital anesthesia for ECT found no difference in outcome as measured by MADRS scores. Such experiences suggest that if benzodiazepines are to be continued during ECT, they may be less problematic with bilateral than with unilateral ECT and with higher than with lower stimulus intensities. Lower benzodiazepine doses may be less likely than higher doses to impair the response to ECT.

USE IN PREGNANCY

Since 1.9% to 3.1% of pregnant women take a benzodiazepine, the question of benzodiazepine use during pregnancy is not trivial. Data on the topic are contradictory, and reports of associations of adverse outcomes and use of medications such as benzodiazepines during pregnancy often do not account for confounding variables such as the effects of increased hypothalamic–pituitary–adrenal activity in stress-related disorders for which benzodiazepines are prescribed, underreported psychiatric disorders, especially substance use disorders, use of substances including nicotine and alcohol during pregnancy not meeting criteria for a formal disorder, past history of problem pregnancies (which are more common in women taking benzodiazepines), and other lifestyle and environmental factors.

A risk of major congenital malformations with exposure during pregnancy to clobazam, a benzodiazepine used to treat epilepsy and anxiety in some countries other than the United States, was suggested but not proven in a network meta-analysis. A Norwegian questionnaire cohort study analyzed data from 82,030 singleton pregnancies among 69,434 women (mean age 30). Exposure to benzodiazepines or Z-drugs was reported as 0.8%. Lower birth weight, lower gestational age at birth, and higher risk of preterm birth were associated with the use of benzodiazepines or Z-drugs. The effect of benzodiazepine use on birth weight was probably related to earlier birth, not intrauterine growth retardation, and the magnitude of the association with gestational age was not considered clinically significant. In a meta-analysis of eight studies, benzodiazepine exposure in utero was not associated with an increased risk of congenital malformations, including in the five studies that specifically examined first-trimester exposure. There was no increased risk of cardiovascular malformations in four studies that examined this specific malformation. However, concurrent use of an antidepressant and a benzodiazepine in the first trimester was associated with an increased risk of major malformations (O.R. 1.40, $P = .008$). Specific malformations were not reported.

A systematic review and meta-analysis of 14 studies found significant associations of benzodiazepine use during pregnancy with spontaneous abortion (O.R. 1.86), preterm birth (O.R. 1.96), low birth weight (O.R. 2.24), low Apgar score (O.R. 2.19), neonatal intensive care unit (NICU) admission (O.R. 2.61), and induced abortion (O.R. 2.04). After adjusting for publication bias, early gestational age and small for gestational age continued to have a statistically significant association with antenatal benzodiazepine exposure. The authors concluded that the association with NICU admission was clinically relevant as well as statistically significant. It is unclear whether NICU admissions were driven by neonatal respiratory suppression or withdrawal syndromes.

The question of behavioral teratogenicity of benzodiazepines has also been raised. A Norwegian study of 36,401 children found no significant association between exposure to benzodiazepines and/or Z-drugs during pregnancy in the 273 children with this exposure and internalizing or externalizing behaviors measured on the Child Behavior Checklist at age 5. Another Norwegian study of 4,195 women with depression/anxiety, 5,260 with sleep disorders, and 26,631 with pain-related disorders included 36,086 children, 0.8% of whom (283) were exposed to benzodiazepines or Z-drugs in mid (weeks 17 to 28) or late (week 29 or later) pregnancy. At a mean age of 5.1 years, benzodiazepine/Z-drug–exposed children did not have an increased risk of ADHD symptoms or fine motor deficits with exposure at any time point during pregnancy. Children of women with a depressive or anxiety disorder who took benzodiazepines in late pregnancy had "moderately" more gross motor and communication deficits than unexposed children, suggesting confounding by indication or higher doses in women with anxiety/depression who had late pregnancy benzodiazepine/Z-drug exposure. The authors concluded that there was "no substantial detrimental risk on child fine motor and ADHD symptoms after prenatal benzodiazepine/z-hypnotic exposure alone or in combination with opioids or antidepressants."

Since benzodiazepines are excreted in breast milk, concerns arise about medication effects on the nursing infant. A Japanese study of 11 nursing mothers and their 1-month-old infants taking benzodiazepines including alprazolam, brotizolam, clonazepam, flunitrazepam, and lorazepam, among others, found that the ratio of milk to plasma benzodiazepine level was consistently less than one, and the relative infant dose was always less than 10% except for ethyl loflazepate, which was only slightly greater than 10%. No abnormalities were noted in the infants. The authors concluded that medication exposure is low in infants of mothers taking benzodiazepines. Other experts recommend that if a benzodiazepine is used during breastfeeding, shorter-acting agents such as lorazepam and oxazepam are preferred. Medication exposure can be further reduced by taking the medication after rather than before breastfeeding. The nursing infant should be monitored for sedation, lethargy, and poor sucking. Withdrawal syndromes can occur in the nursing infant if the mother abruptly discontinues the benzodiazepine.

BENZODIAZEPINES IN THE ELDERLY

Elderly patients are considered more vulnerable to benzodiazepine effects as a result of increased adipose/lean ratio, resulting in a greater volume of distribution, a longer elimination half-life, slowed metabolism, and decreased clearance, with increased steady-state concentrations. In addition, since most benzodiazepines are protein-bound, decreased plasma proteins with age can increase the free fraction with no change in the overall concentration but increased levels of active drug. There is also a greater pharmacodynamic effect secondary to changes in receptor function and signaling. These factors can result in greater drug effect and accumulation if the dose is not adjusted and monitored. Data are mixed, particularly for shorter-acting benzodiazepines, supporting the recommendation by the American Geriatrics Society that benzodiazepines and related drugs be avoided in geriatric patients, especially those with cognitive impairment, because such changes make the elderly more vulnerable to falls, automobile crashes, and impaired cognition, memory and psychomotor function.

PRECAUTIONS AND ADVERSE EFFECTS

Although they are effective for most forms of anxiety and generally well-tolerated, benzodiazepines, like other medications, have the potential to reinforce reliance on something outside oneself for relief of anxiety, potentially undermining the development of confidence in the ability to master stressful situations. As noted earlier, rapid reduction of anxiety can enhance confidence in emergency settings such as the CCU, and it can facilitate exposure to phobic and other anxiety-provoking situations, but therapies such as CBT, mindfulness, and desensitization may be more effective at enhancing a sense of personal agency in patients with chronic anxiety.

The most common physical adverse effects of benzodiazepines include sedation, slowed reaction time, and impaired memory and psychomotor function, although these are not as severe as with barbiturates. Especially in older people, benzodiazepines can cause falls, syncope and fractures due to slowed reaction time, impaired balance and gait, and impaired vision. Falls are more frequent with chronic benzodiazepine use. The propylene glycol vehicle in parenteral lorazepam preparations has been linked to hyperosmolar metabolic acidosis.

Cognitive Side Effects

Withdrawal from short-acting, high potency benzodiazepines such as midazolam and triazolam can cause retrograde amnesia after discontinuation or between doses. Withdrawal probably also accounts for amnesia following a single dose of the high potency, highly lipid-soluble “date rape drug” flunitrazepam, especially when it is combined with alcohol. All benzodiazepines can cause anterograde amnesia and can interfere with new learning, although they usually do not impair access to memories that are already acquired. Impaired verbal memory, visuospatial memory, working memory, attention and executive function independent of the degree of underlying anxiety and depression have been demonstrated in people chronically using high doses of benzodiazepines. In a study of older patients with normal cognition, those taking benzodiazepines had poorer cognitive performance, but there was no difference in the rate of cognitive decline between people who were or were not taking benzodiazepines, suggesting the possibility of subclinical or prodromal features of dementia in patients taking benzodiazepines.

In a multicenter prospective depression trial, 353 patients treated with an SSRI alone were compared to 49 patients treated with an SSRI plus a benzodiazepine at baseline, 8 weeks, and 48 weeks of treatment on measures of depression, anxiety and cognitive function. Cognitive function was similar for both groups at baseline. Controlling for differences in severity of depression and anxiety, scores on the Digit Symbol Coding Test (a measure of information processing speed) were slightly better in patients treated with an antidepressant and a benzodiazepine than an antidepressant alone at 8 weeks and distinctly and significantly better at 1-year follow-up. The results suggest that the short-term addition of a benzodiazepine does not impair cognitive function in patients with MDD, while it could improve processing speed after short-term treatment and 1 year later.

Delirium

Delirium is associated with globally impaired cortical functioning, altered network connectivity, and/or suppression of reticular activating system activity, any of which can be impaired by central nervous system depressants. Benzodiazepines, therefore, have the potential to cause or aggravate delirium, especially in patients who were cognitively impaired, to begin with. In one inpatient study, there was a significant association between ongoing benzodiazepine use and delirium (adjusted IRR 2.31 to 2.44). A study of all 2,446 patients admitted to a 32-bed pediatric intensive care unit over a 2 ½-year period found a dose-related contribution of exposure to benzodiazepines to the risk of delirium independent of other clinical factors. A systematic review of the association between benzodiazepine use in the ICU and delirium, depression, anxiety, PTSD and cognitive impairment included 49 studies of adult ICU patients (21 of them high quality) conducted over 10 years (total N 11,138). The data could not be pooled for meta-analysis because of the heterogeneity of samples and settings. Of these studies, 24 identified benzodiazepine use in the ICU as a risk factor for delirium; of this group of studies, 10 of 13 of high methodologic quality found benzodiazepine use to be a risk factor for delirium. Another 10 studies reported no evidence of an association between benzodiazepine use and delirium, and one study suggested a protective effect of midazolam. The risk of delirium was greater with high daily doses, the use of midazolam or lorazepam, and continuous administration. The possibility of confounding by indication (i.e., patients receiving benzodiazepines may have had illnesses that were more likely to predispose them to delirium) could not be excluded.

Benzodiazepines and Dementia

Debate continues about the potential of benzodiazepines to increase the risk of dementia. Proposed mechanisms of such an association include decreased cognitive reserve, downregulation of $GABA_A$ receptors resulting in reduced resilience of information processing systems, and decreased ability to utilize alternative neural networks because of reduced brain activation. However, data on whether benzodiazepines increase the risk of dementia have been conflicting. Reports of an increased risk of dementia with chronic benzodiazepine use may reflect reverse causality—in other words, benzodiazepines are more frequently prescribed for prodromal symptoms of dementia such as depression, which is often treated with benzodiazepines.

A number of studies have emerged to address this question. For example, using claims forms from the public drug plan, a Canadian case-control study correlated benzodiazepine prescriptions 6 years prior to diagnosis in 1,796 cases of dementia and 7,184 controls from 38,741 randomly selected patients over age 60 with a diagnosis of dementia or presumed dementia based on the prescription of a cholinesterase inhibitor or memantine, and 86,259 controls matched for age, sex, and duration of follow-up. Controlling for multiple comorbidities, there was no difference between Alzheimer disease patients and controls in prescriptions for ≤180 prescribed daily doses (6 months duration of use). Use of >180 prescribed daily benzodiazepine doses (>6 months duration) was noted in 32.9% of subjects with Alzheimer disease versus 21.8% of controls (adjusted odds ratio 1.51). The risk of Alzheimer disease increased with the increasing duration of benzodiazepine prescription and was higher with long-acting benzodiazepines. There was no significant effect on anxiety, insomnia, or depression. The data in this study were based on diagnoses and prescriptions in insurance claims submitted by a large number of clinicians and might not reflect consensus diagnoses or clear rationales for the prescription of medications usually associated with Alzheimer disease. Although the authors thought that benzodiazepines prescribed 6 years prior to Alzheimer disease diagnosis would not be likely to be prescribed for prodromes of dementia, the pathology of Alzheimer disease may have developed before patients took benzodiazepines, with apparent anxiety or insomnia either being early features of dementia or incidental symptoms. The possibility that a neurodegenerative process began prior to benzodiazepine prescription is supported by a higher incidence of stroke and hypercholesterolemia in dementia patients than in the controls. There was also no information about whether patients were still taking benzodiazepines at the time of diagnosis, an important issue since cognitive side effects of benzodiazepines could be confused with primary dementia. A comparison of 153 HIV patients taking benzodiazepines for an average of 2 years with 153 HIV patients matched for demographics and comorbidities and adjusted for premorbid functioning, current affective symptoms, and lowest CD4 count found more impairment of global cognitive function, processing speed, executive function, working memory and delayed recall in the benzodiazepine group (OR = 2.13), especially with diazepam, lorazepam, and alprazolam. This finding may have reflected exacerbation of HIV-induced cognitive impairment by the benzodiazepine or an interaction with antiretroviral drugs.

Lack of an impact of benzodiazepine use on the risk of dementia was found in an examination of the relationship between ongoing use of benzodiazepines and related drugs and cognitive function at 18-month follow-up in a European randomized multicenter study of the antihypertensive nilvadipine in 448 patients (mean age 72) with Alzheimer disease (Mini-Mental State Exam score 12 to 26; median duration of symptoms 3.7 years). In the 14% of patients who took a benzodiazepine or Z-drug during the study (most frequently alprazolam, lorazepam, oxazepam, bromazepam, and zolpidem), there was no relationship between ongoing use of the medication over 18 months and changes in ADAS-Cog scores. There was also no additive effect of APOE ε4 status and benzodiazepine use on dementia risk. The authors concluded that active benzodiazepine use did not hasten cognitive decline over 18 months in patients with mild–moderate Alzheimer disease.

A retrospective cohort study of a random sample of patients over 50 years of age using a national healthcare database in South Korea compared benzodiazepine users, nonusers, and users of SSRIs or SNRIs on the grounds that they have similar indications to the benzodiazepines. Among 1,576,452 subjects, there were 1,125,346 benzodiazepine users, 17,677 antidepressant users, and 433,429 nonusers. Each benzodiazepine user was matched with a nonuser or an antidepressant user. Over a mean follow-up of 5.6 years, benzodiazepine users (especially current users) had a 23% higher risk of dementia than nonusers. However, there was no difference in dementia risk between benzodiazepine and antidepressant users. Also, in comparisons of users and nonusers, the *longer* the duration of benzodiazepine (or antidepressant) use, the *lower* the risk of dementia, suggesting that the association between benzodiazepine or antidepressant use and dementia risk was attributable to something other than these medications. Similar findings emerged from a retrospective analysis of data from an open-label randomized trial in 116 family practices in the Netherlands involving 3,526 nondemented people (mean age 74.3) living in the community. After a median of 6.7 years after starting treatment, there was no significant association between the use of short or long-acting benzodiazepines and incidence of dementia and no interaction with any APOE genotype. Persistent high anticholinergic exposure was associated with an increased risk of dementia over 6 years of follow-up, but the association was driven by the use of antidepressants or antipsychotics, suggesting confounding by indication. Similarly, in a sample of 133 patients (mean age 78) with Alzheimer disease, anticholinergic drugs (most frequently quetiapine) but not benzodiazepines were associated with significant cognitive decline.

A number of other large international studies have not found an association between the use of benzodiazepines and the development of dementing illness. For example, a Canadian 10-year multicenter study of 10,263 older people living in the community or in institutions found that benzodiazepine use was associated with an increased risk of cognitive impairment not associated with dementia (presumably a medication side effect) but not with an increased risk of Alzheimer disease or other neurologic dementia. A British prospective follow-up of 8,216 nondemented patients found that 9.3% developed dementia over the next 8 years. Medications with more anticholinergic properties were associated with a higher risk of dementia, but less anticholinergic drugs and benzodiazepines were not. A 10-year Danish cohort and nested case-control registry study of 235,465 adults with a first hospitalization for a mood disorder found no meaningful association between use of any benzodiazepine or Z-drug and subsequent risk of dementia, even considering cumulative exposure and whether exposure was long- or short-term. There was even a suggestion of a protective effect in some analyses. In a British nested case-control database study comparing 40,770 people with dementia with 283,933 controls matched on age, sex, history, and other confounders, there was no association between new prescriptions for benzodiazepines/Z-drugs and development of dementia 4 to 20 years later. A PET amyloid uptake study in 268 nondemented older adults found significantly less amyloid uptake, implying a lower risk of Alzheimer disease, in patients taking benzodiazepines, especially shorter-acting benzodiazepines. Findings suggesting no increased risk of development of dementia with benzodiazepines do not negate the cognitive side effects of these medications, especially in demented patients, and most experts recommend avoiding combining benzodiazepines and anticholinergic drugs in patients prone to cognitive impairment unless absolutely necessary.

Driving

An important psychomotor function that can be impaired by CNS depressants is driving. Driving tests and neurocognitive batteries indicate clinically relevant impairment of executive function, vigilance, and reaction time in association with impaired driving in users of benzodiazepine anxiolytics and hypnotics, to which some degree of tolerance may develop after 3 years of treatment. In a series of 410 suspected drunk or drugged drivers over age 65, alcohol was found in 81% of blood samples, benzodiazepines in 15%, and Z-drugs in 13%; the most frequently detected medications were zopiclone and diazepam. Similarly, in an Australian sample of 616 individuals aged 60 and older hospitalized as a result of a motor vehicle crash, the risk of a crash requiring hospitalization was higher for those who were prescribed benzodiazepines (O.R. 5.3), especially men (O.R. 6.2); the risk of a crash was increased somewhat less in drivers taking an antidepressant (O.R. 3.4). In 72,685 French drivers involved in traffic accidents resulting in injury, the risk of being responsible for the accident was higher in users of benzodiazepine hypnotics (O.R. 1.39), with an even greater risk (O.R. 2.46) for drivers prescribed more than one pill/day of zolpidem. Zopiclone was not associated with an increased risk of accidents in this study.

A series of meta-analyses of 21 epidemiologic studies and 69 experimental studies found that benzodiazepines were associated with a 60% to 80% increased risk of being in a traffic accident and a 40% increased risk of being responsible for an accident; the benzodiazepine-associated risk was lower in people who were older than age 65. Taking benzodiazepines during the day impaired driving independent of drug half-life. Use of diazepam, flurazepam, flunitrazepam, nitrazepam, and zopiclone as nighttime hypnotics also impaired driving, at least during the first 2 to 4 weeks of treatment. The use of alcohol plus a benzodiazepine was associated with a much greater (7.7-fold) increased risk of a traffic accident. Other research supports the observation that the combination of a benzodiazepine and alcohol impairs driving significantly more than a benzodiazepine alone. This observation is important since studies of impaired drivers find that at least 20% take another substance along with alcohol. All patients taking benzodiazepines, therefore, should be warned about the potential for impaired driving, especially in combination with alcohol. Patients may not be aware of impaired driving, tolerance to which does not occur as reliably as does tolerance to sedation.

Disinhibition

Patients who are in tenuous control of their impulses may engage in impulsive behavior or speech in response to decreased ability to suppress behavior consciously when they take benzodiazepines and Z-drugs. Some hypervigilant people become openly suspicious or agitated when their ability to keep track of details of their environment and other people is dulled by the CNS depressant effect of these medications. Additive impairment of vigilance and behavioral control of benzodiazepine receptor agonists and alcohol can lead to impulsive suicidal or aggressive behavior in vulnerable individuals.

Suicide

Benzodiazepines by themselves have a low fatality rate in overdose, but the risk of death with overdose is increased when they are combined with opioids or alcohol. Nevertheless, benzodiazepines and opioids are often prescribed together. In fact, from 1993 to 2014, the U.S. rate of combined use of benzodiazepines and opioids increased from 9.8 to 62.5/100,000, possibly explaining a concomitant increase in benzodiazepine-related deaths.

Is suicide more common in benzodiazepine users? A Swedish study compared 154 psychiatric patients who committed suicide with controls matched for age, sex, and psychiatric diagnosis. Benzodiazepine prescriptions were more common in suicides (42%) than controls (28%) (O.R. 1.83). However, this difference may have reflected a greater likelihood of use of benzodiazepines by patients at higher risk of suicide (i.e., confounding by indication). In a retrospective case-control study of 6,960 patients with anxiety disorders (2,362 of whom filled benzodiazepine prescriptions) and 6,215 patients with sleep disorders (1,237 of whom filled benzodiazepine prescriptions), patients taking benzodiazepines for anxiety who had a shorter duration of benzodiazepine use with concomitant psychotherapy or antidepressant treatment had a 39% decreased odds of suicide (O.R. 0.611; $P = .03$), while differences in suicide rates were not significant between patients who did or did not use benzodiazepines as hypnotics. Controlling for ongoing use of benzodiazepines in patients with more severe illnesses, compelling evidence of increased risk of suicide in patients taking these medications is lacking.

Tolerance

Tolerance is common to certain benzodiazepine actions. One mechanism of tolerance to benzodiazepines is that prolonged benzodiazepine receptor occupation triggers an intracellular calcium ion signaling cascade downstream from the $GABA_A$ receptor, leading to gradual downregulation of receptors via removal from the postsynaptic membrane by endocytosis and uncoupling of benzodiazepine and $GABA_A$ receptors, rendering the system less responsive to benzodiazepines. Administering flumazenil along with diazepam blocks these events, indicating that initial binding to the benzodiazepine receptors is an essential step in the development of tolerance. It remains to be seen whether inhibiting these processes with calcium antagonists or flumazenil might reduce tolerance to benzodiazepines.

Tolerance to benzodiazepine effects develops most frequently to sedation and less frequently to psychomotor impairment. Tolerance to the anxiolytic effect is less common than escalating the dose because of interdose withdrawal or subtherapeutic dosing. With adequate treatment, long-term use of benzodiazepines is usually associated with maintenance of therapeutic benefit without requiring dose escalation.

Discontinuation Syndromes

Three syndromes can follow the cessation of benzodiazepine agonists and related substances. Relapse refers to the return of the original anxiety disorder or insomnia. Relapse begins over weeks to months and follows the inherently chronic or recurrent course of most anxiety disorders. Rebound is a more intense re-emergence of anxiety or insomnia that can occur after cessation of benzodiazepines and Z-drugs, even after short-term use. Rebound symptoms, which are worse than the original symptoms, usually start within days to weeks and last up to 3 weeks. Rebound anxiety can occur 3 to 4 hours after each dose of short-acting benzodiazepines such as alprazolam and is manifested by interdose anxiety or uneasiness and clock-watching that is often mistaken for drug dependence. Similarly, rebound insomnia is more frequent and severe with short-acting, high-potency hypnotics such as triazolam and can occur on the night following the use of the hypnotic.

Syndromes that involve new features of autonomic arousal such as sympathetic signs, myoclonus or seizures are variably called withdrawal or discontinuation syndromes (Table 33.9b–3). Withdrawal begins within hours to days of discontinuation of short-acting benzodiazepines but may not begin for 1 to 2 weeks after abrupt discontinuation of longer-acting preparations; interdose withdrawal may occur with high-potency, highly lipid-soluble, short half-life benzodiazepines such as alprazolam. Withdrawal may occur after discontinuation of 4 to 8 months of treatment with typical benzodiazepine doses or after half that duration of treatment with higher doses. Minor withdrawal symptoms from benzodiazepines include sweating, tachycardia, nausea, myoclonus, restlessness, visual changes, tremor, and confusion; major new withdrawal symptoms include seizures, psychosis, and delirium. Seizures are more common in patients with predisposing factors such as abnormal EEG or brain damage and with concomitant use of medications that lower the seizure threshold. Withdrawal symptoms usually last 2 to 4 weeks and are more common and severe with high-potency, short to medium half-life benzodiazepines, but attenuated, prolonged withdrawal symptoms have been noted after discontinuation of long half-life benzodiazepines. Some reports of persistent withdrawal syndromes after discontinuation of long-term benzodiazepine use include anxiety, depression, psychosis, cognitive impairment, insomnia, sensory phenomena (e.g., tinnitus, paresthesias, pain, numbness, tingling, vibration, strange skin sensations), motor phenomena (muscle pain, cramps, weakness, tremor, shaking, myoclonus, spasms, shaking attacks), and GI symptoms (e.g., food intolerance, abdominal distension). Such features are more common with long-term treatment with short and intermediate half-life drugs and may last 6 to 12 months and sometimes years. Conversely, withdrawal from very short-acting benzodiazepines such as midazolam can be manifested by amnesia following a single dose, while withdrawal from triazolam and zolpidem can be followed by automatisms at night and amnesia the next day. Withdrawal from bedtime doses of zolpidem, zaleplon, and eszopiclone has been associated in a small number of reported cases with complex sleep behaviors resulting in injury and death from automobile crashes, hypothermia, overdoses, falls, and gunshot wounds.

Signs and Symptoms of Benzodiazepine Withdrawal

Anxiety
Depersonalization
Irritability
Insomnia
Hyperacusis
Diaphoresis
Hyperreflexia
Nausea
Difficulty concentrating
Confusion
Tremor
Hyperesthesia
Myoclonus
Seizures
Delirium

A confusing clinical picture may emerge when alcohol-dependent patients who have also been taking long-acting benzodiazepines are admitted to the hospital. The onset of withdrawal seizures or alcohol withdrawal delirium may be postponed up to several weeks because it is prevented by the benzodiazepine, which has a longer duration of action at the GABA-benzodiazepine receptor complex. When the serum level of the benzodiazepine eventually declines, typical alcohol withdrawal emerges, sometimes complicated by benzodiazepine withdrawal. The late onset of symptoms may result in withdrawal delirium being mistaken for postoperative psychosis or a medical or surgical complication.

Withdrawal can probably best be understood as a consequence of benzodiazepine receptor adaptation to chronic use. Benzodiazepine receptors downregulate in response to a large number of benzodiazepine molecules. At the same time, the inverse agonist DBI is upregulated to compensate for the suppression of CNS excitability. When the benzodiazepine is abruptly withdrawn, there are more DBI molecules than there are benzodiazepine molecules competing for fewer benzodiazepine receptors. This results in a shift of the benzodiazepine receptor toward inverse agonism, causing decreased, rather than increased, GABA receptor affinity, reduced, rather than enhanced, chloride influx, and membrane depolarization. CNS excitability increases abruptly, resulting in manifestations of arousal ranging from jitteriness and tremor to myoclonus and seizures. Slower benzodiazepine withdrawal allows the benzodiazepine receptor to upregulate, as DBI is gradually downregulated, but the unpredictability of this accommodation may lead to withdrawal symptoms with a slow taper or even with a simple reduction of benzodiazepine dose. An additional contributing factor to rebound insomnia after discontinuation of long-term benzodiazepine use may be dysregulation of endogenous melatonin rhythms.

Withdrawal can be minimized but not always prevented by slow tapering over 3 to 6 months or longer. Once it has developed, withdrawal from benzodiazepines and related CNS depressants is treated by reinstituting the previous dose and withdrawing the medication more slowly or by substituting a longer-acting benzodiazepine or another CNS depressant with a known pattern of withdrawal, preferably one that acts at the same receptor complex. Since barbiturates are cross-reactive with benzodiazepines, a barbiturate tolerance test can be used to more precisely determine the dose of barbiturate necessary to suppress withdrawal, after which the barbiturate is gradually withdrawn. Possible adjunctive treatments for benzodiazepine withdrawal include melatonin and melatonin agonists, carbamazepine, pregabalin, and CBT.

Management of alprazolam withdrawal can be particularly difficult. If the medication is not administered frequently, interdose symptoms are common. Furthermore, as chronic doses of alprazolam are reduced below approximately 1 to 1.5 mg, the benzodiazepine receptor undergoes paradoxical downregulation instead of continuing to upregulate, resulting in an intensification of withdrawal symptoms, even with a very slow taper. Some clinicians find that substitution of equivalent doses of clonazepam facilitates withdrawal of the final doses of alprazolam, though this benefit is not always reliable. There is no literature on the management of persistent withdrawal syndromes.

Dependence and Misuse

Some experts assume that benzodiazepines have a high risk of misuse. Others contend that anecdotal reports of benzodiazepine misuse and dependence are not generalizable and that data supporting the contention that prescription of benzodiazepines frequently leads to abuse of other substances have been mixed. A 2015–2016 survey found that 17% of people taking benzodiazepines reported misuse, which was defined as using without a prescription or not using as prescribed; rates of benzodiazepine misuse were highest in those aged 18 to 25 (51%, vs. 4% of those aged 65 or older). It is not known how many people reporting misuse were taking medications prescribed for them versus medications obtained on the street or from friends and family. The same limitation applies to the findings of a 2016 national drug adverse event surveillance protocol that reported 358,247 ED visits for harms from nonmedical use of pharmaceuticals. Illicit drugs were involved in 34% of visits, alcohol in 22%, benzodiazepines in 47%, and prescription opioids in 36%. Benzodiazepines were the only substance involved in 6.5% of cases, and prescription opioids were the only drug in 11.3%. The authors concluded that while benzodiazepines are frequently involved in ED visits for nonmedical drug use, they are most frequently used along with other substances. In such instances, a benzodiazepine is used to augment the “high” produced by other substances. A 2017 survey found that 17% of more than 2 million people being treated in publicly funded substance abuse programs identified benzodiazepines as a secondary or tertiary drug of abuse, whereas only 1% said that benzodiazepines were the primary drug of abuse. Data on 86,186 adults from the National Survey on Drug Use and Health confirmed that misuse of benzodiazepines was usually in combination with stimulants or opioids.

A retrospective cohort study using databases from five Massachusetts agencies reported that 24% of 63,345 adults who received buprenorphine in a 4-year period filled at least one benzodiazepine prescription during treatment with buprenorphine. Concomitant use of a benzodiazepine during buprenorphine treatment was associated with a 2.92 times increased risk of fatal opioid overdose, a 2.05 times increased risk of nonfatal opioid overdose, and a 1.90 increased risk of all-cause mortality, but a 13% decreased likelihood of buprenorphine discontinuation. The latter finding is somewhat consistent with a study of urine toxicology and prescriber information from a single payer in which patients receiving methadone maintenance taking nonprescribed benzodiazepines, but not those taking prescribed benzodiazepines, were more likely to drop out of treatment. There may therefore be a difference between prescribed and illicit benzodiazepine use in patients who misuse other substances. In fact, benzodiazepine dependence is relatively uncommon in patients without a history of substance use disorder when the medication is prescribed for an appropriate reason.

Misuse of benzodiazepines may be becoming more of a problem in younger people. Pediatric benzodiazepine use steadily increased from 2000 to 2015, and in 2018, 3.9% of 10th- and 12th-grade high school students reported nonmedical use of benzodiazepines. Some adolescents may be switching from recreational use of illicit drugs to prescription medications on the grounds that they are safer because they are approved by the government. The combination of increased misuse of benzodiazepines and increased distress associated with restrictions due to the COVID-19 pandemic has contributed to escalating overdoses involving benzodiazepines in adolescents: the number of emergency department visits for benzodiazepine overdoses increased by 34% with opioids and 21% without opioids.

Although there were fewer than 3,000 fatal overdoses involving benzodiazepines in 2020, the number increased by 43% (from 1,004 to 1,435) from April–June 2019 to the same period in 2020, including a 22% increase in deaths associated with prescription benzodiazepine overdoses and a 520% increase in deaths associated with nonprescribed benzodiazepines. Aside from alprazolam (LD_{50} 300 to 2,000 mg/kg), the lethality in overdose of benzodiazepines alone other than alprazolam in overdose is low (LD_{50}s in the thousands of mg/kg). Benzodiazepines increase the lethality of opioid and alcohol overdoses. In 2020, 92.7% of fatal benzodiazepine overdoses also involved opioids, especially illegal forms of fentanyl. Such data suggest that the bulk of benzodiazepine misuse and fatal benzodiazepine overdoses involves concomitant misuse of opioids and that administering opioid antagonists should be considered if a benzodiazepine overdose does not respond promptly to flumazenil.

In September 2020, the FDA announced that it would revise the boxed warning for benzodiazepines to include warnings about risks of abuse, addiction, dependence, and withdrawal syndromes. The FDA will also advise that benzodiazepines should primarily be used short-term, that co-prescribing with opioids should be avoided, and that alternative treatments should be considered. This advice may result in inappropriate withholding of benzodiazepines and, in some cases, the use of cannabis, alcohol, and other substances instead. Viewing taking more medication than prescribed as a sign of addiction may lead to unnecessarily discontinuing the medication when it is actually the result of suboptimal prescribing, attempts to eradicate all symptoms completely, interdose withdrawal and rebound, and poor doctor–patient communication rather than attempts to achieve euphoria.

Adverse Effects of Z-Drugs

Healthcare providers often overestimate the benefits and minimize the risks of Z-drugs compared to benzodiazepines. Reports of low rates of problems such as tolerance, withdrawal, and rebound insomnia with Z-drugs have been based on shorter-term studies and less experience than benzodiazepines, and more recent data suggest that tolerance and rebound insomnia do occur. Like benzodiazepines, Z-drugs can cause falls. Physical dependence has been associated with all of the newer benzodiazepine receptor agonist hypnotics, as have sleep-related behaviors, including sleep driving. Because of its short elimination half-life, zolpidem usually does not produce much daytime impairment, but memory impairment similar to that seen with triazolam can occur approximately 1.5 hours after dosing, and complex automatisms including driving and eating during sleep have been reported with amnesia for the behavior. Adverse effects are more common at doses exceeding 20 mg. Concerns about adverse effects and withdrawal have led to a reduction of the recommended dose of zolpidem to 5 mg for the immediate release form and 6.25 mg for the extended-release form.

In doses up to 10 mg, zaleplon has been found to cause dizziness, headache, somnolence, and psychomotor impairment. These side effects usually abate within 2 to 3 hours as a result of the short duration of action of the drug, minimizing daytime impairment. At doses of 60 mg, psychomotor impairment persists for 25 hours. The abuse potential of zaleplon and zolpidem appears to be low. In addition to expected side effects such as somnolence and dizziness, eszopiclone can also cause a bitter taste. An Irish study found that 23% of patients in a methadone maintenance program were abusing zopiclone, most frequently along with benzodiazepines or heroin. Although tolerance and rebound insomnia have been rare in clinical trials, rebound insomnia is more common than other discontinuation syndromes with eszopiclone.

DRUG INTERACTIONS AND LABORATORY INTERFERENCES

Benzodiazepines and Z-drugs all have additive sedative effects with each other and with other CNS depressants. As noted earlier, a number of other medication classes, including barbiturates, are cross-reactive with benzodiazepines and can be substituted for them in discontinuation protocols. Many benzodiazepines are substrates for CYP3A4 and CYP2C19. CYP3A inhibitors such as ketoconazole, nefazodone, and the antiretroviral lopinavir can substantially increase levels of benzodiazepines such as midazolam, diazepam, and triazolam. These medications should not be taken with grapefruit juice, which induces CYP3A4. However, even though alprazolam is a CYP3A4 substrate, it does not seem to be affected by grapefruit juice. L-Type calcium channel blockers and ritonavir may increase zolpidem effects.

No effects of benzodiazepines and Z-drugs on laboratory tests have been reported.

DOSAGE AND ADMINISTRATION

Usual doses of benzodiazepines and Z-drugs are summarized in Table 33.9b–1. Even benzodiazepines with long elimination half-lives are often given in divided doses to avoid oversedating peak levels. In chronic treatment, especially at higher doses, it is sometimes necessary to administer alprazolam frequently (e.g., every 2 to 3 hours) to prevent interdose withdrawal and rebound anxiety. An alprazolam sustained-release preparation (Xanax XR) has acceptable steady-state kinetics with three daily doses. Slow absorption of temazepam administered at bedtime makes this approach most useful for patients who have no trouble falling asleep but wake up early. If this medication is to be used for difficulty falling asleep, it should be taken 1 to 2 hours before bedtime.

Chronic and relapsing anxiety disorders such as GAD and panic disorder often require ongoing treatment, and withdrawing benzodiazepines after a few months of treatment often results in a relapse of chronic and relapsing anxiety disorders such as GAD and panic disorder. If maintenance pharmacotherapy with an antidepressant is planned, but the antidepressant induces intolerable early jitteriness, adding a benzodiazepine can suppress the initial increase in anxiety induced by the antidepressant. As noradrenergic activity is gradually downregulated over the first few months of treatment, the benzodiazepine can be gradually withdrawn. Conversely, for some patients who have been taking stable doses of benzodiazepines for years without evidence of impairment or misuse and who do not tolerate or respond well to an antidepressant, continuing the benzodiazepine is preferable to attempting multiple unsuccessful attempts at drug discontinuation.

The initial bedtime dose of oral zolpidem, sublingual Edluar, and oral spray Zolpimist is 5 mg. The dose can be increased to 10 mg. The controlled-release formulation of zolpidem (Ambien CR) is started at a dose of 6.25 mg, and the dose can be increased to 12.5 mg for males if necessary. The initial dose of Intermezzo is 1.75 mg for women and 3.5 mg for men. Zaleplon is started at a bedtime dose of 5 mg, and the dose can be increased to 10 to 20 mg. The short duration of action of zaleplon makes it applicable for patients who have to get back to sleep after waking up in the middle of the night. Eszopiclone is started at a bedtime dose of 1 mg, and the dose is increased as needed to 2 to 3 mg.

BENZODIAZEPINE RECEPTOR ANTAGONISTS

Neuroscience-Based Nomenclature (NbN)	
Flumazenil	
Pharmacologic Domain	GABA
Mechanism of Action	Receptor Antagonist (GABA-A receptor, α-1,2,3, and 5 subtypes)

As noted earlier, antagonists occupy receptors but have no effect on receptor signaling. The only available benzodiazepine antagonist is flumazenil, which has a benzodiazepine structure and is used to block the action of benzodiazepines and Z-drugs. The most common application of this effect is in the treatment of benzodiazepine overdose or to reverse conscious sedation with benzodiazepines such as midazolam.

Pharmacologic Actions

Flumazenil is administered intravenously because extensive presystemic metabolism results in low bioavailability after oral dosing, necessitating high oral doses that most patients cannot tolerate. Flumazenil has an elimination half-life of approximately 15 minutes and is metabolized to a free acid and a glucuronide, which are excreted in the urine. The drug is completely eliminated within 72 hours. Age and gender do not affect pharmacokinetics, but liver disease slows metabolism and prolongs the half-life and duration of action of flumazenil.

Flumazenil reverses CNS depression caused by benzodiazepines. Although alcohol and barbiturates act on the same receptor complex, their primary action is not at the benzodiazepine receptor, and sedation and other signs of CNS depression caused by these substances are not antagonized by flumazenil. The effects of opioids, which act at an entirely different site, are not affected by flumazenil. Emergency treatment of a known or presumed mixed narcotic/benzodiazepine overdose, or an apparent benzodiazepine overdose that does not respond to the benzodiazepine antagonist, may require administration of an opioid antagonist (naloxone) as well as flumazenil.

Therapeutic Indications

Flumazenil is indicated for the reversal of benzodiazepine-induced CNS depression caused by intentional overdose or reversal of anesthesia or conscious sedation. It has also been used experimentally to treat hepatic coma.

Precautions and Adverse Reactions

Common adverse effects of flumazenil include nausea, vomiting, dizziness, agitation, cutaneous vasodilation, headache, agitation, visual problems, memory impairment, and emotional lability. Benzodiazepine withdrawal may be precipitated by flumazenil, especially in patients taking benzodiazepines chronically. Seizures may occur in patients with epilepsy and in patients who have taken an overdose of TCAs.

The most important interaction of flumazenil is to antagonize the effect of benzodiazepines and Z-drugs. In benzodiazepine overdoses that include other medications, reversal of sedation from the benzodiazepine may uncover intoxication with the other substances. If a mixed overdose includes medications that can induce seizures, reversal of the anticonvulsant effect of the benzodiazepine can lead to the emergence of seizures driven by the other substance.

No interference with laboratory tests has been reported.

Dosing and Administration

The starting dose of flumazenil is 0.2 mg (2 mL), given intravenously over 30 seconds. A 0.3-mg (3-mL) dose is added if the patient does not regain consciousness within 1 minute. This dose can be repeated up to a maximum total dose of 5 mg over approximately 5 minutes. If unconsciousness is not reversed with this dose, it is probably not caused by benzodiazepines, and further treatment with flumazenil is not likely to be effective.

INVESTIGATIONAL DRUGS

Abecarnil is a β-carboline benzodiazepine receptor partial agonist that has anxiolytic and anticonvulsant actions with minimal sedation and psychomotor impairment. This medication may be useful in treating GAD and uncomplicated alcohol withdrawal syndromes. Abecarnil has not been released in the United States. Bretazenil and imepitoin are imidazolone partial benzodiazepine receptor agonists with potential applications in anxiety and seizure disorders that seem to be associated with minimal tolerance and potential for misuse. A benzodiazepine S-enantiomer, (S)-1-(2-fluorophenyl)-3-(2-oxo-5-phenyl-2,3-dihydro-1H-benzo[e] [1,4]-diazepin-3-yl)-urea (RSV604), inhibits respiratory syncytial virus replication by binding to the viral nucleoprotein.

Naturally occurring flavones bind to the benzodiazepine receptor, and multiple synthetic flavonoids have been designed to have agonist and inverse agonist effects. In animal studies, Gardenin A, a flavonoid found in medicinal plants, has been found to have anxiolytic, sedative, antidepressant, and anticonvulsant properties. Later studies contradicted early findings that the flavonoid 6-bromo-3’-nitroflavone, which has a structure derived from plants used in folk medicine as tranquilizers, had potent anxiolytic properties.

The PBR also referred to as the TSPO, is involved in apoptosis, inflammation and steroidogenesis. TSPO ligands have potential antiapoptosis actions that could be useful in Alzheimer disease. Conversely, the PBR ligand PK11195, but not diazepam, induces apoptosis in some cancer cell lines and is a potential adjunctive agent in the treatment of some forms of cancer. In some cell lines, however, PK11195 can prevent cytokine-induced apoptosis. An agonist effect at the

PBR could help protect the brain from oxidative damage and could possibly reduce the progression of some neurodegenerative diseases.

Indiplon, a potential hypnotic that is selective for the benzodiazepine-1 receptor, also inhibits platelet aggregation. Ocinaplon, a full agonist at benzodiazepine-1 receptors and a partial agonist at benzodiazepine-2 and -3 receptors, was withdrawn during Phase III studies because of elevated liver enzymes. Pagoclone is a cyclopyrrolone that is a partial agonist of benzodiazepine-1 and -2 receptors and a full agonist at PBRs that is under study as a treatment for generalized anxiety disorder and panic disorder. A placebo-controlled study followed by an open-label extension found significantly more improvement in stuttering with pagoclone and continued improvement during an open-label extension. Agonists of the $GABA_B$ receptor such as baclofen have been used to treat the misuse of substances such as alcohol, cocaine, and opioids. Experimental $GABA_B$ partial agonists, including CGP7930, GS39783, NVP-BHF177, and BHFF, are associated with less receptor desensitization and, therefore, less tolerance and have been found to have anxiolytic effects. Ongoing studies of $GABA_B$ antagonists appear to have antidepressant and possibly cognitive enhancement properties in preliminary studies. Ligands of peripheral benzodiazepine and $GABA_B$ receptors may be promising targets for the development of nonbenzodiazepine medications with novel applications.

33.10 Cation Function Modulators and Lithium (“Mood Stabilizers”)

33.10a Calcium Channel Inhibitors

Steven L. Dubovsky, M.D., and Dori Marshall, M.D.

The development of novel mood-stabilizing medications has been hampered by the lack of a cohesive neurobiologic model that could explain the frequent mixtures and rapid alternations of elevated and depressed mood, the complex presentations of bipolar mood disorders, and their comorbidity with certain medical conditions. One new model involves intracellular messengers that directly regulate multiple aspects of cellular function in affective, cognitive, vegetative, and behavioral systems and can have enduring effects on those systems through altered gene expression. The same impact of changes in intracellular signaling can modify vascular, cardiac, endocrine, and other bodily systems. Treatments aimed at correcting dysregulated intracellular signaling could have potential therapeutic applications. The intracellular calcium ion (Ca^{2+}) is particularly interesting as a target for pharmacologic intervention. Within neurons, intracellular Ca^{2+} signaling regulates excitability, circadian and other rhythms, the sleep–wake cycle, information processing, sensory perception, cognition, consciousness, neurotransmission, synaptic proteins, regulation of expression of multiple genes, remodeling of neuronal architecture, and neuroplasticity, which is essential for neuronal resilience and stabilization of systems that regulate mood.

Free intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) is normally regulated tightly at around 100 nM, or 1/10,000 of the Ca^{2+} concentration in the extracellular fluid. Most intracellular calcium is inactive by being stored in organelles such as mitochondria and the endoplasmic reticulum or complexed with binding proteins. Free intracellular calcium levels are increased rapidly by release from intracellular stores, while influx through calcium channels replenishes intracellular stores, triggers the release of stored Ca^{2+} and help to regulate the baseline concentration of free intracellular Ca^{2+} ($[Ca^{2+}]_B$), which in turn influences neuronal excitability (Fig. 33.10a–1). Cellular activation, which may be initiated by agonists such as neurotransmitters or may be spontaneous, increases $[Ca^{2+}]_i$, resulting in stimulated free intracellular Ca^{2+} concentration ($[Ca^{2+}]_S$), activating multiple cellular processes. Resting $[Ca^{2+}]_i$ is restored by the active transport of Ca^{2+} into intracellular stores and out of the cell.

Intracellular calcium signaling has a biphasic effect (Fig. 33.10a–1). Moderate increases stimulate cellular activity, whereas greater elevations inhibit the same functions. Increased intracellular Ca^{2+} signaling in excitatory and inhibitory systems could change the balance between these systems, leading to alternations between excitatory and inhibitory states manifested as mania and depression, while these states could occur simultaneously if a hyperactive intracellular Ca^{2+} signal produced behavioral and emotional activation in some systems and suppression in others. This possibility is supported by observations that hypercalcemia can be associated with depression or mania. Enhancement of Ca^{2+} signaling by antidepressants could lead to antidepressant-induced mania, while attenuation by mood stabilizers of increased intracellular calcium signaling could improve both mania and bipolar depression. Increased intracellular calcium signaling can induce oxidative stress and apoptosis, contributing to the neuronal loss that has been observed with recurrent affective episodes. Hyperactive calcium signaling in other organs could play a role in the comorbidity of bipolar mood disorders with other conditions linked to cellular hyperactivity such as migraine headaches, hypertension, and coronary heart disease.

Empirical evidence has continued to accumulate in multiple cellular models of hyperactive intracellular Ca^{2+} signaling in bipolar disorder. Compared with controls, bipolar disorder patients have been found to have elevations of $[Ca^{2+}]_B$ and $[Ca^{2+}]_S$ in blood platelets, lymphocytes, B-lymphoblast cell lines (BLCLs), olfactory neurons, and neuroblastoma cells. Most but not all studies find increased $[Ca^{2+}]_i$ in mania and bipolar depression, but not in unipolar depression, as well as normalization of $[Ca^{2+}]_i$ with normalization of mood regardless of treatment (Fig. 33.10a–2). The same finding, regardless of cell type, along with a lack of increase of $[Ca^{2+}]_i$ in control platelets after incubation with a plasma ultrafiltrate from bipolar disorder patients with elevated platelet $[Ca^{2+}]_i$, suggests that hyperactive intracellular Ca^{2+} signaling represents a generalized change in intracellular calcium ion dynamics rather than the result of a circulating substance. The lack of hyperactive platelet intracellular Ca^{2+} signaling in schizophrenia suggests that the finding is related to a core feature of bipolar disorder and not a feature shared with other conditions such as psychosis.

FIGURE 33.10a–1. Intracellular calcium ion signaling. Intracellular calcium ion concentration ($[Ca^{2+}]_i$) is increased by entry into the extracellular space and by release from intracellular stores. Calcium enters the cytosol through receptor operated (e.g., *N*-methyl-D-aspartate) and potential-dependent ion-specific channels, as well as in exchange for intracellular sodium. Stimulation

of a variety of G-protein–associated receptors (e.g., serotonin type 2 and dopamine type 2) activates turnover of the membrane phosphoinositol system, with production of inositol triphosphate (IP3) and diacylglycerol (DG). IP3 releases calcium ions from intracellular stores, and DG draws protein kinase C (PKC) to the cell membrane, where it is activated by Ca^{2+}. Moderate increases in $[Ca^{2+}]_i$ stimulate cellular processes by activating PKC and a variety of other enzymes that are activated by the calcium–calmodulin (CaM) complex; greater increases suppress the same processes. CBZ, carbamazepine; CCB, calcium channel blocker; Li, lithium; NL, neuroleptic; PIP2, phosphatidylinositol biphosphate; PLC, phospholipase C; TCA, tricyclic antidepressant.

Animal studies support these findings. Heterozygous Myshkin (Myk/+) mice, which have a missense mutation of the neuron-specific sodium/potassium ATPase, exhibit mania-like behavior such as hyperambulation, altered sleep–wake cycle, and increased reward preference. The manic-like behavior, which is reduced by lithium and valproate, is associated with increased release of Ca^{2+} from intracellular stores in cortical neurons and elevated glutamate-induced Ca^{2+} currents. In infant pigtail and bonnet macaque monkeys separated from their mothers or peers, which produces observable agitation, distress, depression, and immune suppression that remit with a reunion, lymphocyte $[Ca^{2+}]_B$ and mitogen-stimulated $[Ca^{2+}]_S$ increased significantly, and levels returned to pre-separation values with a reunion.

Elevated resting $[Ca^{2+}]_i$ in bipolar disorder may be the result of an altered balance between homeostatic mechanisms such as calcium influx through calcium channels, efflux through ion exchange, and intracellular storage (Fig. 33.10a–1). Rapid increases in $[Ca^{2+}]_i$ associated with cellular activation are the result of the release of Ca^{2+} from intracellular stores. One clearly demonstrated the mechanism of release of stored Ca^{2+} involves turnover of the membrane phosphatidylinositol (PI) system, beginning with the hydrolysis of membrane-bound PI bisphosphate (PIP_2) through several intermediate metabolites to produce two end products of metabolism—inositol triphosphate (IP_3) and diacylglycerol (DG). IP_3 acts on mitochondrial and other intracellular receptors to promote the release of stored Ca^{2+}, while DG attracts the intracellular enzyme protein kinase C (PKC) to the cell membrane, where it is activated by free intracellular Ca^{2+} and phosphorylates intracellular proteins that regulate multiple cellular processes. PIP_2 is reconstituted from these metabolites through a number of steps for another round of cellular activation.

Dysfunction at various points in PI turnover has been suggested in bipolar disorder. For example, an allele of IMPA2, the gene for inositol monophosphatase (the rate-limiting step in the reconstitution of membrane PIP_2), has been reported to convey susceptibility to bipolar disorder probably by increasing IP_3 and PKC production. Additional proposed mechanisms of increased free intracellular Ca^{2+} signaling in bipolar disorder include hyperactivity of the calcium-binding protein neuronal calcium sensor-I (NCS-1), which is activated by IP_3, and decreased activity of B-cell lymphoma-2 (Bcl-2), an antiapoptotic and pro-neurotrophic intracellular protein that interacts with the IP_3 receptor to inhibit the release of stored Ca^{2+}. Decreased Bcl-2 activity, which has been reported in bipolar disorder, would contribute to increased Ca^{2+} release from intracellular stores. A single nucleotide polymorphism (SNP) of the Bcl-2 gene associated with decreased gene expression has been found in lymphoblasts of patients with bipolar disorder, along with increased $[Ca^{2+}]_B$ and increased IP_3-mediated $[Ca^{2+}]_S$, presumably associated with greater Ca^{2+} release from intracellular stores. Increased intracellular calcium signaling could exacerbate the loss of the antiapoptotic function, promoting the loss of cerebral grey matter in some bipolar disorder patients.

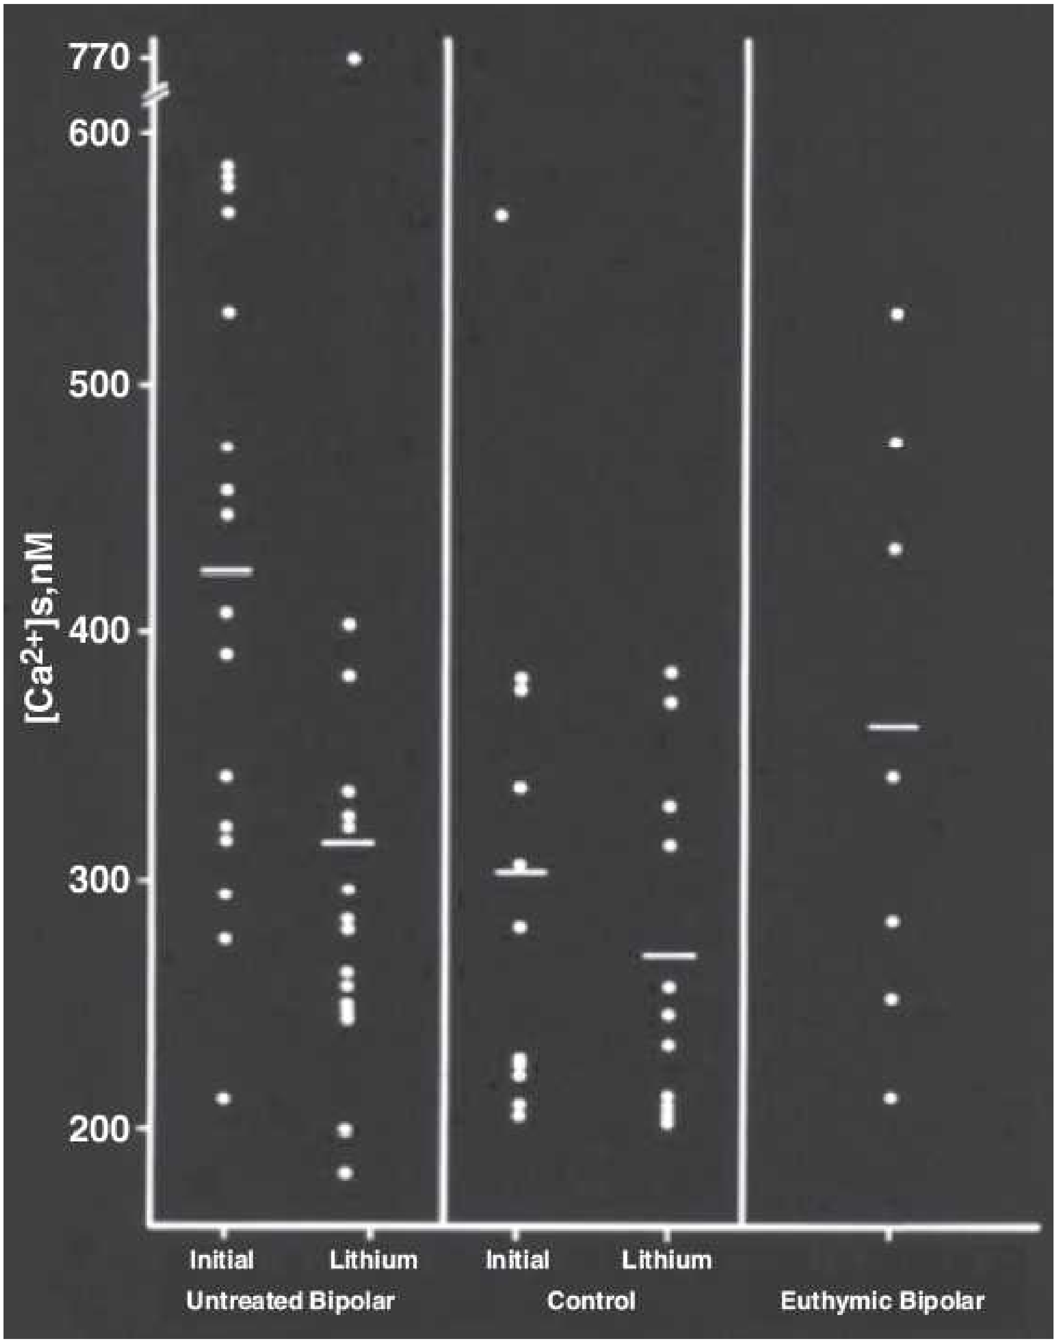

FIGURE 33.10a–2. Elevated platelet intracellular calcium ion concentration in bipolar disorder and normalization by lithium (Eskalith). Resting ($[Ca^{2+}]_B$) and, in this figure, stimulated ($[Ca^{2+}]_S$), as well as interindividual variability, are increased in mania and bipolar depression. Hyperactive intracellular calcium signaling is normalized by in vitro incubation with therapeutic concentrations of lithium, and bipolar patients who are euthymic after treatment with lithium or anticonvulsants have mean $[Ca^{2+}]_S$ levels that are statistically the same as in controls.

Lithium, the prototypical mood-stabilizing medication that is effective for both poles of bipolar mood disorders, reduces elevated $[Ca^{2+}]_B$ and $[Ca^{2+}]_S$ in peripheral cells of patients with bipolar disorder but does not affect normal $[Ca^{2+}]_i$ in most studies (Fig. 33.10a–2). Lithium inhibits inositol monophosphatase, the rate-limiting step in the reconstitution of PIP_2, which is upregulated in some cases of bipolar disorder; inhibition of the enzyme would eventually deplete IP3, decreasing both intracellular Ca^{2+} release and production of PKC. Mechanisms of calcium antagonism by lithium that could be relevant to the reduction of $[Ca^{2+}]_i$ include competitive inhibition of IP_3, inhibition of the calcium-binding protein NCS-1, interfering with calcium release from intracellular stores, decreased calcium influx, enhancement of calcium efflux by stimulating sodium-calcium countertransport, and inhibition of glycogen synthase kinase 3β.

Carbamazepine, which is also a well-established mood stabilizer, inhibits Ca^{2+} currents in a variety of cellular models, and the time course of suppression of calcium-dependent potentials is comparable to that produced by the calcium channel blocker verapamil. Similar to lithium, in vitro incubation with carbamazepine significantly lowers lymphocyte $[Ca^{2+}]_i$ in ill bipolar patients but not in controls or euthymic bipolar disorder patients. Valproate, another anticonvulsant with mood-stabilizing and especially antimanic properties, was found to reduce lysophosphatidic acid (LPA)-stimulated increased $[Ca^{2+}]_i$ in B lymphoblast cell lines from bipolar disorder patients and thapsigargin-stimulated release of Ca^{2+} from intracellular stores to an extent similar to lithium. Lithium, valproate, and ECT have been noted to upregulate Bcl-2 gene expression in some studies in conjunction with reducing elevated $[Ca^{2+}]_i$. Conversely, levetiracetam, an anticonvulsant that antagonizes *N*-type calcium channels, does not reduce hyperactive intracellular calcium ion signaling in bipolar disorder, and it is not effective as a mood stabilizer.

CALCIUM CHANNELS

Calcium ions enter the cytosol from the extracellular space through receptor-operated channels gated by receptors for hormones and neurotransmitters and through potential dependent channels (PDCs or voltage-gated channels), which are gated by membrane potential (Fig. 33.10a–1). In the brain, potential-dependent calcium channels are localized in regions rich in synapses, perhaps because high $[Ca^{2+}]_i$ must be produced rapidly to regulate neurotransmitter release. Additional pathways for calcium entry include leakage through an ungated channel and exchange of extracellular calcium ions for intracellular sodium ions (Na^+). Under physiologic conditions, PDCs can be regulated by receptor-mediated events such as the production of inositol triphosphate, and receptor-operated channels can be gated by changes in membrane potential. Furthermore, extracellular Ca^{2+} entering the cell may release calcium ions from intracellular stores, and trigger amounts of calcium ions released from intracellular stores may facilitate calcium channel opening. Endogenous regulators, which may be altered in disease states, appear to modulate PDC gating. Even subtle alterations of the function of one kind of calcium channel can therefore have significant effects on the overall balance of calcium-dependent cellular activity.

The PDC (Fig. 33.10a–3) consists of a central pore-forming CaV subunit and five allosterically linked units called α_1, α_2, β, γ, and δ. The PDC consists of a central pore-forming CaV subunit and five allosterically linked units: α1, α2, β, γ, and δ. There are 10 CaV-α1 subunits organized into various calcium channels. The mammalian nervous system contains 9 of the 10 major calcium channel types, with even more functional diversity related to alternative splicing events, as well as association with different subunits and regulatory proteins. Thus far, four separate genes coding for the α1 subunit have been identified. The α1C subunit of the CaV1.2 channel, a primary source of Ca^{2+} entry in neurons in the brain, is coded by the CACNA1C gene, an allele of which has been associated with bipolar disorder, as discussed below. The other subunits, and possibly other endogenous circulating factors, can alter the conformation of the α1 subunit, changing the activity of the calcium channel and its affinity for medications that bind to it at specific binding sites.

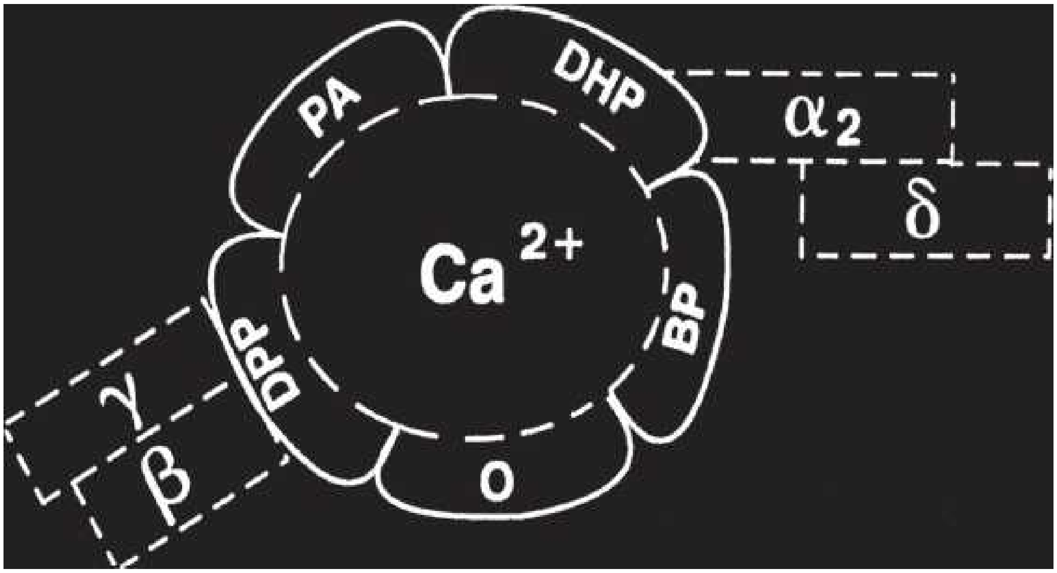

FIGURE 33.10a–3. Structure of the calcium channel blocker–binding site. BP, benzodiazepine-binding site; DHP, 1,4-dihydropyridine-binding site; DPP, diphenylpiperazine-binding site; O, other calcium channel blocking agent binding sites; PA, phenyl alkylamine–binding site.

Table 33.10a–1.
Calcium Channel Subtypes

Channel Type	L	T	N	P	Q	R
Locations	CV, neurons, endocrine, skeletal muscle	Neurons, smooth muscle, SA node	Neurons	Neurons	Neurons	Neurons
Functions	Excitation-contraction coupling, NT release, vascular tone	SA node activity, repetitive neuron depolarization, hormone release	NT release	NT release	NT release	NT release

CV, cardiovascular system; SA, sinoatrial node; NT, neurotransmitter.

Six types of potential-dependent calcium channels have been characterized (Table 33.10a–1). Different calcium channels in the nervous system perform different physiologic functions, and multiple copies of the same channel interact to fine-tune cellular regulation. The L (for long-lasting) channel requires significant depolarization for Ca^{2+} entry and inactivates slowly. Of the four members of the L-type channel family (CaV1.1–1.4), only CaV1.2 and CaV1.3 play a prominent role in the brain, the former in the hippocampus and the latter in the limbic system and striatum. L-Type calcium channels (LTCCs) do not participate directly in neurotransmitter release, but they play an important role in setting overall neuronal excitability; CaV1.2-based channels also influence gene transcription and gene expression.

The T (transient) channel is activated by small depolarizations and inactivates rapidly. T-type calcium channels may be involved in the action of the anticonvulsants ethosuximide, valproic acid, and divalproex in treating absence seizures. Calcium channels that are primarily found on central nervous system (CNS) neurons and participate in neurotransmitter release include N (neither L nor T) channels, P (Purkinje cell) channels, Q channels, and R (resistant to calcium channel blocker) channels. N channels are antagonized by the anticonvulsant levetiracetam and by ziconotide, a peptide toxin used to treat chronic pain, but not by calcium channel blocker drugs. The rapidly inactivating P channel is found in cerebellar Purkinje cells and is insensitive to a class (dihydropyridine) of calcium channel blockers.

L-Type calcium channel dysfunction resulting in increased calcium influx into cells in bipolar disorder could contribute to elevated $[Ca^{2+}]_B$, increasing resting neuronal excitability, as well as to increased intracellular Ca^{2+} storage with subsequent excessive elevations of $[Ca^{2+}]_i$ in response to stimulation. A polymorphism (rs1006737) of the CACNA1C gene, which encodes the α1c subunit of the L-type calcium channel $C_{av1.2}$, has consistently been associated in genome-wide association studies with bipolar disorder, especially early-onset bipolar disorder, as well as with vulnerability to depression and schizophrenia. In patients with bipolar disorder, the CACNA1C risk gene has been associated with crucial clinical aspects of the condition, such as altered circadian rhythms and deficits in executive functioning and cognition. Because this channel plays a central role in regulating gene transcription and the tonic excitatory drive, some cases of bipolar disorder could represent a channelopathy, similar to familial migraine and some seizure disorders.

FIGURE 33.10a–4. Structure of some CCBs.

CHEMISTRY

The first calcium channel inhibitor (calcium channel blocker or CCB) to be synthesized was verapamil, a derivative of papaverine (Fig. 33.10a–4). This medication was found to have applications in cardiovascular disease as a result of reduced excitation-contraction coupling caused by inhibition of calcium ion influx into cardiac cells. Subsequently, a total of 11 CCBs have been approved by the FDA, belonging to four chemical classes: phenylalkylamines (verapamil), benzothiazepines (diltiazem), dihydropyridines or DHPs (nifedipine, amlodipine, felodipine, isradipine, nicardipine, nisoldipine, nimodipine, and clevidipine), and diarylaminopropylamines (bepridil). Because of their heterogeneity of structure, binding site, and action, these medications are not interchangeable. However, they all have the capacity to reduce the excessive excitability of diverse cellular systems.

Verapamil and diltiazem are crystalline powders that are soluble in water and chloroform. Nifedipine is insoluble in water, but it is soluble in ethanol. Nimodipine, which is insoluble in water but is highly lipophilic, has two closely related congeners: isradipine and amlodipine. Amlodipine is a white crystalline powder that is slightly soluble in water and ethanol.

PHARMACOLOGIC ACTIONS

Pharmacokinetics

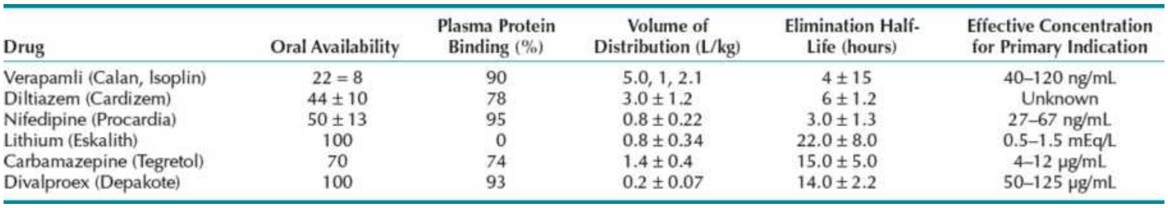
Absorption and Distribution. The CCBs are nearly completely absorbed after oral administration, but bioavailability is decreased by extensive first-pass hepatic and probably intestinal metabolism. First-pass metabolism also results in considerable interindividual variability in blood level at a given dose and in oral bioavailability that is generally less than that of other drugs that are more frequently used to treat bipolar disorder. However, effective concentrations for their primary indications are an order of magnitude lower (Table 33.10a–2). Optimal serum concentrations for mood disorders or conditions other than cardiovascular disorders have not been investigated. The more lipophilic, uncharged nimodipine crosses the blood–brain barrier readily and is approved for the treatment of stroke. Verapamil and its active metabolite can be recovered from human cerebrospinal fluid (CSF) after oral administration, and the concentration of phenylalkylamines and other CCBs in the brain is sufficient to be protective after cerebral ischemia in animal models.

Elimination. Most CCBs have elimination half-lives in the range of 1.3 to 6.0 hours, requiring multiple daily doses, except for amlodipine, a once-daily preparation with a half-life of 35 to 50 hours. Because repeated administration saturates hepatic metabolizing enzymes, bioavailability and half-lives increase with chronic administration, and the medication can be given less frequently. For example, verapamil is administered four times per day initially, but after 1 to 2 months, the frequency of dosing can often be reduced to two to three times daily. Intestinal and hepatic metabolism of many CCBs by CYP450 3A4 results in increased bioavailability when CCBs are taken with CYP3A4 inhibitors such as grapefruit juice.

Pharmacodynamics

Mechanism of Action. Currently available CCBs bind to L channels (i.e., L-type channels or LTCCs), which are found in the cardiovascular, endocrine, and CNS and in muscle. Their actions, therefore, are not limited to the CNS. All CCBs inhibit calcium influx via activity-dependent binding to the α1 subunit of LTCCs. In addition to binding to L-channels, nimodipine, nicardipine, methoxyverapamil, flunarizine, and cinnarizine may also antagonize T-channels, and a phenylalkylamine-binding site exists on the inner mitochondrial membrane. Variations in CCB structure result in variations in potency at different L-channels in different tissues, and depending on the distribution of binding sites for a given chemical class of CCBs, that class may be more or less active in a particular tissue or region. For example, dihydropyridines are more selective for vascular tissue, whereas with more cardiac activity, verapamil and diltiazem have more prominent antiarrhythmic properties.

Table 33.10a–2.
Comparative Chemistry of Some Calcium Channel Blockers and Some Mood Stabilizers



Drug	Oral Availability	Plasma Protein Binding (%)	Volume of Distribution (L/kg)	Elimination Half-Life (hours)	Effective Concentration for Primary Indication
Verapamli (Calan, Isoplin)	22 = 8	90	5.0, 1, 2.1	4 ± 15	40–120 ng/mL
Diltiazem (Cardizem)	44 ± 10	78	3.0 ± 1.2	6 ± 1.2	Unknown
Nifedipine (Procardia)	50 ± 13	95	0.8 ± 0.22	3.0 ± 1.3	27–67 ng/mL
Lithium (Eskalith)	100	0	0.8 ± 0.34	22.0 ± 8.0	0.5–1.5 mEq/L
Carbamazepine (Tegretol)	70	74	1.4 ± 0.4	15.0 ± 5.0	4–12 μg/mL
Divalproex (Depakote)	100	93	0.2 ± 0.07	14.0 ± 2.2	50–125 μg/mL

Along with allosteric regulation and the influence of circulating modulators, membrane potential determines the conformation of calcium channels and, therefore, the affinity of CCB-binding sites. CCB binding to L-channels is generally enhanced by depolarization and reduced by hyperpolarization, resulting in greater activity in hyperactive tissue, the CCB stabilizing the calcium channel in an inactivated state. Most DHPs are uncharged at physiologic pH and easily gain access to the receptor through the cell membrane if it is sufficiently depolarized. CCBs that are charged at physiologic pH, such as amlodipine, verapamil, and diltiazem, have slower onsets of action because of interactions with negatively charged phosphate head groups in the cell membrane. Because they gain access to the receptor through open channels, they are more active when channel openings are more frequent. The activity dependence of charged and uncharged CCBs makes these drugs more potent in hyperactive than in normally active tissue. Actions measured in cell preparations from normal subjects or animals, therefore, may not reflect activity in pathologic human states, a point exemplified by the finding that lithium attenuates elevated $[Ca^{2+}]_i$ in platelets of bipolar disorder patients but not in platelets of controls.

Although the finding of elevated free intracellular Ca^{2+} concentrations in bipolar disorder has been widely replicated and normalization of $[Ca^{2+}]_i$ has been shown to be associated with normalization of mood, there are several possible objections to the hypothesis that attenuation of excessive increases in $[Ca^{2+}]_i$ is directly relevant to mood stabilization or that any thymoleptic effect of CCBs is directly related to their action on intracellular Ca^{2+} signaling. For example, as noted previously, L-channels do not appear to be involved in the action potential-dependent release of neurotransmitters, and calcium channel subtypes that are specific to the CNS, such as N, P, Q and R-channels, are not affected by most L-type CCBs. However, L-channels are ubiquitous in the brain and are activated by neurotransmitters, making these channels an important component of neuronal interaction. Furthermore, it is not certain that neurotransmitter dysfunction is a primary element of the pathophysiology of mood disorders. Low concentrations of CCBs do not affect immediate neuronal Ca^{2+} currents in neurons containing L-channels because depolarization of these cells is normally too brief to permit sufficient CCB binding, but higher concentrations of CCBs may alter neuronal activity in other fundamental ways, and CCBs have greater effects on neurons with prolonged or marked depolarization. Reduction in tonic calcium influx may reduce the intracellular pool from which more immediate release results in rapid neuronal activation.

An alternative hypothesis is that the anticonvulsant property of some CCBs and not their effect on Ca^{2+} currents accounts for their activity in bipolar disorder. In favor of this possibility, prolonged elevations of $[Ca^{2+}]_i$ can contribute to the development and maintenance of seizure disorders by altering GABA receptor recycling, gene transcription, protein synthesis, and neuronal sprouting. In animal studies, nifedipine, diltiazem, and verapamil blocked the effect of subconvulsive doses of pentylenetetrazole (PTZ) to the same extent as valproate diltiazem enhanced the anticonvulsant effect of valproate, and amlodipine blocked PTZ-induced seizures in mice. Both verapamil and nimodipine inhibit amygdala-kindled seizures. Possibly as a result of T-channel antagonism, nimodipine has more of a potential for anticonvulsant actions. However, verapamil did not improve epilepsy control in phenobarbital-resistant canine epilepsy. The finding noted earlier that levetiracetam, which is clearly an anticonvulsant, does not normalize increased $[Ca^{2+}]_i$ in bipolar disorder and has little efficacy as a mood stabilizer tends to contradict the proposition that anticonvulsant properties are inherent to mood stabilization. Additional features of some CCBs that could be relevant to mood-stabilizing properties include antagonism of nicotinic cholinergic receptors and reduction of dopamine D_2 receptor signaling.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

The first published use of a calcium antagonist medication in psychiatry was a 1979 report of temporary reduction of agitation in three manic patients by subcutaneous injection of salmon calcitonin, which lowers $[Ca^{2+}]_i$ by driving Ca^{2+} into intracellular storage sites, but not placebo. Subsequently, the same group found that subcutaneous salmon calcitonin reduced agitation and manic behavior and improved sleep and Brief Psychiatric Rating Scale scores in 12 patients. Another approach to attenuating the impact of hyperactive intracellular Ca^{2+} signaling tamoxifen, an estrogen receptor antagonist used to prevent breast cancer recurrence that inhibits protein kinase C (PKC), had acute antimanic properties in small open and controlled Turkish trials.

In 1982, the first report emerged on the use of a CCB in the treatment of mania in a double-blind, placebo-controlled trial of verapamil in a single manic patient. The rationale for choosing this particular CCB was that it was the only CCB that could be obtained at a time at which none of these medications had yet been approved for use in the United States. Subsequently, case reports appeared of prevention by verapamil of antidepressant-induced hypomania and prevention of affective recurrence in bipolar disorder. Open trials of verapamil were effective in 4 of 7 manic patients, and in all patients with mania, ¾ of patients with mixed episodes, and about 1/3 of acutely depressed patients in a sample of 28 women.

Formal studies of CCBs have generally been small and relatively brief, with an emphasis on acute treatment of mania. In double-blind placebo-controlled trials, verapamil was superior to placebo in six manic patients and seven manic or schizoaffective-manic patients. Double-blind comparisons reported equivalent antimanic efficacy to lithium and clonidine. In open trials, the addition of verapamil or diltiazem improved the response to lithium in primary mania, but not mania secondary to CNS disease. A retrospective analysis of open administration of diltiazem suggested a benefit in treatment-resistant bipolar disorder, but no further investigation of this possibility has been published. A negative single-blind comparison of lithium and verapamil and a negative placebo-controlled double-blind trial of verapamil in mania were limited by verapamil doses that were lower and administered less frequently and for a shorter period of time than in positive trials. In the lithium comparison, patients treated with that medication were still very symptomatic at the end of the trial, and in the placebo-controlled study, patients only took verapamil for an average of 9.3 days, which would not be sufficient for established antimanic drug monotherapy.

Case reports have appeared of remission with nimodipine of chronic ultradian cycling refractory to all standard treatments in a 13-year-old patient and of the effectiveness of nimodipine for ultradian cycling after amygdalohippocampectomy. A 1-week open trial of nimodipine in six manic inpatients reported a significant response in all patients. Another open trial of nimodipine reported improvement in four manic patients, remission in one patient, and no response in two patients with mania secondary to CNS disease. In an 18-month open trial in 12 patients with rapidly cycling bipolar disorder, the combination of a low dose of nimodipine and lithium appeared to be significantly more effective than either medication alone in reducing recurrences of affective episodes, while anticycling effects of nimodipine were reported in two patients with rapid cycling when other treatments had failed. Careful longitudinal observations in small numbers of patients have suggested the possible usefulness of nimodipine for refractory recurrent mania and depression, ultradian cycling and recurrent brief depression, including in some patients with neurologic disorders. In double-blind studies using an off-on-off-on method, improvement has been noted with nimodipine, relapse on placebo, and then re-response on nimodipine. In doses sometimes exceeding the recommended maximum, several other small controlled studies have suggested the usefulness of nimodipine alone or combined with lithium, valproate, or carbamazepine in rapid and ultradian cycling bipolar mood disorders.

As is true of most putative mood stabilizers, the usefulness of CCBs in the treatment of depression is not as well studied as their potential applications in mania. Nifedipine reduces immobility in the behavioral despair test, which is believed to be an animal model of antidepressant activity; this effect is synergistic with antidepressants. Flunarizine was thought to reduce recurrences of bipolar depression in one patient, and one patient with recurrent brief depression responded to blind trials of nimodipine or verapamil. Improvement was reported in 27 of 30 patients with late-life depression when treated with nimodipine, and a significantly higher rate of improvement in patients with involutional depression occurred with nimodipine or amitryptiline versus placebo. Verapamil appeared to augment the antidepressant action of imipramine in a patient with unipolar depression who had previously responded to lithium augmentation; when imipramine was discontinued 6 months later, the patient remained euthymic on verapamil alone. An 8-month, double-blind placebo-controlled trial of the addition of nimodipine to fluoxetine in the treatment of major depression secondary to cerebrovascular disease (N = 101) found a number needed to treat of four both for remission and reduced risk of recurrence. In addition, a greater proportion of patients treated with fluoxetine-nimodipine (54% vs. 27%) exhibited full remission (P = 0.006). A Czech study found that overall, verapamil was no more effective than placebo, and was inferior to amitriptyline, in the treatment of depression, although a few patients did seem to have a genuine antidepressant response to verapamil. As the investigators did not differentiate between bipolar and unipolar depression, it is possible that, as would be expected with lithium, those with bipolar depression were more likely to respond to verapamil than were those with unipolar depression. Compared to placebo, treatment with nicardipine during ECT resulted in a better antidepressant response to ECT. In a single-blind pilot protocol involving 10 patients with bipolar depression generally of more than 6 months duration, acute treatment with isradipine resulted in significant improvement in six patients and remission in two. In open and controlled studies, nimodipine has appeared to be particularly useful in the treatment and prevention of both manic and depressive episodes. However, nifedipine was not effective for depression in a small study, and an animal study suggested that nifedipine interfered with the effects of antidepressants and electroconvulsive shock on the density of corticosteroid receptors.

The two negative antimanic trials of verapamil mentioned earlier led to conclusions by some reviewers that this and other CCBs are ineffective for bipolar disorder, a generalization that is not applied to contradictory experience with other medications with proposed antimanic and mood-stabilizing effects such as some anticonvulsants and atypical antipsychotic drugs. One factor may be the lack of industry sponsorship of larger CCB studies. In addition, studies supporting the thymoleptic properties of currently popular medications have relied on sample enrichment for patients with no comorbidities or complications who were shown a priori to be likely to respond to the experimental drug, while CCB studies have enrolled more heterogeneous samples of patients and have included subjects with complex and comorbid disorders. Since clinical testing of hypotheses of actions on intracellular processes has not been of as much interest as studies of neurotransmitter, receptor, and anticonvulsant hypotheses and development of “me too” products, conceptual as well as financial limitations on clinical research involving CCBs have limited the data available to reliably assess the place of CCBs in the treatment of bipolar disorder.

Bearing these limitations in mind, clinical experience suggests that verapamil is most likely to be useful for the treatment and prevention of mania and hypomania in patients who are responsive to lithium. It may be more likely to prevent bipolar depression recurrence than to treat it acutely. Nimodipine seems to have the potential for treating refractory and complex bipolar disorder, especially in combination with other thymoleptic medications. Nimodipine may be more useful acutely than verapamil for bipolar depression. However, larger controlled studies are necessary to assess its precise role. Very limited data suggest that isradipine, which is closely related to nimodipine, may have similar applications. Limited early research suggesting the possible benefit of verapamil, diltiazem, and nimodipine as adjuncts in the treatment of anxiety disorders has not been followed up in subsequent research.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Animal studies and clinical experience with verapamil in the treatment of fetal arrhythmias and premature labor, as well as with the prenatal treatment of hypertension with nicardipine and pre-eclampsia with isradipine, suggest relative safety of CCBs during pregnancy. A report of three patients for whom verapamil was effective for mania during pregnancy without any evidence of teratogenicity was amplified by a study of 28 pregnant women with acute episodes of mania or bipolar depression and 9 euthymic pregnant women who switched to verapamil maintenance from another mood stabilizer who had no complications of pregnancy and no teratogenicity, with a 100% response rate in mania, a 77% response rate in mixed states, and a 39% response rate in depression; six of eight patients who continued verapamil maintenance therapy remained well. A few case reports of similar outcomes with nimodipine during pregnancy have emerged. The number of reported cases is still too small to draw definitive conclusions about the use of nimodipine, verapamil, and isradipine in pregnancy, and there is virtually no information about other CCBs during pregnancy.

Concerns have been raised about an increased risk of reinfarction or mortality in elderly patients taking short-acting CCBs compared with long-acting agents following myocardial infarction (MI), possibly as a result of coronary vessel steal caused by diffuse vasodilatation. Such assumptions have been limited by the lack of control for the severity of hypertension. CCBs are usually used as second-line treatments for more severe hypertension, raising the possibility that patients treated with CCBs had worse cardiovascular outcomes because their hypertension was more severe. Furthermore, CCBs are known to reduce the risk of ventricular fibrillation after MI. Amlodipine and extended-release nifedipine were found not to increase the risk of acute cardiac events in older patients, and the large Danish Verapamil Infarction Trial (DAVIT) found that CCBs reduced the risk of reinfarction when used prophylactically after an index MI.

Arguing that CCBs could interfere with apoptosis in patients prone to cancer, early research suggested a slightly increased risk of cancer in patients taking CCBs. In support of this speculation, a meta-analysis suggested a statistically significant association between the use of CCBs and breast cancer but a decreased risk of prostate cancer nine years later. A review of observational studies suggested an increased risk of lung cancer with CCB use, although the lower limit of the 95% CI was only 1.01. However, uncontrolled cell growth is also calcium-dependent, and in studies suggesting increased cancer risk, antihypertensive use was assessed prior to the onset of cancer, without data that might inform whether these medications were being taken at the time when carcinogenesis was initiated or even whether CCBs were still being taken when cancer was diagnosed. Other cancer risk factors such as smoking, obesity and diet also were not controlled in these studies. A meta-analysis found no increased risk of breast cancer with long-term CCB use, and another large meta-analysis of trials involving a total of more than 334,000 subjects also found no increased risk of cancer with CCB use. A 5-year prospective RCT found no differences in cancer risk in older hypertensive patients treated with CCBs versus other antihypertensives, and the DAVIT trial found no increased risk of cancer in 10,474 patient-years experience in preventing MI. Furthermore, a mechanism of resistance to cancer chemotherapy is the induction of the MDR1 gene, which codes for Pglycoprotein, a drug extrusion protein that removes chemotherapy drugs from cancer cells. Verapamil, which inhibits P-glycoprotein, can reduce chemotherapy resistance. Since cell proliferation is a calciumdependent process, CCBs can inhibit tumor cell growth, and the ability of T-channels to generate rapid calcium currents at resting membrane potentials may account for findings that experimental T-channel antagonists reduce cancer cell proliferation in vitro.

THERAPEUTIC INDICATIONS

Because of their capacity to reduce cellular hyperactivity without suppressing normally active cells, CCBs have been used to treat angina, hypertension, Raynaud phenomenon, esophageal spasm, premature labor, and epilepsy. Verapamil and diltiazem, but not the DHPs, have class IV antiarrhythmic activity and are used to treat supraventricular arrhythmias. Verapamil can reduce migraine recurrence.

In view of the role of excessive elevations of $[Ca^{2+}]_i$ in neuronal apoptosis, nimodipine has the potential to reduce the progression of brain damage in neurodegenerative disease. Nimodipine is approved for the reduction of the risk of extension of neuronal damage by vasospasm following hemorrhaging stroke, and it has been reported to improve cognition following ischemic stroke. In an early study that randomized 87 elderly patients with cognitive decline to nimodipine and 88 patients to placebo for 12 weeks, there were more favorable changes in all cognitive measures and in depression with nimodipine. The drug was well tolerated and equally effective for “primary degenerative” and vascular dementia. There was a greater improvement in cognition after 3 months of treatment with nimodipine in 16 patients with mild cognitive impairment (MCI) compared with 15 controls. In a randomized trial in 230 patients (mean age 75) with vascular dementia to nimodipine or placebo, nimodipine was associated with better lexical production and Mini-Mental State Exam scores and had less deterioration and behavioral disturbances requiring intervention, as well as fewer dropouts and adverse events, than placebo. A randomized controlled study found nimodipine to be superior to placebo in slowing the deterioration of Alzheimer disease. A 2002 Cochrane review concluded that nimodipine “can be of some benefit” in dementia of various causes. Results of multicenter clinical trials of nimodipine for dementia have not been published. Verapamil has been reported to ameliorate tardive dyskinesia.

PRECAUTIONS AND ADVERSE REACTIONS

The most common CCB side effects involve consequences of excessive vasodilatation, such as dizziness, postural hypotension, headache, skin flushing, tachycardia, nausea, lightheadedness, weakness, and digital dysesthesia; aggravation of myocardial ischemia may rarely occur because of coronary steal related to vasodilatation elsewhere. Precapillary dilatation with reflex postcapillary constriction can increase capillary hydrostatic pressure and cause peripheral edema. Verapamil and diltiazem are more likely than other preparations to produce sinus bradycardia and atrioventricular block, which may aggravate heart failure. Coughing, shortness of breath, wheezing, rashes, somnolence, constipation, seizures, and, rarely, depressed level of consciousness or psychosis may be caused by the CCBs. Possibly because of inhibition of calcium signaling in postsynaptic dopamine receptors, akathisia, parkinsonism, and delirium have occasionally been associated with the use of calcium channel antagonists. Nimodipine sometimes causes bad dreams. Toxic serum concentrations of CCBs have not been defined. Possibly because of compensatory changes in calcium channels or CCB receptors, tachyphylaxis and withdrawal do not occur. CCBs do not alter exercise tolerance. Treatment of severe toxicity is with calcium, glucagon, volume expansion, and vasopressors.

Although inhibition of hyperactive intracellular calcium activity may reduce excitotoxicity in adult neurons, postnatal brain development depends on periodic increased intracellular calcium ion signaling, and animal studies suggest that neonatal (but not later) neurons are highly sensitive to reductions in intracellular calcium by CCBs, which can damage these neurons. The use of CCBs in very young children, therefore, requires substantial caution.

Drug Interactions

Adding CCBs to β-adrenergic blocking agents can result in additive cardiac slowing and atrioventricular block, whereas additive effects with α-adrenergic blocking agents may produce hypotension. Verapamil and nitrendipine increase plasma concentrations of digoxin and cause bradycardia, hypotension, or atrioventricular block when combined with quinidine. Because verapamil and nifedipine inhibit cytochrome P450 CYP3A4, they raise serum concentrations of CYP 3A4 substrates, such as carbamazepine and the triazolobenzodiazepines, which can result in carbamazepine neurotoxicity. Neurotoxicity also occurs occasionally when verapamil is combined with lithium or nifedipine due to inhibition of lithium clearance. Additive suppression of the spontaneous rate of depolarization of the sinus node and of conduction through the atrioventricular node can increase the risk of bradycardia when lithium is combined with verapamil.

Laboratory Interferences

As mentioned previously, verapamil and nifedipine raise serum levels of carbamazepine, digoxin, and other CYP 3.44 substrates. CCBs do not primarily affect other laboratory tests.

DOSAGE AND ADMINISTRATION

Verapamil is available in 40-, 80-, and 120-mg tablets. A 120-mg sustained-release preparation used to treat hypertension was effective for mania in one report of three cases, but it generally is not as reliably effective for mood disorders as the immediate release forms, possibly because higher peak levels are necessary for this indication. The usual daily doses of verapamil in the treatment of mania have been between 240 and 480 mg per day, although some patients may need higher doses because of low bioavailability resulting from extensive intestinal and hepatic first-pass metabolism. The short elimination half-life of verapamil requires three to four times per day dosing. Nimodipine is available as a 30-mg capsule and a 60 mg/20 mL solution and is administered in doses of 90 mg per day for dementia and stroke. However, doses for bipolar illness have ranged from 180 mg to as much as 720 mg per day, the latter dose being substantially greater than the maximum dose approved by the FDA. A frequency of dosing less than four times daily does not result in consistent levels, although less frequent dosing is sometimes effective. Isradipine, which is available as a tablet or capsule, is available in 2.5- and 5.0-mg immediate-release capsules and 5.0- and 10.0-mg extended-release tablets and is administered in doses of 2.5 to 20.0 mg per day in a frequently divided dose for hypertension. Amlodipine, the only CCB that is effective when it is administered once daily, is available in 2.5-, 5.0-, and 10.0-mg tablets and a 1 mg/mL oral suspension; the usual dose for hypertension and coronary heart disease is 5 to 10 mg per day. There is little experience with this medication in mood disorders.

INVESTIGATIONAL DRUGS AND PREDICTION OF RESPONSE

Research into psychiatric applications of CCBs has been limited by the relative lack of interest by manufacturers in developing and marketing them for such indications. Nimodipine and related dihydropyridine CCBs will probably turn out to have greater potential in psychiatric disorders than verapamil because they cross the blood–brain barrier more readily, and they act on T- as well as L-type channels. Future development of CCBs for psychiatric indications might profitably focus on selective antagonists of channels such as N-, P-, Q- and R-type channels that are primarily expressed in the CNS and would not be limited by cardiovascular and other systemic side effects, although the N-type channel blocker levetiracetam does not alter platelet $[Ca^{2+}]_i$ and is not effective for bipolar disorder. Further investigation of medications that antagonize other aspects of intracellular calcium ion dynamics, such as the estrogen receptor antagonist and PKC inhibitor tamoxifen, may also prove fruitful.

No mood stabilizer is effective for all patients, but few validated predictors have emerged of which medication may be most likely to be useful for which patients. In the case of CCBs, a few preliminary studies may provide future directions for research into predictors of response. A 2-week trial in which manic patients received 360 mg per day of verapamil found a 61% reduction in manic symptoms and a correlation between the degree of improvement of mania and increased plasma calcium levels. Since changes in extracellular calcium concentration are easy to measure, further investigation of a possible relationship between changes in plasma calcium levels and later response to a CCB may be justified. Similarly, a correlation was suggested between clinical response and the degree to which in vitro incubation of lithium with platelets of patients with bipolar disorder reduced elevated $[Ca^{2+}]_i$. Assessing the predictive value of incubation of a CCB with platelets could clarify whether reduction of

$[Ca^{2+}]_i$ might predict response to a CCB. Using this time-consuming and difficult assay, which is most valid when compared with a control, is not likely to be practical in clinical practice, but it could be used as a proxy for simpler and cheaper measures of potential response to a CCB. A positron emission tomography (PET) study finding that nimodipine responders had left insular hypometabolism compared with nonresponders, whereas carbamazepine responders had the opposite finding, may inform studies of neuroimaging changes as possible predictors of CCB response, either by themselves or as proxies to be used to study other possible laboratory predictors. Most of these lines of investigation have not been followed up due to a general lack of interest in psychiatry in the use of CCBs.

A more recent finding that suggests another line of research into possible predictors of CCB response is a study of healthy subjects reporting greater normalization by nimodipine of frontal metabolic activity measured by PET during a working memory task in those with the rs1006737 CACNA1C bipolar risk gene compared with those with a different allele. There was a "gene-dose effect" for the peak cluster of nimodipine action on working memory. Subjects with the AA genotype demonstrated a 62.32% decrease in BOLD activation with nimodipine compared to 37.42% for GA carriers and 16.05% for GG carriers. Since CCB binding is increased in hyperactive channels, such findings support the hypothesis that nimodipine may induce more blockade of a hyperactive CACNA1C variant that is linked to bipolar disorder than other CACNA1C genotypes. Some investigators, therefore, propose examining CACNA1C genotype as a predictor of CCB- or at least nimodipine-response. Imaging studies of the binding of labeled CCBs to central calcium channels may also turn out to predict clinical response.

The scatter in $[Ca^{2+}]_i$ in bipolar disorder patients (Fig. 33.10a–2) is one observable marker of the biologic heterogeneity of the disorder. Preliminary observations that patients with elevated platelet $[Ca^{2+}]_i$ that normalized with incubation with lithium may inform prospective studies of the use of this marker to predict CCB response. The heterogeneity of calcium channels and of CCB-binding sites may also provide for different spectra of action of different CCBs. Just as patients with one bipolar variant may do better with CCBs than those with another variant, it is possible that patients who do not respond to one CCB class may have a good response to another. For example, the rs1006737 variant of the CACNA1C gene may predict a preferential response to nimodipine or some other CCB. Combinations of CCBs with each other and with other antimanic drugs could have additive effects in treatment-resistant bipolar disorder. In view of the limited benefit from medications that are now commonly used as mood stabilizers and the tolerability of CCBs, more experience with this novel class of medications seems justified.

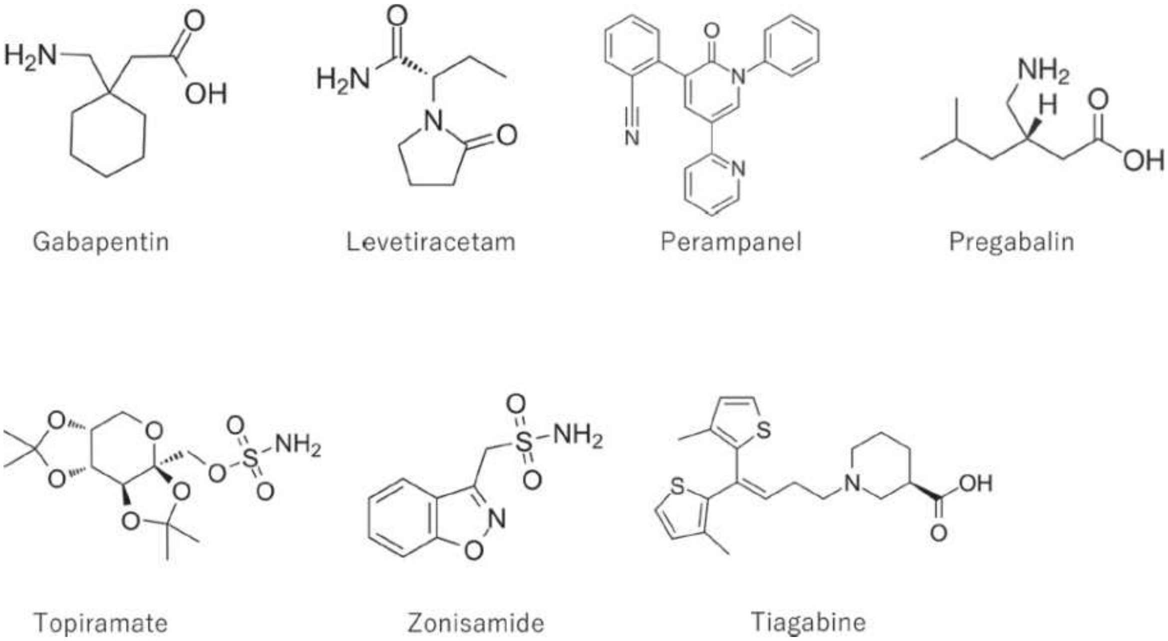
33.10b Gabapentin, Topiramate, Tiagabine, Levetiracetam, Zonisamide, and Pregabalin

Hiroyuki Uchida, M.D., Ph.D.

Newer drugs for epilepsy, marketed over the past three decades, have generally been developed to have enhanced tolerability, simpler kinetics, and fewer drug–drug interactions. The chemical structures (Fig. 33.10b–1) and pharmacodynamic effects of these drugs are diverse. Some purported mechanisms of action include enhancing neuronal inhibition by increasing GABAergic function or decreasing neuronal excitation by decreasing glutamatergic function via blockade of AMPA receptors. These agents have potential psychotropic benefits, and these amino acid neurotransmitters have been implicated in psychiatric disorders. Thus, newer drugs for epilepsy appear to have distinctive efficacy profiles for the treatment of epilepsy and diverse psychotropic and analgesic effects (Table 33.10b–1). A few of these agents can provide psychotropic benefits and have received Food and Drug Administration (FDA) indications for acute mania (valproate and carbamazepine) and bipolar maintenance treatment (lamotrigine). To address this discrepancy between drug categories and indications, the use of Neuroscience-Based Nomenclature (NbN) is encouraged.



Gabapentin Levetiracetam Perampanel Pregabalin

Topiramate Zonisamide Tiagabine

FIGURE 33.10b–1. Chemical structures of selected glutamate and GABA modulators.

In 2008, the FDA announced a class warning regarding the increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders based on data from diverse "anticonvulsants," six of which are described in detail in this chapter (gabapentin [Neurontin], topiramate [Topamax], tiagabine [Gabitril], levetiracetam [Keppra], zonisamide [Zonegran], and pregabalin [Lyrica]), and five of which are not described in this chapter (carbamazepine [Tegretol], felbamate [Felbatol], lamotrigine [Lamictal], oxcarbazepine [Trileptal], and valproate [Depakote]). This warning has been applied to subsequent anticonvulsants, including perampanel [Fycompa].

GABAPENTIN

Introduction and History

Gabapentin (Neurontin), which has a biochemical structure similar to the inhibitory amino acid neurotransmitter GABA, was developed by Warner-Lambert to create an agent for the treatment of spasticity. Gabapentin proved to be more effective as an anticonvulsant than an antispasticity agent. Gabapentin was found to be effective in several animal models of epilepsy, so it was developed as an antiepileptic drug and marketed for the adjunctive treatment of partial seizures in the United States in 1994 by Parke-Davis.

Due to its generally good tolerability, fewer clinically significant drug–drug interactions than older drugs for epilepsy, and initial, postmarketing, open, uncontrolled clinical experience suggesting efficacy in various neurologic and psychiatric conditions, gabapentin has become increasingly used in conditions other than seizure disorders. The use of gabapentin for other nonepileptic conditions substantially exceeded that in epilepsy. Double-blind randomized placebo-controlled trials later confirmed the efficacy of gabapentin for some, but not all, neurologic and psychiatric conditions suggested in open studies. Specifically, gabapentin appears to be effective in neuropathic pain and is marketed for the management of postherpetic neuralgia in adults. Gabapentin also appeared to be effective in anxiety disorders (social phobia and panic disorder) but not as the main intervention in mania or treatment-resistant mood disorders. Thus, gabapentin has emerged as a safe and effective agent in epilepsy and postherpetic neuralgia and has more widespread use adjunctively to relieve symptoms and pain and improve anxiety and insomnia in a dimensional fashion across diverse neurologic and psychiatric conditions. Moreover, gabapentin enacarbil (a prodrug of gabapentin) was found to be effective against moderate to severe restless legs syndrome. Finally, recent controlled data suggested that gabapentin could be effective for relapse prevention in people with alcohol dependence.

Chemistry

Gabapentin, 1-(aminomethyl)-cyclohexane acetic acid, is a novel amino acid derived from the addition of a cyclohexyl group to GABA (Fig. 33.10b–1). Immediate-release gabapentin preparations currently marketed in the United States include 100-, 300-, and 400-mg capsules; 600- and 800-mg tablets; and a 250 mg/5 mL oral solution. Generic immediate-release gabapentin is available in comparable formulations. Extended-release gabapentin and gabapentin enacarbil (a prodrug of gabapentin) are available in 300- and 600-mg tablets.

Pharmacologic Action

Pharmacokinetics. Gabapentin is available in immediate-release (Neurontin) and sustained-release (Gralise) formulations. In addition, gabapentin enacarbil is available in an extended-release formulation (Horizant). Immediate-release gabapentin has sublinear kinetics due to saturable gastrointestinal absorption, with oral bioavailability of approximately 60% at 300 mg three times a day, which decreases to 33% with 1,200 mg twice a day. In practice, the maximum individual doses of immediate-release gabapentin should not exceed 1,200 mg. Sustained-release gabapentin can be titrated up to 1,800 mg once daily with an evening meal. Gabapentin enacarbil was designed to have high-capacity absorption compared to gabapentin, even at doses greater than 1,200 mg, but the recommended dose is only 600 mg once or twice daily. Sustained-release gabapentin and gabapentin enacarbil are not interchangeable with other gabapentin products because of differing pharmacokinetic profiles that affect the frequency of administration. Food only modestly affects the rate and extent of immediate-release gabapentin absorption but more significantly affects the absorption of sustained-release gabapentin and gabapentin enacarbil, which needs to be taken with food. Gabapentin circulates in the blood largely unbound, with less than 3% bound to plasma proteins, and has a moderate volume of distribution of approximately 1 L/kg. Immediate-release gabapentin has a half-life of approximately 6 hours and is thus administered in three divided doses in patients with epilepsy. Sustained-release gabapentin and gabapentin enacarbil have an elimination half-life of approximately 6 hours, but due to differential absorption and indications, they are dosed once daily and once to twice daily, respectively. Gabapentin is not appreciably metabolized in humans, is eliminated unchanged by renal excretion, and can be removed by hemodialysis. Gabapentin clearance correlates with that of creatinine. Therefore, dosage adjustments are required in patients with impaired renal function. Clearance may be increased in children under the age of 5 years and decreased in the older adults, requiring dosage adjustments to be made.

Pharmacodynamics. Gabapentin has multiple biochemical actions, and the relationship between these and direct clinical effects remains to be established. Although gabapentin is a structural analog of GABA, it appears to lack direct GABAergic actions. Gabapentin appears to have indirect GABAergic effects, as both acute and chronic gabapentin increases cerebral GABA levels in humans. Gabapentin may also have antiglutamatergic actions, mediated by the inhibition of glutamate synthesis by branched-chain amino acid aminotransferase. It also modulates (but does not directly block) sodium channels and increases human whole-blood serotonin concentrations. Gabapentin has high-affinity regional (including neocortical and hippocampal) binding to $\alpha_2\delta$ subunits of voltage-activated calcium channels and thus may modulate calcium channels to reduce monoamine release. Several of these biochemical mechanisms may underlie the psychotropic effects of gabapentin.

Clinical Drug Studies

Seizure Disorders. Adjunctive immediate-release gabapentin was more effective than an adjunctive placebo in double-blind, randomized placebo-controlled trials involving adults and adolescents aged 12 years or older with refractory partial seizures and in one trial in children aged three to 12 years with refractory partial seizures.

Postherpetic Neuralgia. Gabapentin appeared to be more effective than a placebo in double-blind, randomized placebo-controlled trials in adults with postherpetic neuralgia, relieving pain and sleep interference and improving mood and quality of life. Moreover, gabapentin enacarbil appeared to be more effective than a placebo in several double-blind, randomized placebo-controlled trials in adults with postherpetic neuralgia. In contrast, one double-blind, randomized placebo-controlled trial found no significant relief from acute herpetic pain or prevention of postherpetic neuralgia with additional gabapentin to the usual treatment of herpes zoster within 72 hours of rash onset.

Other Pain Syndromes. Gabapentin appears to have analgesic effects in other pain syndromes, particularly in neuropathic pain. Thus, immediate-release gabapentin was more effective than placebo in relieving pain and, in some instances, yielded benefits on other measures such as sleep, mood, and quality of life in diabetic neuropathy, trigeminal neuralgia, neuropathic cancer pain when added to opioids, Guillain–Barré syndrome, fibromyalgia, painful human immunodeficiency virus (HIV)-associated sensory neuropathy, and diverse neuropathic pain. Immediate-release gabapentin was also more effective than a placebo in relieving post-amputation pain (in one of two studies), post-radical mastectomy pain, post-lumbar discectomy pain (when added to fentanyl but not when added to morphine), post-abdominal hysterectomy pain (when added to rofecoxib), and catheter-related bladder discomfort and postoperative pain in patients with percutaneous nephrolithotomy. Immediate-release gabapentin was more effective than placebo in chronic masticatory myalgia, complex regional pain syndrome type one (formerly known as reflex sympathetic dystrophy), and in suppressing nausea and vomiting and postoperative rescue analgesic requirements in laparoscopic cholecystectomy patients. Compared to a placebo, immediate-release gabapentin reduced migraine frequency and intensity in patients with migraines, relieved symptoms, and improved function and quality of life in patients with chronic daily headaches. It may attenuate hypobaric hypoxia-induced headache (a syndrome commonly experienced by newcomers to high-altitude areas). However, immediate-release gabapentin was no better than a placebo for chemotherapy-induced peripheral neuropathy.

Restless Legs Syndrome. Immediate-release gabapentin appeared to be more effective than a placebo in a small crossover design study of adults, reducing periodic leg movements, pain, sleep quality, sleep architecture, and overall clinical impression, and in another small crossover design study of adult hemodialysis patients. Gabapentin enacarbil was more effective than a placebo in double-blind, randomized placebo-controlled trials in adults with restless legs syndrome, relieving restless leg movements and improving sleep quality.

Other Neurologic Disorders. Immediate-release gabapentin compared to a placebo relieved essential tremor in two of three studies, primary orthostatic tremor in one study, and impairment of spasticity in multiple sclerosis in one study. Moreover, compared to a placebo, immediate-release gabapentin attenuated rigidity, bradykinesia, and tremor in Parkinson disease. Immediate-release gabapentin compared to no treatment improved lower, but not upper, extremity function in patients with spinal muscular atrophy. However, compared to a placebo, immediate-release gabapentin failed to slow the decline of arm strength in patients with amyotrophic lateral sclerosis in two studies and failed to increase muscle strength in patients with spinal muscular atrophy.

Alcohol and Substance Use Disorders. Data from numerous double-blind, randomized placebo-controlled trials on alcohol use disorders have found immediate-release gabapentin efficacious as monotherapy or in combination with either flumazenil or naltrexone, specifically associated with more abstinence days and longer time to relapse. Efficacy in opiate use disorders was found in two double-blind randomized placebo-controlled add-on (to methadone or buprenorphine) studies with less opiate use and fewer withdrawal symptoms, but not in one study of monotherapy with gabapentin. The efficacy of stimulant (methamphetamine or cocaine) use disorders is not well established for gabapentin, where only one double-blind, randomized placebo-controlled trial with immediate-release gabapentin to flumazenil had less drug use and cravings. However, three controlled studies (monotherapy and add-on) found no difference from placebo. One double-blind, randomized placebo-controlled trial of immediate-release gabapentin monotherapy for marijuana use disorder found less marijuana use and improved executive functioning on neuropsychological testing. Thus, gabapentin has the strongest evidence of efficacy for alcohol use disorders, with less robust evidence in other substances of abuse.

Anxiety Disorders. Controlled studies have confirmed immediate-release gabapentin utility in some anxiety disorders, with double-blind randomized placebo-controlled trials demonstrating efficacy in social phobia (social anxiety disorder), and in a post hoc analysis, in moderate to severe panic disorder.

Mood Disorders. Well-controlled studies found that immediate-release gabapentin was ineffective, despite early, open, uncontrolled reports suggesting that adjunctive immediate-release gabapentin was well tolerated and may offer benefits in patients with refractory mood disorders. In a double-blind, randomized placebo-controlled trial of patients with bipolar disorder suffering from mania or hypomania, while taking lithium, valproate, or lithium and valproate, adjunctive placebo tended to lower mania scores better than adjunctive immediate-release gabapentin. In treatment-resistant (primarily rapid-cycling bipolar) mood disorders, immediate-release gabapentin monotherapy was no more effective than a placebo, while lamotrigine monotherapy was more effective than both the immediate-release gabapentin and placebo. However, a small randomized clinical trial suggested that adjunctive immediate-release gabapentin compared to an adjunctive placebo might provide some prophylactic benefit in patients with bipolar disorder. Although the antidepressant efficacy of adjunctive immediate-release gabapentin in patients with bipolar disorder has been suggested in several open trials, controlled studies have not supported the primary use of gabapentin for mood disorders.

Therapeutic Indications

Seizure Disorders. Immediate-release gabapentin is indicated as an adjunctive treatment of partial seizures with and without secondary generalization in patients with epilepsy aged >12 years and as an adjunctive treatment of partial seizures in pediatric patients aged 3 to 12 years.

Postherpetic Neuralgia. Immediate- and extended-release gabapentin and gabapentin enacarbil are indicated for the management of postherpetic neuralgia in adults.

Restless Legs Syndrome. Gabapentin enacarbil is indicated for the treatment of moderate to severe restless legs syndrome in adults.

Precautions and Adverse Reactions

In general, the adverse effects of gabapentin are mild to moderate, can be attenuated by dosage rescheduling or decreases, and do not typically require discontinuation. Common adverse effects of adjunctive immediate-release gabapentin in adult patients with epilepsy include somnolence, dizziness, ataxia, fatigue, and nystagmus. Common adverse effects of immediate-release gabapentin in adult patients with postherpetic neuralgia are dizziness, somnolence, and peripheral edema. In pediatric (age 3 to 12 years) patients with epilepsy, the most common adverse effects of adjunctive gabapentin are viral infection, fever, nausea or vomiting, somnolence, and hostility. Interestingly, psychiatric adverse effects in pediatric patients with epilepsy have been sufficiently troublesome for the immediate-release gabapentin. The U.S. Prescribing Information (USPI) includes warnings about the risks of (1) emotional lability or behavioral problems in 6% (vs. 1.3% with placebo); (2) hostility or aggressiveness in 5.2% (vs. 1.3% with placebo); (3) thought disorder, concentration, or academic performance problems in 1.7% (vs. 0% with placebo); and (4) hyperkinesia, restlessness, or hyperactivity in 4.7% (vs. 2.9% with a placebo). Similar to other anticonvulsants, gabapentin has an increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders.

Gabapentin is classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals but to date not in humans. Gabapentin was classified as “Probably Safe” for lactation, although it is excreted in breast milk, with nursing infants receiving approximately 1 mg/kg per day. Therefore, gabapentin should only be administered to breastfeeding only if the potential benefits clearly outweigh the (unknown) risks.

Drug Interactions

Gabapentin bioavailability may decrease by as much as 20% when administered at the same time as antacids. Therefore, gabapentin should be taken at least 2 hours following antacids. Hydrocodone and morphine may increase blood gabapentin concentrations. However, as gabapentin is renally excreted, it generally lacks clinically significant hepatic drug–drug interactions. In addition, gabapentin may not have major drug–drug interactions with renally excreted drugs.

Dosage and Administration

The immediate-release gabapentin USPI recommends that adjunctive therapy in adolescents and adults with epilepsy should start at 300 mg three times a day and be increased up to 1,800 mg/day in three divided doses. However, in adults with epilepsy, immediate-release gabapentin is generally well tolerated at doses as high as 3,600 and 2,400 mg/day in short- and long-term studies, respectively. Adjunctive immediate-release gabapentin in pediatric seizures is recommended to start at 10 to 15 mg/kg per day in three divided doses and to increase over three days to 25 to 40 mg/kg per day in three divided doses. A long-term epilepsy study suggested that immediate-release gabapentin doses up to 50 mg/kg per day may be well tolerated. Plasma gabapentin concentrations in patients with epilepsy commonly range between approximately 12 and 20 µg/mL (70 and 120 µM/L) but did not appear to be systematically related to antiseizure effects and thus were not routinely monitored.

Immediate-release gabapentin for adults with postherpetic neuralgia or neuropathic pain is recommended to start with 300 mg on day one, increase to 600 mg on day 2, 900 mg on day 3, and subsequently increase as needed to relieve pain up to 1,800 mg/day in three divided doses. Extended-release gabapentin for postherpetic neuralgia is recommended to start at 300 mg daily, increased to 600 mg on day 2, and then further increased to 300 mg every 4 days, with a maximum dose of 1,800 mg. Gabapentin enacarbil for postherpetic neuralgia is recommended to start at 600 mg daily with food for 3 days, then increase to 600 mg twice daily, and for restless legs syndrome is suggested to start and maintain at 600 mg per evening with food.

Off-label gabapentin is typically used adjunctively at similar doses. In some (nonepilepsy) applications, clinicians may administer more of the dosage at bedtime to enhance sleep and decrease daytime somnolence. However, individual doses of immediate-release gabapentin above 1,200 mg are divided due to saturable absorption. In psychiatric outpatients, immediate-release gabapentin may be started at 300 mg at bedtime and increased by 300 mg every 4 days as necessary. Starting on a dose of 1,200 mg at bedtime is typically well tolerated. Occasionally, older adult patients or patients on complex combination therapies may require doses as low as 100 to 200 mg due to sedation. The final total daily doses tend to be between 1,200 and 2,400 mg/day but may range as high as 4,800 mg/day.

TOPIRAMATE

Introduction and History

Topiramate (Topamax) was developed by R. W. Johnson Pharmaceutical Research Institute. After effectiveness was observed in several animal models of epilepsy, topiramate was studied as an antiepileptic drug and then marketed for the adjunctive treatment of epilepsy in the United States in 1997 by Ortho-McNeil Pharmaceutical, Inc.

Double-blind, randomized placebo-controlled trials revealed that topiramate was useful for some, but not all, neurologic and psychiatric conditions reported in initial postmarketing, open, and clinical studies. Topiramate appeared to be effective in migraine prevention and was approved for this indication. In addition, topiramate appeared effective in obesity, bulimia, binge eating disorder with obesity, and alcohol dependence.

Chemistry

Topiramate, 2,3:4,5-bis-*O*-(1-methylethylidene)β-*D*-fructo-pyranose sulfamate, has a novel sulfamate-substituted monosaccharide structure (Fig. 33.10b–1). Two oral topiramate preparations are currently marketed in the United States: 25-, 50-, 100-, and 200-mg tablets, and 15- and 25-mg sprinkle capsules, which can be swallowed whole or opened and sprinkled on food.

Pharmacologic Action

Pharmacokinetics. Topiramate has an oral bioavailability of approximately 80% and linear kinetics that are not significantly altered by food. Topiramate is only 15% bound to plasma proteins and has a moderate volume of distribution of approximately 0.8 L/kg. Topiramate is approximately 70% excreted unchanged in the urine. Therefore, in the absence of enzyme inducers, clearance does not extensively involve hepatic mechanisms. However, in the presence of hepatic enzyme inducers (such as carbamazepine or phenytoin), hepatic metabolism increases, and renal clearance decreases by approximately 50%. Topiramate has a half-life of approximately 24 hours with monotherapy. The half-life decreases by approximately 50% with enzyme inducers, so topiramate is administered in two divided doses. Topiramate clearance is generally approximately 25 mL/min. Enzyme inducers can almost double clearance rates, and moderate to severe renal impairment decreases clearance rates by approximately 50%. Topiramate clearance may also be decreased in patients with hepatic impairment, requiring dosage adjustment.

Pharmacodynamics. Topiramate has multiple biochemical actions, and the relationship between these and clinical effects remains to be established. Topiramate is a state-dependent sodium channel blocker. Topiramate also has GABAergic effects, as it positively modulates $GABA_A$ receptors, and both acute and chronic administration appears to increase cerebral GABA in humans. Topiramate has antiglutamatergic effects, as it blocks kainite and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors. Topiramate also weakly inhibits carbonic anhydrase CA-II and CA-IV isoenzymes.

Clinical Drug Studies

Seizure Disorders. Topiramate was found to be superior to placebo as initial monotherapy in adults and children aged 10 years and older with partial-onset or primary generalized seizures in a double-blind, randomized placebo-controlled trial. Adjunctive topiramate appeared to be more effective than an adjunctive placebo in several double-blind, randomized placebo-controlled trials in patients with partial-onset seizures, one trial in children aged 2 to 16 years with partial-onset seizures, one trial in patients aged 2 years or older with primary generalized tonic–clonic seizures, and one trial in patients aged 2 years or older with Lennox–Gastaut syndrome.

Migraine Prevention. Topiramate was more effective than placebo in double-blind randomized placebo-controlled trials, decreasing the frequency of migraine headaches. Topiramate also appeared to improve daily activities and patient functioning.

Other Neurologic Disorders. Adjunctive topiramate was more effective than a placebo in attenuating essential tremor in two of three studies but was ineffective in patients with amyotrophic lateral sclerosis.

Weight Loss, Obesity, Bulimia, and Binge Eating Disorder With Obesity. Topiramate has been associated with weight loss in controlled studies of patients with epilepsy, psychiatric illness, and obesity and has shown efficacy in the treatment of adiposity in women receiving olanzapine, as well as bulimia and binge eating disorder associated with obesity in controlled trials. The combination of topiramate and phentermine was approved by the FDA as an adjunct to a reduced-calorie diet and increased physical activity for chronic weight management in adults with obesity.

Alcohol Use Disorder. Topiramate was superior to placebo in patients with alcohol dependence in numerous double-blind randomized placebo-controlled trials.

Smoking Cessation. In a controlled trial, topiramate promoted smoking abstinence among alcohol-dependent smokers.

Bipolar Disorders. Several double-blind, placebo-controlled trials have failed to demonstrate the efficacy of topiramate monotherapy in acute mania in adults. A similar trial in children and adolescents was inconclusive, perhaps because of premature termination. In a controlled trial, the addition of topiramate to lithium or valproate was no better than adding a placebo in patients with acute manic or mixed episodes. In one small single-blind study, adjunctive topiramate and adjunctive sustained-release bupropion had similar efficacy in bipolar depression, although topiramate appeared to yield more weight loss and adverse effects.

Schizophrenia. In one double-blind, placebo-controlled clinical trial, adjunctive topiramate compared to an adjunctive placebo in patients with schizophrenia yielded greater improvement in general psychopathological symptoms but not positive or negative symptoms.

Posttraumatic Stress Disorder. One double-blind, placebo-controlled clinical trial showed that topiramate was effective in improving reexperiencing and avoidance/numbing symptom clusters in patients with posttraumatic stress disorder. However, another controlled study in male veterans with posttraumatic stress disorder did not show any benefit with topiramate.

Therapeutic Indications

Seizure Disorders. Topiramate is indicated as an adjunctive treatment for adults and pediatric patients aged 2 to 16 years with partial-onset seizures or primary generalized tonic–clonic seizures and in patients aged 2 years or older with Lennox–Gastaut syndrome. Topiramate is also indicated as initial monotherapy in patients 2 years of age and older with partial-onset or primary generalized tonic–clonic seizures.

Migraine Prevention. Topiramate is indicated for adolescents (age ≥12 years) and adults for the prevention of migraine headaches.

Precautions and Adverse Reactions

The most common adverse effects of topiramate 400 mg/day monotherapy in patients with epilepsy were paresthesia, weight decrease, somnolence, anorexia, dizziness, and memory problems in adults, and weight decrease, upper respiratory tract infection, paresthesia, anorexia, diarrhea, and mood problems in children. The most common adverse effects of adjunctive topiramate at 200 to 400 mg/day in adult patients with epilepsy were somnolence, dizziness, ataxia, speech problems, psychomotor slowing, visual problems, memory problems, paresthesia, and diplopia. The most common adverse effects of adjunctive topiramate at 5 to 9 mg/kg per day in pediatric patients with epilepsy were fatigue, somnolence, anorexia, nervousness, concentration or attention problems, memory problems, aggression, and weight loss. The most common adverse effects of topiramate monotherapy in migraine prevention trials were paresthesia, fatigue, nausea, anorexia, upper respiratory tract infection, taste perversion, and dizziness. In many cases, the adverse effects of topiramate are mild to moderate and can be attenuated by dosage rescheduling or decrease.

Topiramate can cause appetite suppression and weight loss in patients with epilepsy, psychiatric disorders, and obesity. Although this is clearly a desirable effect in patients who are overweight or obese, it may be problematic in patients that are underweight. However, in epilepsy studies, weight loss with topiramate was more evident in patients with higher baseline weights. In these studies, topiramate-induced weight loss was more evident in females than in males with similar baseline weights.

The topiramate USPI includes a warning of the risk of hyperchloremic, non-anion gap metabolic acidosis (low serum bicarbonate without chronic respiratory alkalosis), which can occur in a dose-dependent manner with topiramate and yield hyperventilation, fatigue, anorexia, increased risk of nephrolithiasis, nephrocalcinosis, and osteomalacia, decreased growth rate, and rarely cardiac arrhythmias and stupor. Measurement of baseline and periodic serum bicarbonate is recommended, and if metabolic acidosis is detected, decreasing or discontinuing topiramate or treating it with alkali should be considered. Topiramate is rarely associated with acute myopia and secondary angle-closure glaucoma, characterized by acute onset of decreased visual acuity or ocular pain. Symptoms can occur in pediatric and adult patients, typically present within 1 month of starting topiramate and reverse with discontinuation. As with other anticonvulsants, topiramate is associated with an increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders.

An important warning in the topiramate USPI concerns the risks of cognitive or neuropsychiatric adverse events. These are common and include cognitive problems (confusion, psychomotor slowing, concentration or attention, memory, speech, or language problems), psychiatric problems (depression, mood problems), sedation, and fatigue.

Approximately 1.5% of adults exposed to topiramate develop nephrolithiasis. Maintaining adequate fluid intake may help decrease the risk of nephrolithiasis. Topiramate is a weak carbonic anhydrase inhibitor that decreases urinary citrate excretion and increases urinary pH, which may contribute to the increased risk of nephrolithiasis. Carbonic anhydrase inhibition may also contribute to the increased risk of paresthesia with topiramate.

In patients with or without a history of epilepsy, topiramate should be gradually withdrawn to minimize the potential for seizures.

Acute oral overdoses of topiramate have been associated with convulsions, drowsiness, speech disturbance, blurred vision, diplopia, impaired mentation, lethargy, impaired coordination, stupor, hypotension, abdominal pain, agitation, dizziness, depression, and severe metabolic acidosis. In most instances, the clinical consequences were not severe, but deaths have been reported in polydrug overdoses involving topiramate.

Topiramate is classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals, and use during pregnancy may cause cleft lip and/or palate in humans. It is unknown the degree to which topiramate is excreted in breast milk, so it was classified as “safety unknown” for lactation and should be administered to breastfeeding women with caution and only if the potential benefits clearly outweigh the (unknown) risks.

Drug Interactions

The large renal component of topiramate disposition is resistant to the effects of enzyme inhibitors, yet the limited hepatic metabolism component makes it susceptible to enzyme inducers. For example, in patients with epilepsy, carbamazepine yields clinically significant decreases in topiramate serum concentrations, but topiramate does not yield clinically significant changes in carbamazepine serum concentrations. In contrast, valproate and lamotrigine do not appear to have clinically significant pharmacokinetic interactions with topiramate in patients with epilepsy. However, concomitant administration of topiramate and valproate has been associated with hyperammonemia with and without encephalopathy, and hypothermia (with and without hyperammonemia), most likely due to pharmacodynamic drug interactions. Given its substantial renal clearance, topiramate can affect lithium levels. However, the clinical significance of such putative effects remains to be established. Although topiramate at doses over 200 mg/day may affect serum lithium concentrations, the clinical importance of this phenomenon remains to be adequately characterized. Nevertheless, the topiramate USPI recommends monitoring lithium concentrations when co-administered with high-dose topiramate. The effects of lithium on the pharmacokinetics of topiramate remain to be established. Although levetiracetam does not alter topiramate concentrations, this combination may yield adverse effects through a pharmacodynamic interaction. In addition, the combination of topiramate with other carbonic anhydrase inhibitors, such as acetazolamide and zonisamide, is not recommended because of concerns about increasing the risks of metabolic acidosis, nephrolithiasis or heat-related problems (oligohydrosis and hyperthermia). Topiramate is a mild enzyme inducer that can decrease the blood concentrations of hormonal contraceptives, potentially compromising their efficacy. This effect may be less problematic at doses of 200 mg/day or less. Because of the potential of topiramate to cause central nervous system (CNS) depression, as well as other cognitive and/or neuropsychiatric adverse reactions, combination with alcohol and other CNS depressants should only be performed with caution.

Dosage and Administration

The topiramate USPI recommends that topiramate monotherapy in adults and children aged 10 years or older with epilepsy be started at 25 mg twice daily for the first week, increased to 50 mg twice daily for week 2, 75 mg twice daily for week 3, 100 mg twice daily for week 4, 150 mg twice daily for week 5, and 200 mg twice daily from week 6 onward. In adult (age 17 years or older) patients with epilepsy, topiramate adjunctive therapy is recommended to start with 25 to 50 mg/day and be increased by 25 to 50 mg on a weekly basis, up to 400 mg/day in two divided doses. In pediatric (2 to 16 years) patients with epilepsy, topiramate adjunctive therapy is recommended to start with 1 to 3 mg/kg per day at bedtime and increase by 1 to 3 mg/kg on a weekly basis, up to 5 to 9 mg/kg per day. Plasma topiramate concentrations in patients with epilepsy commonly range between 5 and 20 μg/mL (15 to 60 μM/L), but they do not appear to be systematically related to antiseizure effects and thus are not routinely monitored. For migraine prevention, topiramate is recommended to start with 25 mg in the evening for the first week, increase to 25 mg twice daily for week 2, 25 mg in the morning plus 50 mg in the evening for week 3, and 50 mg twice daily for week 4 onward. Doses may need to be decreased by 50% in patients with moderate to severe renal impairment (creatinine clearance less than 70 mL/1.73 m^2 per minute) and doubled in patients receiving concurrent enzyme inducers such as carbamazepine and phenytoin. Topiramate doses may need to be decreased in patients with hepatic impairment.

Off-label topiramate is typically used adjunctively, starting with 25 mg at bedtime and increasing weekly by 25 mg, as necessary and tolerated. Dosage increases of 25 mg/day every 2 to 4 weeks during initiation may sometimes improve tolerability. Final doses to promote weight loss are often between 75 and 200 mg/day at bedtime. Lower doses appear to suppress appetite less consistently, and higher doses, at least early in therapy, tend not to be well tolerated due to sedation or cognitive difficulties. However, continuing to gradually increase topiramate by 25 mg/day on a monthly basis may allow some patients to eventually achieve doses of 400 mg/day. In some (non-epilepsy) applications, clinicians may administer most or all of the dosage at bedtime to enhance sleep and decrease daytime somnolence.

TIAGABINE

Introduction and History

Tiagabine (Gabitril), a lipophilic derivative of nipecotic acid, was developed by Novo Nordisk. The addition of a lipophilic group to nipecotic acid (a hydrophilic GABA reuptake inhibitor that does not cross the blood–brain barrier) allowed tiagabine to enter the CNS more easily. Tiagabine was found to be effective in several animal models of epilepsy. Abbott Laboratories developed it as an antiepileptic drug and initially marketed it for the adjunctive treatment of partial seizures in the United States in 1997. Tiagabine was later marketed by Cephalon, Inc.

Limited, postmarketing, open, and uncontrolled clinical experience has suggested efficacy in some psychiatric conditions. Safety concerns were raised paradoxically for this drug regarding the risk of seizures in patients with bipolar disorder, particularly if the drug was dosed aggressively. Limited double-blind, placebo-controlled studies have revealed that tiagabine may be useful for treating generalized anxiety disorder and primary insomnia. Safety concerns, along with a lack of controlled efficacy data, have limited the use of tiagabine in disorders other than epilepsy.

Chemistry

Tiagabine, (-)-(R)-1-[4,4-Bis(3-methyl-2-thienyl)-3-butenyl] nipecotic acid, is a lipophilic derivative of the hydrophilic cyclic amino acid nipecotic acid (comprising nipecotic acid linked to a lipophilic group by an aliphatic chain), which inhibits GABA reuptake in neurons and glial cells (Fig. 33.10b–1). Tiagabine is available in 2-, 4-, 12-, and 16-mg tablets for oral administration.

Pharmacologic Action

Pharmacokinetics. Tiagabine is well absorbed with a bioavailability of approximately 90%, extensively (96%) bound to plasma proteins, and has linear kinetics at doses between 2 and 24 mg/day. Giving tiagabine with meals decreases the rate of absorption and delays and lowers peak plasma concentrations but does not significantly affect the extent of absorption. In monotherapy, tiagabine has a half-life of approximately 8 hours and clearance of approximately 110 mL/min. In the presence of enzyme inducers (as in the pivotal epilepsy studies), the half-life decreased to approximately 4 hours, and clearance doubled to approximately 220 mL/min. Tiagabine is a CYP3A substrate that is extensively transformed into inactive 5-oxo-tiagabine and glucuronide metabolites, with only 2% excreted unchanged in the urine. The remainder is excreted as metabolites in the feces (65%) and the urine (25%).

Pharmacodynamics. Tiagabine has a putative specific single major biochemical action that may account for its clinical effects. Tiagabine acts on the GABA transporter, blocking the reuptake of the inhibitory amino acid neurotransmitter GABA into neurons and glia, thus enhancing the inhibitory action of GABA. Actions at both $GABA_A$ and $GABA_B$ receptors putatively yield anticonvulsant and antinociceptive effects, respectively. Tiagabine has antiseizure activity in the pentylenetetrazole mice, amygdala kindled rats, and other animal models of seizures but only has weak activity in the maximal electroshock mouse model.

Clinical Drug Studies

Seizure Disorders. Adjunctive tiagabine appeared to be more effective than an adjunctive placebo in double-blind, randomized placebo-controlled trials and placebo-controlled crossover studies involving patients with refractory partial seizures who were taking at least one enzyme-inducing anticonvulsant.

Pain Syndromes. Limited data suggest the possible utility of tiagabine in bruxism and associated temporomandibular joint pain, painful tonic spasms in multiple sclerosis, chronic pain, and chronic painful neuropathy.

Cocaine Use Disorder. Although preliminary studies were somewhat encouraging, in a larger controlled trial, tiagabine at 20 mg/day was no better than a placebo in treating cocaine dependence.

Therapeutic Indications

Seizure Disorders. Tiagabine is indicated as an adjunctive treatment of partial seizures in adults and adolescents aged 12 years and older with epilepsy.

Precautions and Adverse Reactions

In patients with epilepsy also taking enzyme-inducing anticonvulsants, tiagabine's adverse effects are mild to moderate, can be attenuated by dosage rescheduling or decreases, and do not typically require discontinuation. In patients with epilepsy, the most common adverse effects of adjunctive tiagabine were dizziness or lightheadedness, asthenia or lack of energy, somnolence, nausea, nervousness or irritability, tremor, abdominal pain, and abnormal thinking or difficulty with concentration or attention.

The tiagabine USPI dosing recommendations were based on patients with epilepsy taking enzyme-inducing anticonvulsants, which lower tiagabine plasma concentrations by approximately 50%. Administering tiagabine without enzyme inducers will approximately double tiagabine plasma concentrations compared to those attained in published epilepsy trials, which provided guidance for dosing. Thus, tiagabine administered without enzyme inducers needs to have doses of approximately 50% of those in the USPI. If this adjustment is not made, patients are at an increased risk of adverse effects, some of which are serious.

The tiagabine USPI includes a boldface warning regarding the risk of seizures in patients without epilepsy. As noted above, rapid loading of open primarily adjunctive tiagabine in patients with acute mania, starting at 20 mg/day, yielded unacceptable adverse effects. One patient had a seizure, and gradual initiation in outpatients with bipolar disorder at 4 mg/day and increased weekly as tolerated by 4 mg/day (mean final dose

8.7 mg/day) raised tolerability concerns, with two of 13 patients having seizures.

Other warnings in the tiagabine USPI include the risks of withdrawal seizures, cognitive or neuropsychiatric problems (impaired concentration, speech or language problems, somnolence, and fatigue), status epilepticus, and sudden unexpected death in epilepsy. As with other anticonvulsants, tiagabine is associated with an increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders.

Tiagabine is classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals, but to date, not in humans. The degree to which tiagabine is excreted in breast milk is unknown, so it was classified as “safety unknown” for lactation and should be administered to breastfeeding women with caution and only if the potential benefits clearly outweigh the (unknown) risks.

Drug Interactions

Tiagabine does not induce or inhibit hepatic enzymes, but it is a target for pharmacokinetic drug interactions. Thus, enzyme inducers such as carbamazepine can yield clinically significant decreases in serum tiagabine concentrations, possibly by inducing CYP3A. Valproate does not yield clinically significant changes in serum total tiagabine concentrations but appears to displace tiagabine from protein-binding sites, yielding an increase in free tiagabine and thus potentially higher tiagabine toxicity. Tiagabine does not yield clinically significant changes in the pharmacokinetics of carbamazepine, phenytoin, and valproate. The presence or absence of pharmacokinetic interactions between tiagabine, lamotrigine, or lithium remains to be established. Tiagabine does not yield clinically significant changes in the kinetics of hormonal contraceptives.

Dosage and Administration

Most importantly, tiagabine should not be rapidly loaded or rapidly initiated due to the risk of serious adverse effects, namely potential seizures. The tiagabine USPI recommends that in adults and adolescents aged 12 years of age or older with epilepsy who were also taking enzyme inducers, tiagabine be initiated at 4 mg/day and increased weekly by 4 mg/day during the first month, and then increased weekly by 4 to 8 mg/day for weeks 5 and 6, yielding 24 to 32 mg/day administered in two to four divided doses by week 6. In adults (but not adolescents), tiagabine doses may be further increased weekly by 4 to 8 mg/day to as high as 56 mg/day. Plasma tiagabine concentrations in patients with epilepsy commonly range between approximately 20 and 100 ng/mL (50 and 250 nM/L) but do not appear to be systematically related to antiseizure effects and thus are not routinely monitored.

In pivotal epilepsy trials, tiagabine was administered with meals, which decreased the rate (later, lower peak plasma concentration) but not the extent of absorption. Thus, to limit the risk of adverse effects, the USPI recommends that tiagabine be administered with meals.

If tiagabine is administered in the absence of enzyme-inducing anticonvulsants, the dosing needs to be even more conservative (50% lower doses) to limit the risk of adverse effects. Thus, it is prudent that tiagabine be initiated at no more than 2 mg/day and increased weekly by 2 mg/day during the first month and then increased weekly by 2 to 4 mg/day for weeks 5 and 6, yielding 12 to 16 mg/day administered in two to four divided doses by week 6. In adults (but not adolescents), tiagabine doses may be further increased weekly by 2 to 4 mg/day to as high as 28 mg/day.

LEVETIRACETAM

Introduction and History

Levetiracetam (Keppra), developed in an effort to create second-generation nootropic (memory enhancing) medications, proved to be a potent anticonvulsant in the audiogenic-susceptible mouse model of epilepsy. In 1999, UCB, Inc. began marketing levetiracetam as an adjunctive treatment for refractory partial seizures in the United States.

Postmarketing, open, uncontrolled clinical experience has suggested potential benefits in patients with depressive symptoms with seizure disorders, bipolar disorder, and premenstrual dysphoric disorder. On the other hand, there have also been reports of levetiracetam-related depression and aggressive behavior, and placebo-controlled studies did not find the efficacy of levetiracetam for behavioral or overall clinical improvement in children with autism. Controlled studies are lacking that assess the effects of levetiracetam in patients with bipolar disorder and other psychiatric disorders.

Chemistry

Levetiracetam, (-)-(*S*)-α-ethyl-2-oxo-pyrrolidine acetamide, is the (*S*)-enantiomer of the ethyl analog of the nootropic agent piracetam (Fig. 33.10b–1) and has a structure unrelated to other anticonvulsants. Levetiracetam preparations currently marketed in the United States include: 250-, 500-, 750-, and 1,000-mg immediate-release tablets, 500- and 750-mg extended-release tablets; a 100 mg/mL oral solution, and a 100 mg/mL injectable intravenous solution.

Pharmacologic Action

Pharmacokinetics. Levetiracetam has a favorable pharmacokinetic profile, with absorption unaffected by food, bioavailability greater than 95%, binding to plasma proteins of less than 10%, a moderate volume of distribution of approximately 0.6 L/kg, linear elimination pharmacokinetics at clinically relevant doses (between 500 and 5,000 mg/day), a half-life of approximately 8 hours, and clearance of 40 mL/min. Levetiracetam is 66% excreted unchanged in the urine and is 24% hydrolyzed (in the blood rather than in the liver) to an inactive metabolite. Dosage may need to be decreased in patients with impaired renal function. However, levetiracetam has a low potential for pharmacokinetic drug interactions because only a minor metabolic component involves hydrolysis (rather than cytochrome P450 [CYP] oxidation or glucuronidation), and levetiracetam does not yield clinically significant changes in hepatic oxidation or glucuronidation.

Pharmacodynamics. Levetiracetam has multiple biochemical actions, and the relationship between these and its clinical effects remains to be established. Levetiracetam has GABAergic and anti-kindling effects, reduces voltage-dependent potassium currents, and binds to the synaptic vesicle protein SV2A. Levetiracetam lacks antiseizure activity in the pentylenetetrazole and maximal electroshock acute seizure models but is potently active in chronic seizure models such as kindled seizures and genetic animal models. Levetiracetam also has antinociceptive activity in animal models of neuropathic pain and anxiolytic-like effects in animal models of anxiety disorders such as the rat conflict and elevated plus-maze.

Clinical Drug Studies

Seizure Disorders. Adjunctive levetiracetam appeared to be more effective than an adjunctive placebo in three double-blind, randomized placebo-controlled trials involving adults with refractory partial seizures with or without secondary generalization; one each in children (age 4 to 16 years) with refractory partial seizures; patients aged 12 years and older with juvenile myoclonic epilepsy; and patients aged 6 years and older with idiopathic primary generalized tonic–clonic seizures.

Other Neurologic Disorders. Levetiracetam was superior to placebo for migraine prevention in children aged 4 to 17 years in a double-blind randomized placebo-controlled trial. Levetiracetam was no better than a placebo for essential tremor and Tourette syndrome.

Psychiatric Disorders. Adequately powered controlled studies are lacking to assess the effects of levetiracetam on psychiatric disorders. A series of uncontrolled case reports and case series suggested that levetiracetam may be effective in patients with bipolar disorder. In a small open-label study, patients with premenstrual dysphoric disorder showed some improvement with levetiracetam. However, in controlled pilot studies, levetiracetam was no better than a placebo in patients with social anxiety disorder and autism. There are reports of levetiracetam-related depression and aggressive behavior.

Therapeutic Indications

Seizure Disorders. Levetiracetam is indicated as an adjunctive treatment for partial-onset seizures in adults and children aged 4 years and older with epilepsy; myoclonic seizures in adults and adolescents aged 12 years and older with juvenile myoclonic epilepsy; and primary generalized tonic–clonic seizures in adults and children aged 6 years and older with idiopathic generalized epilepsy.

Precautions and Adverse Reactions

Levetiracetam is generally well tolerated but can cause somnolence, fatigue, coordination problems, mood, anxiety, and adverse behavioral effects. In adult patients with epilepsy, somnolence was observed in 14.8% (vs. 8.4% with a placebo), asthenia occurred in 14.7% (vs. 9.1%

with a placebo), and coordination problems were evident in 3.4% (vs. 1.6% with a placebo). In adult patients with epilepsy, psychosis occurred in 0.7% (vs. 0.2% with a placebo), and other behavioral problems were observed in 13.3% (vs. 6.2% with a placebo). Behavioral problems included aggression, agitation, anger, anxiety, apathy, depersonalization, depression, emotional lability, hostility, and irritability. Behavioral adverse effects occurred early in treatment (often in the first month of therapy) and led to discontinuation in 1.7% (vs. 0.2% with a placebo). Suicide attempts occurred in 0.5% (vs. 0% with a placebo).

In pediatric patients with epilepsy, somnolence was observed in 22.8% (vs. 11.3% with a placebo), and asthenia occurred in 8.9% (vs. 3.1% with a placebo). In pediatric patients with epilepsy, behavioral problems were observed in 37.6% (vs. 18.6% with a placebo). Behavioral problems in pediatric epilepsy included agitation, anxiety, apathy, depersonalization, depression, emotional lability, hostility, hyperkinesia, nervousness, neurosis, and personality disorder, leading to discontinuation in 10.9% (vs. 6.2% with placebo).

As with other anticonvulsants, levetiracetam is associated with an increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders. Acute oral overdoses of levetiracetam have been associated with somnolence, agitation, aggression, respiratory depression, and coma.

Levetiracetam is classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals but to date not in humans. Levetiracetam was classified as “probably safe” for lactation, though it is excreted in breast milk, so levetiracetam should be administered to breastfeeding women only if the potential benefits clearly outweigh the (unknown) risks.

Drug Interactions

Levetiracetam’s high degree of renal clearance and hydrolytic metabolism yields a low potential for pharmacokinetic drug interactions. Hence, levetiracetam does not appear to have clinically significant pharmacokinetic interactions with valproate or lamotrigine in patients with epilepsy. Levetiracetam does not significantly alter the serum concentrations of carbamazepine or carbamazepine epoxide in patients with epilepsy. However, levetiracetam plus carbamazepine may still yield adverse effects through pharmacodynamic interactions. Carbamazepine may decrease serum levetiracetam concentrations, but with variable reports of potential clinical significance. Oxcarbazepine may also modestly decrease the serum concentrations of levetiracetam. Levetiracetam does not appear to have clinically significant pharmacokinetic interactions with gabapentin or topiramate in patients with epilepsy, although a combination of levetiracetam and topiramate combination may yield adverse effects through a pharmacodynamic interaction. Despite being renally cleared, levetiracetam and lithium pharmacokinetic interactions remain to be established.

Dosage and Administration

In adult patients with epilepsy, adjunctive levetiracetam is commonly started at 500 to 1,000 mg/day and increased as necessary and tolerated every 2 weeks by 1,000 mg/day, up to a maximum of 3,000 mg/day in two divided doses. In pediatric patients with epilepsy, adjunctive levetiracetam is commonly started at 20 mg/kg per day and increased as necessary and tolerated every 2 weeks by 20 mg/kg per day, up to a maximum of 60 mg/kg per day in two divided doses. Plasma levetiracetam concentrations in patients with epilepsy commonly range between approximately 6 and 20 µg/mL (35 and 120 µM/L) but do not appear to be systematically related to antiseizure effects and thus are not routinely monitored. In view of substantive renal clearance, levetiracetam dosage needs to be adjusted in patients with impaired renal function based on the degree of renal insufficiency.

ZONISAMIDE

Introduction and History

Zonisamide (Zonegran) was synthesized by Dainippon Pharmaceutical Company while screening arylsulfonamides for anticonvulsant effects, putatively related to carbonic anhydrase inhibition. Although zonisamide only weakly inhibited carbonic anhydrase, it was found to be effective in several animal models of epilepsy. Zonisamide was subsequently developed as an antiepileptic drug and marketed for over a decade in Japan and South Korea prior to being marketed for the adjunctive treatment of partial seizures in the United States in 2000 by Elan Pharmaceuticals and more recently by Eisai, Inc.

Limited, open, uncontrolled clinical experience and controlled trials suggest potential efficacy in other neurologic and psychiatric conditions.

Chemistry

Zonisamide (3-[sulfamoylmethyl]-1,2-benzisoxazole) is a 1,2-benzisoxazole-3-methanesulfonamide, which is structurally different from other marked anticonvulsants (Fig. 33.10b–1). Zonisamide is available in 25- and 100-mg capsules for oral administration.

Pharmacologic Action

Pharmacokinetics. Zonisamide generally has favorable pharmacokinetic properties, with good (close to 100%) bioavailability, only 40% to 60% binding to plasma proteins (but extensive binding to erythrocytes), a clearance of 20 mL/min, and a moderate volume of distribution of 1.5 L/kg. Zonisamide has linear pharmacokinetics between 200 and 400 mg/day but has disproportionate serum concentrations at 800 mg, presumably related to saturable binding to carbonic anhydrase in erythrocytes. As a monotherapy, zonisamide has a half-life of 60 hours, which decreases to 30 hours when administered with enzyme inducers. Zonisamide is reduced to 2-sulfamoylacetylphenol (SMAP), primarily by CYP3A4, but is also excreted unchanged in the urine by 30%. Marked renal impairment (creatinine clearance less than 20 mL/min) increased plasma zonisamide concentrations by 35%.

Pharmacodynamics. Zonisamide has multiple biochemical actions, and the relationship between these and its clinical effects remains to be established. Zonisamide blocks sodium channels, reduces T-type calcium currents, facilitates dopaminergic and serotonergic neurotransmission, and is a weak carbonic anhydrase inhibitor. Although zonisamide binds to the GABA/benzodiazepine receptor complex, it does not alter chloride currents and does not appear to have major GABAergic activity.

Clinical Drug Studies

Seizure Disorders. Adjunctive zonisamide appeared to be more effective than an adjunctive placebo in numerous double-blind, randomized placebo-controlled trials in patients with refractory partial seizures, with and without secondary generalization.

Diabetic Neuropathy. Zonisamide was no better than a placebo for diabetic neuropathy in a small double-blind, randomized placebo-controlled trial.

Other Neurologic Disorders. A randomized, double-blind, placebo-controlled study suggested that adjunctive zonisamide was effective in treating motor symptoms in patients with Parkinson disease. However, zonisamide was no better than a placebo for essential tremor in a small double-blind, randomized placebo-controlled trial.

Eating Disorders. In double-blind, randomized placebo-controlled trials, zonisamide was superior to placebo for obesity and for binge eating disorders associated with obesity.

Bipolar Disorder. Open, uncontrolled reports suggest that zonisamide may have some utility in bipolar disorder, including for the treatment of weight gain.

Therapeutic Indications

Seizure Disorders. Zonisamide is indicated as an adjunctive treatment of partial seizures in adults with epilepsy.

Precautions and Adverse Reactions

In epilepsy registration trials, adverse effects with adjunctive zonisamide were generally mild to moderate, commonly attenuated by dosage rescheduling or decreased, and did not typically require discontinuation (adverse effect discontinuation rate 12 vs. 6% with a placebo). The most common adverse effects of adjunctive zonisamide in epilepsy trials were somnolence, anorexia, dizziness, headache, nausea, and agitation or irritability. The appetite suppression effect of zonisamide has been used in patients with obesity and binge eating disorders.

In patient populations other than epilepsy, zonisamide tolerability may be more challenging, with reports of higher adverse effect discontinuation rates in patients with binge eating disorder with obesity (27% vs. 13% with a placebo), diabetic neuropathy (38% vs. 0% with a placebo), essential tremor (30% vs. 0% with a placebo), and bipolar disorder (32% due to worsening mood symptoms with open treatment).

Zonisamide has been associated with nephrolithiasis in approximately 4% of patients (but only symptomatic in approximately 1% of patients), presumably due to carbonic anhydrase inhibition. Zonisamide increases serum creatinine and blood urea nitrogen by approximately 8% but does not alter the glomerular filtration rate (GFR) or yield progressive renal damage. Due to toxicity risks, zonisamide is not recommended in patients with renal failure (GFR less than 50 mL/min). Sudden unexplained death in epilepsy, status epilepticus, and rare creatine phosphokinase elevation and pancreatitis have been reported.

The zonisamide USPI includes a warning regarding the risks of severe reactions (Stevens–Johnson syndrome, toxic epidermal necrolysis, fulminant hepatic necrosis, agranulocytosis, aplastic anemia, and other blood dyscrasias) seen with sulfonamides. Therefore, if signs of such reactions occur, zonisamide should be discontinued immediately. Rash was seen in 2.2% of patients taking zonisamide in pivotal trials, resulting in discontinuation in 1.4% of patients. Other warnings include the risks of metabolic acidosis and nephrolithiasis, oligohydrosis and hyperthermia in pediatric patients, withdrawal seizures, teratogenicity, cognitive or neuropsychiatric problems (depression, psychosis, psychomotor slowing, impaired concentration or speech, language, word finding), somnolence, fatigue, and rare serious hematologic events (two cases of aplastic anemia and one case of agranulocytosis in the first 11 years of marketing in Japan, and no case of aplastic anemia but two cases of agranulocytosis in the United States, European, and Japanese development programs). As with other anticonvulsants, zonisamide is associated with an increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders.

The experience with zonisamide overdose is limited. Acute oral overdoses of zonisamide have been associated with coma, bradycardia, hypotension, and respiratory depression.

Zonisamide is classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals but to date not in humans. The degree to which zonisamide is excreted in breast milk is unknown, so it was classified as “safety unknown” for lactation and should be administered to breastfeeding women with caution, and only if the potential benefits clearly exist and outweigh the (unknown) risks.

Drug Interactions

Zonisamide does not inhibit CYP450 isoenzymes, does not induce its own metabolism, and is a target rather than an instigator of drug interactions. Carbamazepine decreases serum zonisamide concentrations, while zonisamide does not appear to yield clinically significant changes in the pharmacokinetics of carbamazepine. Zonisamide, valproate, zonisamide, and lamotrigine have clinically significant pharmacokinetic interactions in patients with epilepsy. The presence or absence of pharmacokinetic interactions between zonisamide and lithium remains to be established. Phenytoin and phenobarbital decrease the serum zonisamide concentrations. Combining zonisamide with other carbonic anhydrase inhibitors such as acetazolamide and topiramate is not recommended because of concerns about increasing the risk of nephrolithiasis or heat-related problems (oligohydrosis and hyperthermia).

Dosage and Administration

In patients with epilepsy, adjunctive zonisamide is started at 100 mg/day and increased every 2 weeks (no faster due to a 60 hours half-life) as necessary and tolerated by 100 mg/day, with final doses commonly ranging between 300 and 600 mg/day in two divided doses. Adverse effects were more common at doses of 300 mg/day or higher. Plasma, and zonisamide concentrations in patients with epilepsy, commonly range between approximately 10 and 38 µg/mL (45 and 180 µM/L) but do not appear to be systematically related to antiseizure effects and thus are not routinely monitored. In controlled studies, the mean final zonisamide doses were 160 mg/day for essential tremor, 427 mg/day for obesity, 436 mg/day for binge eating disorder with obesity, and 540 mg/day for painful diabetic neuropathy. As zonisamide undergoes both hepatic metabolism and renal excretion unchanged, patients with hepatic or renal disease may require more conservative dosing and titration as well as more frequent monitoring.

PREGABALIN

Introduction and History

Pregabalin (Lyrica) was developed in a fashion similar to that of gabapentin as a compound with a structure similar to the inhibitory amino acid neurotransmitter GABA, which easily crosses the blood–brain barrier.

Although these agents lack direct GABAergic effects, they were found to be effective in animal models of pain and epilepsy (with pregabalin being more potent) and developed as an analgesic and antiepileptic drugs. Pregabalin was marketed for the treatment of neuropathic pain associated with diabetic peripheral neuropathy in the United States in 2005 by the Parke-Davis division of Pfizer, Inc. Pregabalin subsequently received approval for the treatment of postherpetic neuralgia, adjunctive treatment of adults with partial-onset seizures, for the treatment of fibromyalgia, and for the treatment of neuropathic pain associated with spinal cord injury. Pregabalin also appeared effective in controlled trials for generalized anxiety disorder and social anxiety disorder, but as of late 2014, it had not been approved for these indications.

Chemistry

Pregabalin, *S*-(+)-3-isobutyl GABA, is a novel amino acid derived from GABA (Fig. 33.10b–1), with a structure and mechanisms that overlap those of gabapentin and some structural similarities to other anticonvulsants that resemble GABA, such as valproate. Pregabalin is currently marketed in the United States as an oral preparation in 25-, 50-, 75-, 100-, 150-, 200-, 225-, and 300-mg capsules and as a 20 mg/mL oral solution.

Pharmacologic Action

Pharmacokinetics. Pregabalin appears to have generally favorable pharmacokinetic properties, similar to gabapentin. Pregabalin is not bound to plasma proteins, has a moderate volume of distribution of 0.5 L/kg, a half-life of 6 hours (requiring twice-daily dosing), is greater than 95% excreted unchanged in the urine, and has a clearance of 80 mL/min that varies with creatinine clearance. Pregabalin clearance is highly dependent on renal function, and dosage reduction may be necessary for patients with renal impairment. Pregabalin lacks hepatic metabolism, does not induce or inhibit hepatic metabolism, and lacks metabolic drug interactions. Unlike gabapentin, pregabalin has higher (greater than 90%) bioavailability and absorption that is proportional to dose, without the gastrointestinal absorption saturation of gabapentin. Food has no clinically relevant effect on pregabalin absorption.

Pharmacodynamics. Pregabalin has multiple biochemical actions, and the relationship between these and its clinical effects remains to be established. Pregabalin, like gabapentin, is a structural analog of GABA, but these agents appear to lack direct GABAergic actions. However, both of these agents have selective inhibitory effects on voltage-gated calcium channels containing the $\alpha_2\delta$ subunit, reducing depolarization-induced calcium influx at nerve terminals, resulting in decreased release of excitatory neurotransmitters such as glutamate and noradrenaline.

Clinical Drug Studies

Seizure Disorders. Adjunctive pregabalin was more effective than an adjunctive placebo in double-blind, randomized placebo-controlled trials in adults with partial-onset seizures.

Postherpetic Neuralgia. Pregabalin was more effective than a placebo in double-blind, randomized placebo-controlled trials in adults with postherpetic neuralgia. Mood, sleep, and quality of life measures improved, in addition to the improvement of pain problems.

Diabetic Peripheral Neuropathy. Pregabalin was more effective than a placebo in double-blind, randomized placebo-controlled trials in adults with diabetic peripheral neuropathy. Similar to postherpetic neuralgia, pain, mood, sleep, and quality of life measures improved.

Neuropathic Pain Associated With Spinal Cord Injury. In adults with neuropathic pain associated with spinal cord injury, pregabalin was more effective than a placebo in double-blind, randomized, placebo-controlled trials. Similar to postherpetic neuralgia, pain, mood, sleep, and quality of life measures all improved.

Fibromyalgia. Pregabalin was more effective than placebo for fibromyalgia in one double-blind, randomized placebo-controlled trial (with superior relief of pain, disturbed sleep, and fatigue) and in a 6-month randomized withdrawal study.

Other Pain Syndromes. Pregabalin was effective for central neuropathic pain associated with spinal cord injury, improving pain, sleep, anxiety, and overall patient status. Pregabalin appeared to be effective for pain associated with chronic pancreatitis, postoperative mastectomy, and neuropathic pain due to severe burns. Pregabalin was not found to be more effective than a placebo for pain associated with prostatitis and HIV.

Other Neurologic Disorders. In a pilot, double-blind, randomized placebo-controlled trial, pregabalin was superior to placebo in the treatment of essential tremor, whereas no significant improvement was found in a double-blind, randomized placebo-controlled, crossover trial.

Anxiety Disorders. In double-blind, randomized placebo-controlled trials, pregabalin was effective as both short- and long-term treatment for adult and older adult patients with generalized anxiety disorder and social anxiety disorder.

Therapeutic Indications

Diabetic Peripheral Neuropathy. Pregabalin is indicated for the treatment of diabetic peripheral neuropathy.

Postherpetic Neuralgia. Pregabalin is indicated for the treatment of postherpetic neuralgia.

Neuropathic Pain Associated With Spinal Cord Injury. Pregabalin is indicated for the treatment of neuropathic pain associated with spinal cord injury.

Seizure Disorders. Pregabalin is indicated for the adjunctive treatment of adults with partial-onset seizures.

Fibromyalgia. Pregabalin is indicated for the treatment of fibromyalgia.

Precautions and Adverse Reactions

In general, the adverse effects of pregabalin are mild to moderate, can be attenuated by dosage rescheduling or decreases, and do not typically require discontinuation. The most common adverse effects in patients with diabetic neuropathy include dizziness, somnolence, peripheral edema, dry mouth, and asthenia. The most common adverse effects in patients with postherpetic neuralgia were dizziness, somnolence, peripheral edema, infection, and headache. In patients with partial-onset seizures, the most common adverse effects of adjunctive pregabalin were dizziness, somnolence, ataxia, weight gain, blurred vision, diplopia, and accidental injury. The most common adverse effects in patients with fibromyalgia were dizziness, somnolence, headache, weight gain, blurred vision, and dry mouth. The pregabalin USPI includes warnings regarding the risks of several of the above adverse effects (dizziness, somnolence, peripheral edema, weight gain, and blurred vision), as well as angioedema, hypersensitivity, withdrawal symptoms, tumorigenic potential (hemangiosarcoma in mice), elevated creatine kinase, thrombocytopenia, and PR interval prolongation. Like other anticonvulsants, pregabalin is associated with an increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy and psychiatric disorders.

Pregabalin is a schedule V-controlled substance, with abuse and dependence potential concerns based on its potential to yield euphoria and the potential for withdrawal reactions.

Pregabalin is classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals but to date not in humans. It is not unknown the degree to which pregabalin is excreted in breast milk, so it was classified as “safety unknown” for lactation and should be administered to breastfeeding women with caution and only if the potential benefits clearly outweigh the (unknown) risks.

Drug Interactions

Similar to gabapentin, in view of the absence of hepatic metabolism, pregabalin lacks metabolic drug interactions. Thus, in patients with epilepsy, pregabalin lacks clinically significant pharmacokinetic drug interactions with carbamazepine, valproate, and lamotrigine. The presence or absence of pregabalin pharmacokinetic interactions with lithium remains to be established. In patients with epilepsy, pregabalin lacks clinically significant pharmacokinetic drug interactions with gabapentin and topiramate. Although tiagabine does not affect the pharmacokinetics of pregabalin, the effect of pregabalin on the pharmacokinetics of tiagabine remains to be established. The presence or absence of pregabalin pharmacokinetic interactions with oxcarbazepine, levetiracetam, and zonisamide remains to be established.

Dosage and Administration

The pregabalin USPI recommends that therapy for diabetic neuropathy, postherpetic neuralgia, fibromyalgia, partial-onset seizures, and neuropathic pain associated with spinal cord injury should start at 150 mg/day in two to three (two for fibromyalgia and neuropathic pain associated with spinal cord injury) divided doses, and be increased within 1 week (based on efficacy and tolerability) to 300 mg/day in two or three (two for fibromyalgia and neuropathic pain associated with spinal cord injury) divided doses. Patients with insufficient efficacy may be further increased to 450 mg/day in divided doses for fibromyalgia and 600 mg/day in divided doses for partial-onset seizures, postherpetic neuralgia, and neuropathic pain associated with spinal cord injury. Plasma pregabalin concentrations in patients with epilepsy do not appear to be systematically related to antiseizure effects and thus are not routinely monitored. In controlled trials, pregabalin doses ranged from 150 to 600 mg/day in generalized anxiety disorder and social anxiety disorder, although pregabalin lacks a specific indication for anxiety disorders. In patients with renal impairment, pregabalin doses may need to be decreased, depending on the degree of renal insufficiency.

PERAMPANEL

Introduction and History

Perampanel (Ficompa), which acts as a highly selective, noncompetitive antagonist of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, was developed by Eisai to create an agent for the treatment of epilepsy. The AMPA receptor is one of the four ionotropic transmembrane receptors for glutamate, and it plays a pivotal role in fast synaptic transmission in the CNS. This compound is postulated to reduce excessive neuronal excitation associated with seizures by blocking AMPA receptors expressed on postsynaptic membranes. Perampanel was first marketed in 2012 in Europe and the United States and is approved for monotherapy and adjunctive use in the treatment of partial-onset seizures with or without secondarily generalized seizures in patients with epilepsy aged 4 years and older and adjunctive therapy for primary generalized tonic–clonic seizures in patients with epilepsy aged 12 years and older.

Chemistry

Perampanel, 2-(2-oxo-1-phenyl-5-pyridin-2-yl-1,2-dihydropyridin-3-yl) benzonitrile, has a 2,3’-bipyridin-6’-one core structure, which distinguishes it from other AMPA receptor antagonists. Perampanel preparations marketed in the United States, Europe, and Japan include 2-, 4-, 6-, 8-, 10-, and 12-mg tablets; a 0.5 mg/mL oral suspension; and 1% fine granule.

Pharmacologic Action

Pharmacokinetics. The half-life of perampanel is approximately 105 hours, and its steady state is reached in 2 to 3 weeks. Perampanel is rapidly and completely absorbed after oral administration with negligible first-pass metabolism. The drug is approximately 95% to 96% bound to plasma proteins. Perampanel is extensively metabolized via primary oxidation, followed by glucuronidation. The oxidative metabolism is primarily mediated by CYP3A4. Moreover, 70% of the dose is excreted in the feces and 30% in the urine. The area under the curve (AUC) of perampanel increased in a dose-proportional manner after single-dose administration of 0.2 to 12 mg tablets and after multiple-dose administration of 1- to 12-mg tablets once daily.

Its oral suspension and fine granules have comparable bioavailability to tablets. No significant effect of age on the apparent clearance of perampanel was found.

Pharmacodynamics. The precise mechanism by which perampanel exerts its antiepileptic effects in humans remains to be fully elucidated. Activation of AMPA receptors by glutamate is considered to be primarily responsible for fast excitatory synaptic transmission in the brain. In in vitro studies, perampanel did not compete with AMPA for binding to the AMPA receptor, but perampanel binding was displaced by noncompetitive AMPA receptor antagonists, indicating that perampanel is a noncompetitive AMPA receptor antagonist. In vitro, perampanel inhibited the AMPA-induced increase in intracellular calcium levels. In vivo, perampanel significantly prolonged seizure latency in an AMPA-induced seizure model.

Clinical Drug Studies

Seizure Disorders. Both monotherapy and adjunctive use of perampanel in partial-onset seizures, with or without secondary generalization, were more effective than a placebo in patients who were not adequately controlled with one to three drugs for epilepsy in patients aged 12 years and older in double-blind, randomized placebo-controlled trials. Adjunctive therapy for primary generalized tonic–clonic seizures also showed superiority over placebo in patients with epilepsy aged 12 years and older. Although one systematic review suggested the potential of perampanel as a broad-spectrum antiseizure medication, more data are needed.

Therapeutic Indications

Seizure Disorders. Perampanel was first marketed in 2012 in Europe and the United States and is approved for monotherapy and adjunctive use in the treatment of partial-onset seizures with or without secondarily generalized seizures in patients with epilepsy aged 4 years and older and adjunctive therapy for primary generalized tonic–clonic seizures in patients with epilepsy aged 12 years and older.

Precautions and Adverse Reactions

Hostility- and aggression-related adverse reactions occurred in 12% and 20% of patients randomized to receive perampanel at 8 mg and 12 mg/day, respectively, compared to 6% in the placebo group. These effects were dose-dependent and generally appeared within the first 6 weeks of treatment, although new events continued to be observed for more than 37 weeks. Other adverse events included irritability, aggression, anger, and anxiety, which occurred in 2% or more of perampanel-treated patients and twice as frequently as in placebo-treated patients. Patients, their caregivers, and families should be informed that perampanel may increase the risk of psychiatric events.

Like all other drugs for epilepsy, perampanel increases the risk of suicidal thoughts or behavior in patients taking these drugs for any indication. Patients taking these medications should be monitored for the emergence or worsening of depression, suicidal thoughts or behavior, and/or any unusual changes in mood or behavior.

Common dose-related adverse reactions in patients receiving 8 or 12 mg/day in clinical trials (≥4% and occurring at least 1% higher than the placebo group) included dizziness (36%), somnolence (16%), fatigue (10%), irritability (9%), falls (7%), nausea (7%), ataxia (5%), balance disorder (4%), gait disturbance (4%), vertigo (4%), and weight gain (4%).

Perampanel was classified as pregnancy category C. It is unknown the degree to which perampanel is excreted in breast milk, so it was classified as “safety unknown” for lactation and should be administered to breastfeeding women with caution and only if the potential benefits clearly outweigh the (unknown) risks.

Drug Interactions

Concomitant use of perampanel at 12 mg/day reduced the C_{max} and AUC of levonorgestrel by approximately 40%. Concomitant use of moderate and strong CYP3A4 inducers, including carbamazepine, phenytoin, or oxcarbazepine with perampanel, decreased the plasma concentrations of perampanel by approximately 50% to 67%. Concomitant use of perampanel with CNS depressants, including alcohol, may increase the depressant effects.

Dosage and Administration

For monotherapy or adjunctive therapy for partial-onset seizures, the starting dose in adults and pediatric patients aged 4 years and older is recommended to be 2 mg/day once at bedtime. Dose increases should be performed no more frequently than at weekly intervals in increments of 2 mg/day based on individual clinical response and tolerability. The recommended maintenance dose ranges from 8 to 12 mg/day, although some patients may respond to 4 mg/day. Dosage adjustment is recommended in cases where moderate or strong CYP3A4 enzyme-inducing drugs are concomitantly used.

For adjunctive therapy for primary generalized tonic–clonic seizures, the recommended starting dose in adults and pediatric patients aged 12 years and older is 2 mg/day once at bedtime, and dose increases should be performed no more frequently than at weekly intervals in increments of 2 mg/day based on individual clinical response and tolerability. The recommended maintenance dose was 8 mg/day at bedtime. Dosage adjustment is recommended with the concomitant use of moderate or strong CYP3A4 enzyme-inducing drugs.

33.10c Carbamazepine

ROBERT M. POST, M.D., AND MARK A. FRYE, M.D.

Neuroscience-Based Nomenclature (NbN)	
Glutamate Channel Blocker	
Pharmacologic Domain	Glutamate
Mechanism of Action	Voltage-gated sodium and calcium channel blocker

Carbamazepine (Tegretol) is an iminostilbene drug possessing some structural similarity to the tricyclic antidepressant imipramine (Tofranil) but having a very different clinical spectrum of efficacy. It was approved for use in the United States for the treatment of trigeminal neuralgia in 1968 and for temporal lobe epilepsy (complex partial seizures) in 1974. Interestingly, carbamazepine was first synthesized as a potential antidepressant, but because of its atypical profile in a number of animal models, it was initially developed for use in pain and seizure disorders. It is now recognized in most guidelines as a first- or second-line mood stabilizer useful in the treatment and prevention of both phases of bipolar affective disorder. A long-acting sustained-release formulation (Equetro) was approved by the FDA for the treatment of acute mania in 2002.

The structure and chemistry of carbamazepine are closely related to the more recently introduced anticonvulsant oxcarbazepine (Trileptal). As illustrated in Figure 33.10c–1, whereas carbamazepine has a double bond in its middle ring, oxcarbazepine has a keto-oxygen attached. These differences result in very different routes and profiles of drug metabolism, yet, apparently, a generally similar clinical spectrum of efficacy in seizure, pain, and mood disorders. Oxcarbazepine is not FDA approved for acute mania. Although double-blind comparisons showed equal response to oxcarbazepine and haloperidol (Haldol) or lithium (Eskalith), these results were contaminated by the concomitant use of high-potency benzodiazepines. One study suggested better efficacy of oxcarbazepine in less severe mania compared with more severe mania, while carbamazepine is effective in severe forms of mania.

FIGURE 33.10c–1. Comparative metabolism of carbamazepine and oxcarbazepine. Both parent and first metabolite are active anticonvulsants—the top two are potent enzyme inducers; the bottom two are not.

CHEMISTRY

Carbamazepine is oxidized by cytochrome P450 oxidase of the 3A4 subtype to an active 10,11-epoxide metabolite that also possesses both anticonvulsant and antinociceptive properties. This epoxide is stable but can be further hydrolyzed to an inactive dihydroxy compound via an enzyme called epoxide hydroxylase. In contrast, oxcarbazepine is metabolized directly to its monohydroxy metabolite, which is also metabolically and physiologically active. Neither oxcarbazepine nor its active monohydroxy metabolite is readily oxidized by P450 liver enzymes, resulting in a lesser number of pharmacokinetic interactions with other drugs compared with carbamazepine. These and other differences are highlighted in Table 33.10c–1.

Carbamazepine is highly insoluble in water and difficult to dissolve in most preparations. It is commonly given in preclinical studies to animals in a solution of ethanol and propylene glycol, but no clinically available intravenous formulation exists.

Two long-acting preparations are now available. One of these preparations, extended-release carbamazepine, needs to be taken with food, as its absorption depends on normal gastrointestinal transit time, and it leaves a residual capsule ghost. Another long-acting preparation (Carbatrol or Equetro) uses a microtrol delivery system with 25% uncoated intermediate release beads, which are absorbed almost as soon as the pill is swallowed; 40% extended-release beads, which dissolve gradually over a period of 8 to 12 hours because of a polymer coating that allows carbamazepine to diffuse slowly through tiny micropores; and 35% enteric release beads, which release the drug very slowly as a result of special pH-sensitive coating.

Such a formulation makes the long-acting forms suitable for single bedtime administration in affectively ill patients (although this is not recommended in epilepsy).

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Carbamazepine is absorbed slowly and somewhat erratically through the gastrointestinal tract. Bioavailability is 80%, and the drug should not be exposed to high humidity because this can decrease bioavailability. Peak plasma levels are reached 2 to 8 hours after a single dose. Carbamazepine is 70% to 80% bound to plasma protein. The average half-life after a single dose is 26 hours, with a range of 18 to 54 hours. However, with long-term administration in humans, the half-life decreases to approximately 12 hours (range, 10 to 25 hours). This change occurs with the induction of hepatic P450 3A4 enzymes, which increase the rate of metabolism of carbamazepine itself (autoinduction) and a variety of other agents, as referred to in Table 33.10c–2.

Table 33.10c–1.
Comparative Effects of Carbamazepine (CBZ) and Oxcarbazepine (OXC)

	CBZ	OXC	Comment on OXC
Hepatic enzyme 3A4 induction	+++	+	No autoinduction
Decrease WBC	+++	±	No WBC suppression
Rash	6.5%	2.5%	Lower rate of rash[a]
Hyponatremia	+	++	More hyponatremia
LFT↑	+	±	Less liver enzyme elevation
Teratogenic	++	±	Lesser incidence of spina bifida
Agranulocytosis Aplastic anemia	1/10,000	±	Lower incidence of hematologic reaction

[a] With benign rash on CBZ did not rerash on OXC. 3/3 with exfoliative rash did, however.

Drugs Whose Serum Concentrations Are Decreased by Carbamazepine Via Prominent Induction of Cytochrome P450 3A4

Drug Group	Drugs
Analgesics	Alfentanil; buprenorphine; fentanyl (?); levobupivacaine; methadone; tramadol
Anticoagulants	Dicoumarol (?); phenprocoumon; warfarin[a]
Antiepileptics	Carbamazepine[a]; ethosuximide; felbamate; lamotrigine[a]; oxcarbazepine; phenytoin; primidone; tiagabine; topiramate; valproic acid[b]; zonisamide
Antidepressants	Bupropion; citalopram; mirtazapine; tricyclic antidepressants
Antimicrobials	Caspofungin; doxycycline
Antipsychotics	Aripiprazole; clozapine; fluphenazine (?); haloperidol[a]; lurasidone[a]; olanzapine; quetiapine; risperidone; thiothixene (tiotixene); ziprasidone; brexpiprazole; cariprazine
Antivirals	Delavirdine; protease inhibitors
Anxiolytics/	Alprazolam (?); buspirone
Sedatives	Clonazepam; midazolam; zopiclone (?)
Immunosuppressants	Cyclosporine (?); sirolimus (rapamycin); tacrolimus
Muscle relaxants	Doxacurium chloride; pancuronium bromide; rapacuronium bromide; rocuronium bromide; vecuronium bromide
Estrogen; steroids	Estrogen in hormonal contraceptives[a]; dexamethasone[b]; mifepristone; prednisolone
Stimulants	Methylphenidate[b]; modafinil
Others	Bepridil; oxiracetam (?); paclitaxel;

	quinidine; remacemide (?); repaglinide; theophylline (?); thyroid hormones

[a] Clinical most important.

[b] Important.

(?) Signifies doubtful evidence/clinical significance.

The degree of carbamazepine autoinduction is somewhat dose-dependent but is usually complete after 3 to 5 weeks of treatment. Thus, doses that are not initially tolerated may become so after several weeks, and blood levels usually fall despite the use of the same daily dose, necessitating later dose increases to maintain similar blood levels and clinical effect. Long-term use of carbamazepine is associated with a markedly increased ratio of the amount of the 10,11-epoxide to carbamazepine. The half-life of the 10,11-epoxide is approximately 6 hours.

Carbamazepine is metabolized in the liver and then excreted by the kidneys, as only 1% is eliminated by biliary excretion. Oxcarbazepine is a white to faintly orange crystalline powder, and, like carbamazepine, it is practically insoluble in ethanol, ether, or water. It is slightly soluble in chloroform, acetone, and methanol.

Because there is no or minimal autoinduction with oxcarbazepine, its half-life remains relatively stable over time. The half-life of oxcarbazepine is approximately 2 hours, and because of the rapid conversion to the monohydroxide, which has a half-life of approximately 9 hours, the monohydroxide is responsible for most of the anticonvulsant activity. Dosing is usually twice or three times daily. There is an FDA-approved long-acting preparation of oxcarbazepine (Oxtellar) for complex partial seizures, but efficacy in bipolar disorder has not been demonstrated. However, single nighttime dosing is possible with it. Oxcarbazepine is 96% absorbed and 60% bound to plasma proteins. Its monohydroxy derivative is 40% bound to plasma proteins. The monohydroxy derivative, eslicarbazepine, was FDA approved for seizures in 2013, although the results of earlier trials in mania have not been reported.

PHARMACODYNAMICS

Mechanisms of Antinociceptive, Antimanic, and Antidepressant Action

The onset of anticonvulsant and antinociceptive effects of carbamazepine is rapid and can occur after a single dose in appropriate animal model studies or after 24 to 48 hours in most clinical studies of paroxysmal pain syndromes, such as trigeminal neuralgia (Fig. 33.10c–2). Its antimanic actions can also be relatively rapid in onset, beginning within the first several days of treatment, but several weeks are typically required for maximum treatment response in patients. In contrast, the antidepressant effects of carbamazepine are often delayed, with 3 to 4 weeks required before maximum effects are observed. However, because carbamazepine can be relatively sedating, an improvement in sleep may occur much earlier, yet as with other antidepressant modalities, the degree of improvement in sleep is not correlated with the degree of subsequent antidepressant response.

In assessing the mechanism of action related to clinical effects, the actions of carbamazepine at clinically relevant blood levels and in the appropriate time frame should be considered, as schematized in Figure 33.10c–2. Immediate effects would be more likely related to the anticonvulsant and antinociceptive profile of the drug, whereas effects requiring more chronic administration would be those more likely linked to the parallel time course of antidepressant effects of carbamazepine.

The anticonvulsant effects of carbamazepine have been most closely linked to the blockade of type 2 or batrachotoxin-sensitive sodium channels. When these channels are inactivated, they tend to decrease the release of excitatory amino acids such as glutamate and inhibit sustained rapid neuronal firing in a variety of in vitro models. This action of sodium channel blockade is shared by oxcarbazepine, as well as a variety of other anticonvulsant compounds, including phenytoin (Dilantin), lamotrigine (Lamictal), and topiramate (Topamax), and, to a lesser extent, valproate (Depakene; Depakote). Although these are acute effects of the drug and are associated with decreased neurotransmitter release, Robert Belmaker and colleagues have postulated that the potency of sodium channel blockade is related to the antimanic efficacy of the anticonvulsant compounds as a group. This potential relationship, which is discordant with the time frame of clinical action and violated by topiramate (which is not antimanic), remains to be further investigated.

The acute anticonvulsant effects of carbamazepine have been closely linked to those that can be readily studied in a variety of animal models, including amygdala-kindled seizures. Carbamazepine appears to exert its actions on amygdala-kindled seizures through the so-called peripheral-type or mitochondrial benzodiazepine receptor. It is at this receptor that the peripheral-type ligand Ro 5–4864 is proconvulsant and an agonist, whereas PK1195 is an anticonvulsant and an antagonist. Carbamazepine appears to share PK1195-like antagonist activities at the peripheral-type benzodiazepine receptor.

In contrast to the anticonvulsant effects of diazepam (Valium), which are reversed by a pure central benzodiazepine antagonist such as Ro 15–1788 or flumazenil (Romazicon), carbamazepine actions are reversed by Ro 5–4864 in a PK1195-blockable fashion, strongly implicating this peripheral-type benzodiazepine receptor in carbamazepine's anticonvulsant actions on amygdala-kindled seizures (as illustrated in Fig. 33.10c–3A). Whether this peripheral-type effect is related to any of carbamazepine's psychotropic properties remains to be further investigated.

The peripheral-type benzodiazepine receptors have been linked to cholesterol transport and calcium influx through mitochondrial membranes. Cholesterol is converted to pregnenolone in mitochondria, and this compound subsequently becomes transformed into neuroactive steroids: allopregnanolone and allotetrahydro-DOC (which enhance γ-aminobutyric acid type A [$GABA_A$] receptors); pregnenolone sulfate (which inhibits TBPS [t-(35)S]butyl-bicyclophosphorothionate] binding and voltage-gated Ca^{++} channels, but enhances NMDA receptors); and dehydroepiandrosterone sulfate (which inhibits the barbiturate binding site). Thus, it remains possible that some of carbamazepine's actions initiated at peripheral-type benzodiazepine receptors may be achieved indirectly at other receptors through these effects on neurosteroid metabolism.

FIGURE 33.10c–2. Schematic and time course of clinical and biochemical effects of carbamazepine. Seizure(s) and paroxysmal pain(p) syndromes respond rapidly to carbamazepine, whereas maximal effects in mania(m) and depression are delayed 2 to 3 weeks or more, respectively. The acute effects observed in animal and humans are probably related to anticonvulsant and antinociceptive efficacy, whereas chronic effects are more likely to be related to antidepressant mechanisms. Candidate mechanisms for each clinical effect are listed according to their occurrence at clinically relevant concentrations. Chr>A, chronic greater than acute; CSF, cerebrospinal fluid; DA, dopamine; GABA, γ-aminobutyric acid; HVA, homovanillic acid; l.c., locus ceruleus; NE, norepinephrine.

In addition to its blockade of glutamate release, carbamazepine is also potent at adenosine A_1 receptors. Its agonist properties at these receptors could account for not only some of its anticonvulsant properties but also its sedative properties.

It is also of interest that a variety of mood stabilizers beyond carbamazepine, such as lithium, valproate, and lamotrigine, are able to weakly block calcium influx through glutamate receptors of the NMDA subtype. Thus, the possibility remains that carbamazepine could exert relatively antiglutamatergic effects both by decreased release of glutamate and by relative decreases in glutamate’s postsynaptic efficacy by inhibiting calcium influx. Glutamate NMDA receptor antagonist actions, in general, have been increasingly linked to potential antidepressant (ketamine) and possible mood-stabilizing effects (memantine), but further investigation of this possible linkage to carbamazepine’s actions is required.

In common with both lithium and valproate, carbamazepine blocks inositol transport at the myoinositol transporter. Other common and differential effects of carbamazepine compared with lithium and valproate are illustrated in Figure 33.10c–4.

The antinociceptive effects of carbamazepine have been most closely linked to effects at $GABA_B$ or baclofen-like receptors. Carbamazepine and baclofen share structural similarities, and the antinociceptive actions of both drugs are specifically inhibited by $GABA_B$ antagonists. It is also of interest that chronic but not acute administration of lithium, carbamazepine, and valproate are all associated with upregulation of $GABA_B$ receptors in the hippocampus, yielding this action as a potential convergent mechanism for mood stabilization. In contrast, unimodal antidepressants appear to upregulate $GABA_B$ receptors in the frontal cortex.

Carbamazepine also exerts a variety of interesting effects on aminergic and indolaminergic systems. Carbamazepine is a very weak blocker of norepinephrine reuptake, which is probably not clinically relevant, but it does decrease the induced release of norepinephrine at clinically relevant concentrations. These preclinical findings converge with carbamazepine’s ability to decrease CSF norepinephrine in manic patients.

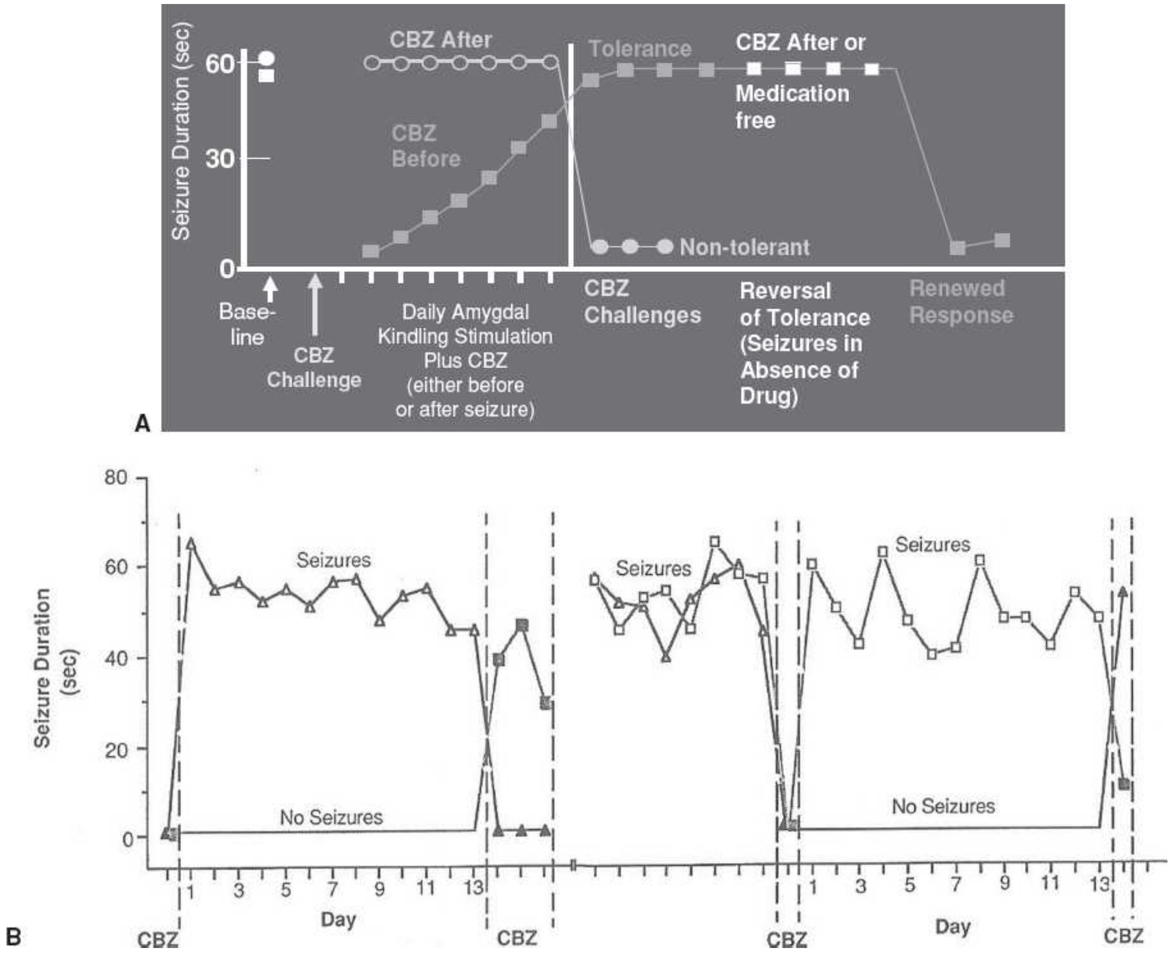

FIGURE 33.10c–3. **A:** Schematic illustration of contingent tolerance to carbamazepine (CBZ): development and reversal. In fully kindled animals (*open circles, squares*), carbamazepine treatment inhibits kindled seizures (*filled squares*). Repeated drug administration before (*filled squares*), but not after (*filled circles*), stimulation results in tolerance development. Tolerance induced in this matter (*filled squares*) can be reversed by a period of kindled seizures with drug administration after each seizure (*open squares, dotted lines*). **B:** Seizures enable carbamazepine's anticonvulsant effect. *Left side:* In fully kindled animals, CBZ was administered (15 mg/kg, i.p.) and produced complete seizure suppression (CBZ-first day). Animals were then divided into two groups that received either 13 daily amygdala-kindled seizures (at 800 μA [*open triangles*]) or no treatment. Following this, both groups of animals received 3 days of kindling stimulation preceded by CBZ administration on each day (15 mg/kg). The rats that did not experience seizures for the 13-day interval showed only a partial response to CBZ (*closed squares*), whereas the rats that underwent seizures again showed complete seizure suppression by CBZ. Both groups were then given repeated seizures (*open squares and triangles*) to reinstate the original CBZ effect. *Right side:* A crossover design was used to replicate the initial finding. Animals that previously were given no treatment now received 13 days of seizures (*open squares*) and vice versa.

> Again, and even more robustly, the animals that did not experience seizures for 13 days showed no anticonvulsant response to CBZ administration (day 14), whereas the animals experiencing seizures showed almost complete seizure suppression.

Actions at noradrenergic α_2 receptors are of special interest in that the α_2 agonist in clonidine (Catapres) reverses some of carbamazepine's effects in some seizure models, whereas, paradoxically, the α_2 antagonist yohimbine reverses carbamazepine's anticonvulsant effects in other models. In epilepsy-prone animals, carbamazepine's ability to increase serotonin in the hippocampus appears to be important, as depletion of serotonin by several different mechanisms is associated with a loss of carbamazepine's anticonvulsant effects in this model.

Consistent with other mood-stabilizing drugs (lithium and valproate), carbamazepine is also able to decrease dopamine turnover, an action that could be related to its antimanic and mood-stabilizing properties. In contrast to the antipsychotics that directly block dopamine receptors, carbamazepine is not a direct antagonist at dopamine receptors and exerts its actions on the dopamine system through some other series of mechanisms. Dopamine levels have been reported to be increased in the prefrontal cortex after chronic carbamazepine administration. Carbamazepine decreases levels of the dopamine metabolite homovanillic acid (HVA) in the CSF of affectively ill patients following probenecid administration, consistent with its ability to decrease dopamine turnover in animals.

Taken together, these data suggest that different mechanisms of carbamazepine's actions could be related differentially to its anticonvulsant efficacy in different seizure models. To the extent that this is clearly delineated in epilepsy research, as, for example, in relationship to α_2 receptors, it raises the possibility that different components of carbamazepine's actions could also be related to different aspects of its efficacy and side effect profile in the affective disorders.

In addition to those mentioned above, carbamazepine's actions on a variety of neuropeptides appear to require chronic administration and, thus, could be pertinent to antidepressant actions. Chronic, but not acute, drug administration increases substance P levels and sensitivity in the striatum, findings of particular interest, as they are shared by lithium.

Substance P antagonists have been studied in depression but have a mixed record for effectiveness.

Carbamazepine decreases levels of somatostatin in CSF, in contrast to nimodipine (Nimotop; Nymalize), which increases CSF somatostatin. These differential effects of carbamazepine and nimodipine exist not only in terms of their blockade of calcium influx via NMDA-type glutamate receptors versus L-type calcium channels, respectively but also in terms of their physiologic effects on brain metabolism, as assessed by PET. Ketter and associates have found a differential relationship of metabolism in paralimbic areas, particularly in the left insula, to the degree of antidepressant response to carbamazepine, with higher baseline levels of activity being associated with better antidepressant response. In contrast, low levels of metabolism in the left insula are associated with a better antidepressant response to the dihydropyridine calcium channel blocker nimodipine. In both instances, response to the drug was associated with a relative normalization of the baseline abnormalities in the activity of the insula and related paralimbic areas of the brain.

Carbamazepine's antidepressant effects may be mediated by those that are atypical of many other antidepressant modalities. For example, most antidepressants decrease β-adrenergic receptors in the prefrontal cortex, whereas carbamazepine upregulates them. Most antidepressants upregulate mineralocorticoid and glucocorticoid receptors and, thus, decrease cortisol, whereas carbamazepine increases plasma and urinary free cortisol. This unusual profile of carbamazepine may explain why it is effective in some depressed patients with affective syndromes that are resistant to more traditional antidepressant modalities. A possible link of carbamazepine to antidepressant response in depressed and PTSD patients with low baseline cortisol or increased dexamethasone suppression has not been adequately studied, however.

As noted earlier, carbamazepine has both convergent and contrasting effects with other mood stabilizers, such as lithium and valproate. Whereas lithium and carbamazepine block cAMP and G proteins, their effects on phosphoinositide turnover diverge. Lithium inhibits several inositol phosphatases, whereas valproate does not, and carbamazepine may enhance their activity. This contrasts with the common effects of the three drugs in blocking the inositol transporter and in decreasing arachidonic acid turnover.

Carbamazepine, as well as the mood stabilizers lithium, valproate, and most antidepressant modalities, increase BDNF. This action may be of considerable importance because the Val66 met allele of pro-BDNF and early life adversity can reduce hippocampal volume and yield low levels of BDNF in the hippocampus and cortex in adulthood. Stressors, affective episodes (both mania and depression), and substances of abuse all can lower BDNF in the hippocampus or serum of bipolar patients. As such, effective prophylaxis will indirectly prevent episode-related BDNF decrease, and mood stabilizer treatment may also directly increase BDNF and help correct persisting BDNF decreases.

Whereas lithium is a blocker of vasopressin effects via its inhibition of the second messenger cAMP, carbamazepine appears to exert indirect facilitatory effects at the vasopressin receptor. Therefore, because carbamazepine’s effects are at the level of the receptor and lithium’s blockade is below the receptor (in the transduction system), carbamazepine is unable to reverse the effects of lithium on the development of diabetes insipidus.

Carbamazepine, like phenytoin and lamotrigine, is not effective in blocking the initial developmental phase of electrical kindling of the amygdala but is a highly effective anticonvulsant in the midphase of full-blown kindled seizures. In contrast, chronic treatment with carbamazepine does block the initial or developmental phase of pharmacologic kindling with the local anesthetics lidocaine (Xylocaine) or cocaine. Chronic carbamazepine should thus make the development of cocaine-related seizures in humans less likely as well. This effect could contribute to carbamazepine’s utility in helping with cocaine abstinence, an effect that has only been demonstrated compared with placebo in those with concomitant affective disorders.

Mechanisms of Tolerance Development

It is of interest that carbamazepine is acutely effective against completed amygdala-kindled seizures, but tolerance rapidly develops to this effect with repeated daily administration (Fig. 33.10c–3A). This form of tolerance is called contingent tolerance, as it only develops when the drug is given before the amygdala stimulation, but not when the drug is given immediately after the stimulation. In this way, tolerance is contingent on having the drug present during the seizure-inducing stimulation and is clearly based on pharmacodynamic and not pharmacokinetic mechanisms. This tolerance that develops to the anticonvulsant effects of carbamazepine may provide an indirect but useful model for considering mechanisms potentially associated with clinical tolerance development in seizure and mood disorders and ways of slowing its development or reversing it once tolerance has occurred.

A gradual loss of efficacy after many years of successful treatment has been reported in a subgroup of patients via an apparent pharmacodynamic tolerance mechanism in patients with: paroxysmal pain syndromes such as trigeminal neuralgia, the prophylaxis of bipolar illness (Fig. 33.10c–5), and to a lesser extent in clinical epilepsy syndromes. Some of the ways of slowing tolerance development in the preclinical seizure model could be tested clinically for their relevance to human therapeutics, either in epilepsy patients specifically or in other syndromes such as bipolar disorder as well.

As noted above, the tolerance that develops to carbamazepine's anticonvulsant effects on amygdala-kindled seizures is not related to pharmacokinetics or a drop in carbamazepine blood levels. This can be demonstrated by the fact that tolerance only develops when the drug is given to the animal just before each amygdala stimulation, but not when the same dose of the drug is administered immediately after each kindled seizure has occurred. Animals administered daily carbamazepine just after each seizure has occurred (and drug levels again become negligible prior to the next stimulation the next day) never become tolerant. In this fashion, tolerance development is contingent on the drug's being in the brain concurrently with the amygdala stimulation. This type of contingent tolerance can be reversed either by a period off the drug (and the occurrence of seizures in the medication-free state) or, remarkably, by a period of continuing to give the drug daily, but now after (rather than before) each of a series of several once-daily seizures has occurred.

The neurobiology of this anticonvulsant tolerance development has been preliminarily explored in the kindled seizure model and appears to involve differential regulation of a variety of seizure-induced adaptations at the level of gene expression. Seizures ordinarily induce a variety of neurotransmitter and receptor effects that have been linked either to the primary pathology of kindled seizure progression or to more short-lived secondary compensatory or endogenous anticonvulsant effects (Table 33.10c–3, left column). For example, thyrotropin-releasing hormone (TRH) peptide and its messenger ribonucleic acid (mRNA) are increased for approximately 4 days after an amygdala-kindled seizure. However, TRH does not increase after a seizure that occurs when animals are tolerant to carbamazepine.

TRH is likely an anticonvulsant adaptation based on the finding that its bilateral injection of TRH into the hippocampus decreases amygdala-kindled seizures. Further supporting this perspective are the observations that after a period of 4 or more days after the last amygdala-kindled seizure, endogenous TRH levels and other putative endogenous anticonvulsant adaptations dissipate and carbamazepine loses its anticonvulsant effectiveness (even in nontolerant animals) (Fig. 33.10c–3B; day 14). These data suggest that TRH is one example of many endogenous substances that are induced postictally in an attempt to prevent further seizures from occurring and, at the same time, are also required for carbamazepine's efficacy. Thus, the failure of seizures to induce TRH and other anticonvulsant peptides in carbamazepine tolerant animals could be relevant to this loss of efficacy. TRH also has antidepressant effects when administered intravenously or intrathecally to depressed patients. Therefore, it remains a possibility to be further studied that loss of depressive-episode induced increases in TRH could be related to clinical tolerance development in mood disorders.

Similarly, in carbamazepine-tolerant animals, the breakthrough seizures selectively fail to induce other endogenous adaptations, such as increases in $GABA_A$ receptors, although increases in benzodiazepine receptors continue to occur (Table 33.10c–3, right columns). The inability of GABA receptors to show their normal increase after a seizure is also observed at the level of the $GABA_A$ receptor subunit mRNAs. The mRNA for the α_4 subunit is one of several subunits that ordinarily increase after seizures, but it fails to do so in the carbamazepine-tolerant state. Thus, in addition to an anticonvulsant neuropeptide such as TRH, transient seizure-induced increases in other inhibitory neurotransmitter receptors, such as those of $GABA_A$, and its α_4 subunit are also selectively suppressed during carbamazepine tolerance, which could contribute to its loss of anticonvulsant efficacy. That is, some of the needed episode-induced adaptations fail to occur.

These are just two examples of several neural systems that are selectively impaired after seizures in carbamazepine-tolerant animals but are consistently induced by seizures in nontolerant animals that have been exposed to the same number of prior seizures and the same amount of carbamazepine (but given after the seizure has occurred) (Fig. 33.10c–3A). Also supporting this view that seizure-induced adaptations are important to carbamazepine's efficacy is the observation that carbamazepine again becomes effective in tolerant animals after a series of seizures are given in the absence of medication (which then re-induce the full range of adaptive effects on gene expression).

Clinical case studies suggest that this renewal of efficacy may also be seen after a period of time off medications in the instance of clinical tolerance development in seizure or mood disorders, but it would be preferable to find a new treatment agent that did not show cross-tolerance to carbamazepine so as to avoid the necessity of experiencing further episodes while off medication.

In the preclinical model of anticonvulsant tolerance to carbamazepine on amygdala-kindled seizures, cross-tolerance is observed to the anticonvulsant effects of PK11195 (a peripheral type of benzodiazepine antagonist), lamotrigine, and, surprisingly, valproate and levetiracetam (Keppra), but not to diazepam or phenytoin. How these cross-reactivities for seizure tolerance in the rodent relate to those in the clinical condition of recurrent affective disorders remains to be further studied. Finding ways to address clinical tolerance development is potentially important because a substantial group of treatment-refractory patients (perhaps some 20% to 40%) who initially experience an excellent prophylactic response to carbamazepine begin to show breakthrough episodes consistent with a tolerance process, which often begins after a period of 2 to 3 years of effective treatment (see years 1986 to 1988 in Fig. 33.10c–5).

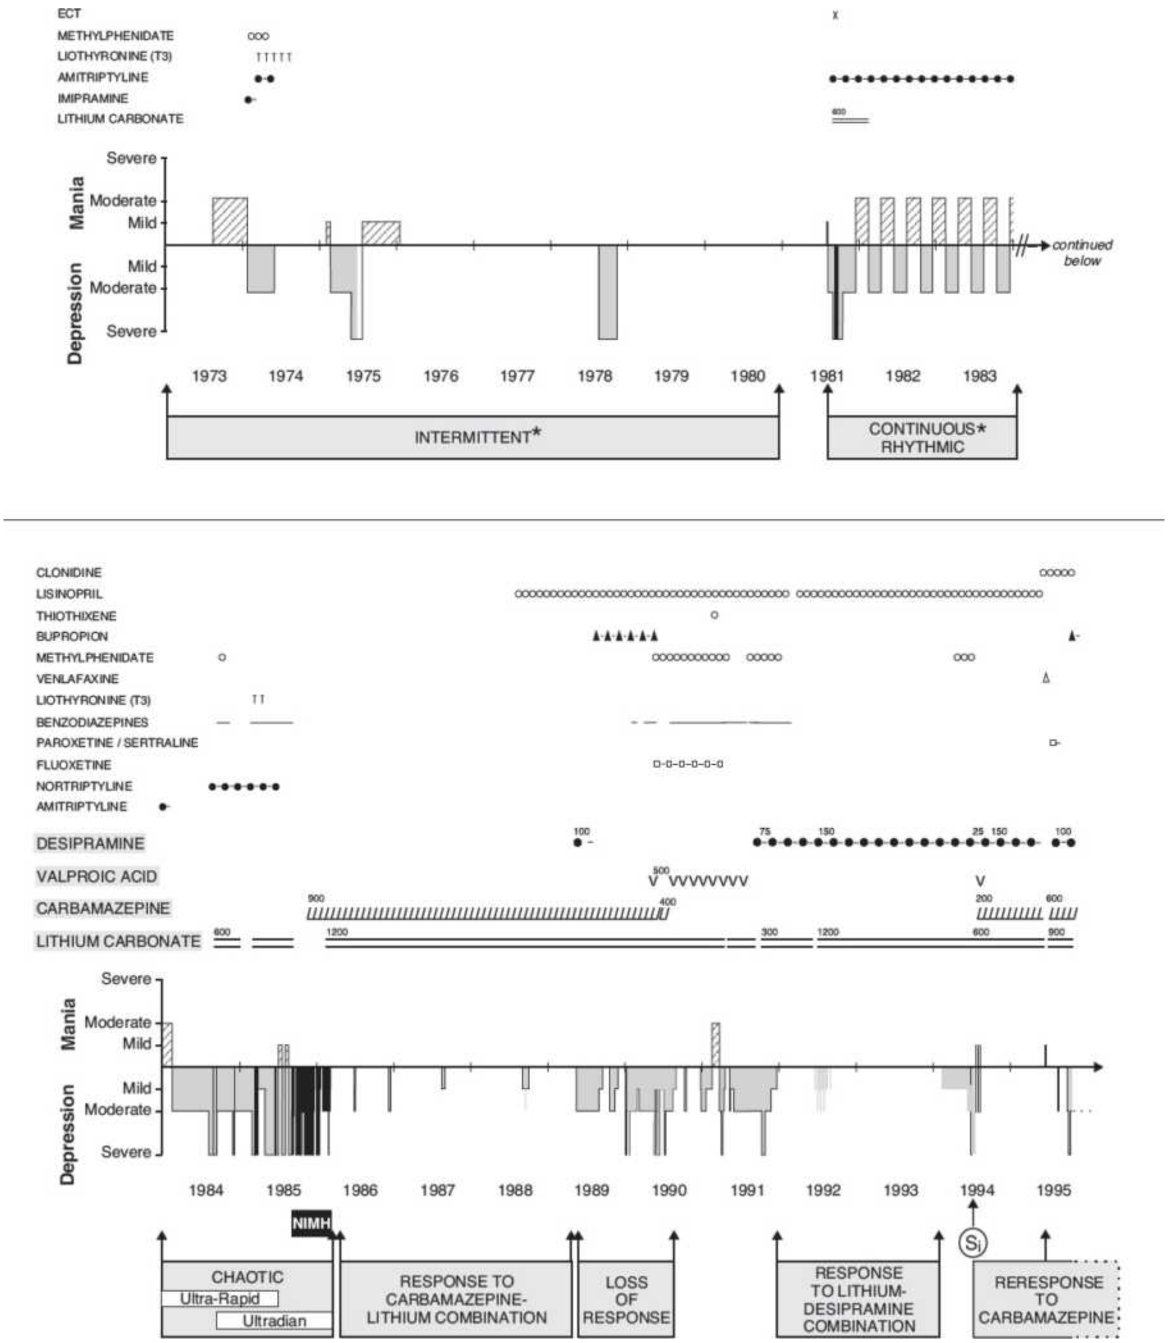

FIGURE 33.10c–5. Life chart showing the phases in evolution and treatment response in a female patient with bipolar II disorder. This life chart illustrates the phenomena of illness progression, probable antidepressant-induced cycle acceleration (m 1981), lack of response to lithium in a rapid cycler (1984–5), response to the combination therapy of lithium and carbamazepine, development of loss of responsiveness to this treatment regimen via tolerance (1989), and cross-tolerance to valproate (1990). Key: Lithium (= = = =); carbamazepine (//////); valproic acid (VVVV); tricyclics (-.-.-.); benzodiazepines (–.–.–.); thyroid (TTTT); other (oooo). CBZ, carbamazepine; Dep, depression; ECT, electroconvulsive therapy; VPA, valproic acid.

Interestingly, as in the seizure model of cross-tolerance between carbamazepine and valproate, the patient illustrated in Figure 33.10c–5 failed to respond to valproate when she was becoming tolerant to carbamazepine. Further exploration of ways to circumvent tolerance development and ascertain which drugs do not possess cross-tolerance is of considerable interest. A number of approaches have been examined that slow tolerance development in the amygdala-kindled seizure model. These include: initially using sustained higher rather than marginal doses of the drug; combining carbamazepine with valproate; treating earlier rather than later in the course of kindling, and reducing the stimulation intensity (or lowering illness drive). Whether some of these are also pertinent to slowing tolerance development during clinical treatment of seizure and mood disorders remains to be studied systematically, but they are listed here for their potential heuristic value.

Table 33.10c–3.
Selective Failure of Some Kindled Seizure-Induced Neurochemical Changes in CBZ-Contingent Tolerance

Seizure-Induced Adaptation (in Nontolerance Animals)	Seizure-Induced Adaptations Present in CBZ-Tolerant Animals	Seizure-Induced Adaptations Absent in CBZ-Tolerance Animals
↑ c-fos mRNA		No ↑ c-fos
↑ DZP receptors	↑ DZP-R	
↑ GABA receptors (3H) muscimol		No ↑ GABA-R
↑ Subunit		No ↑ subunit
↑ Subunit	↑ Subunits	
↑ TBPS binding		No ↑ TBPS
↑ Glucocorticoid-R mRNA		No ↑ Glucocorticoid-R
↑ Mineralocorticoid-R mRNA	↑ Mineralocorticoid-R	
↑ BDNF mRNA		No ↑ BDNF
↑ NT_3 mRNA	↑ NT_3	
↑ TRH mRNA		No ↑ TRH
↑ CRH mRNA		No ↑ CRH
↑ CRH-BP mRNA		No ↑ CRH-BP
↑ NPY mRNA		No ↑ NPY
↑ Enkephalin mRNA		No ↑ Enkephalin
↑ Dynorphin mRNA	↑ Dysmorphia	

Treated with CBZ after each daily amygdala kindling stimulation; nontolerance animals were matched for amount of drug and number of seizures seen in tolerant animals.

CBZ, carbamazepine; DZP, diazepam; GABA γ-aminobutyric acid; TBPS (35S) t-butylbicyclophosphorothionate; BDNF, brain-derived neurotrophic factor; NT_3, neurotrophin-3; TRF, thyrotropin-releasing hormone; CRH, corticotropin-releasing hormone; CRH BP, corticotropin-releasing hormone-binding protein.

CLINICAL DRUG STUDIES

Acute Mania

Numerous double-blind studies of various designs have compared carbamazepine to placebo or other active agents that indicate antimanic efficacy. Two large placebo-controlled, parallel-group design trials have recently revealed that the long-acting formulation of carbamazepine (Equetro) was significantly more effective than a placebo in acute mania. Similar acute antimanic effects of carbamazepine that roughly parallel those of lithium and antipsychotics are illustrated in Figure 33.10c–6.

Moreover, acute antimanic responsivity has been documented in double-blind, off-on–off-on study designs, as illustrated in Figure 33.10c–7, in a patient who was a clear nonresponder to lithium, as revealed by a breakthrough episode during carefully monitored lithium treatment upon hospital discharge. The patient was readmitted in a full-blown manic episode despite lithium treatment and showed a third excellent re-response to active carbamazepine and, subsequently, has been able to remain out of the hospital during long-term prophylaxis with carbamazepine as supplemented by other agents. Response to carbamazepine but not to valproate has also been seen in some patients (Figs. 33.10c–3 and 33.10c–8). Other patients with bipolar disorder have shown the opposite pattern of clear-cut responses to valproate but not carbamazepine, emphasizing the principle that response to one anticonvulsant is not predictive of response to another.

Acute Depression

Fewer studies have addressed the acute antidepressant effects of carbamazepine, but several are highly suggestive of efficacy. One large parallel-group study of carbamazepine compared with placebo has been completed recently by Zhang and associates (Table 33.10c–4). These authors found 50% reductions in Hamilton Depression Rating Scale scores in 34.8% on placebo (*N* = 23), 63.8% on carbamazepine (*N* = 47), and 84.8% on carbamazepine plus a Chinese herbal preparation (Free and Easy Wanderer Plus [FEWP]) (*N* = 46; *P* < .05), further supporting the acute antidepressant effects of the drug. Zhang et al. have also demonstrated acute antidepressant effects of carbamazepine compared with placebo in unipolar depression.

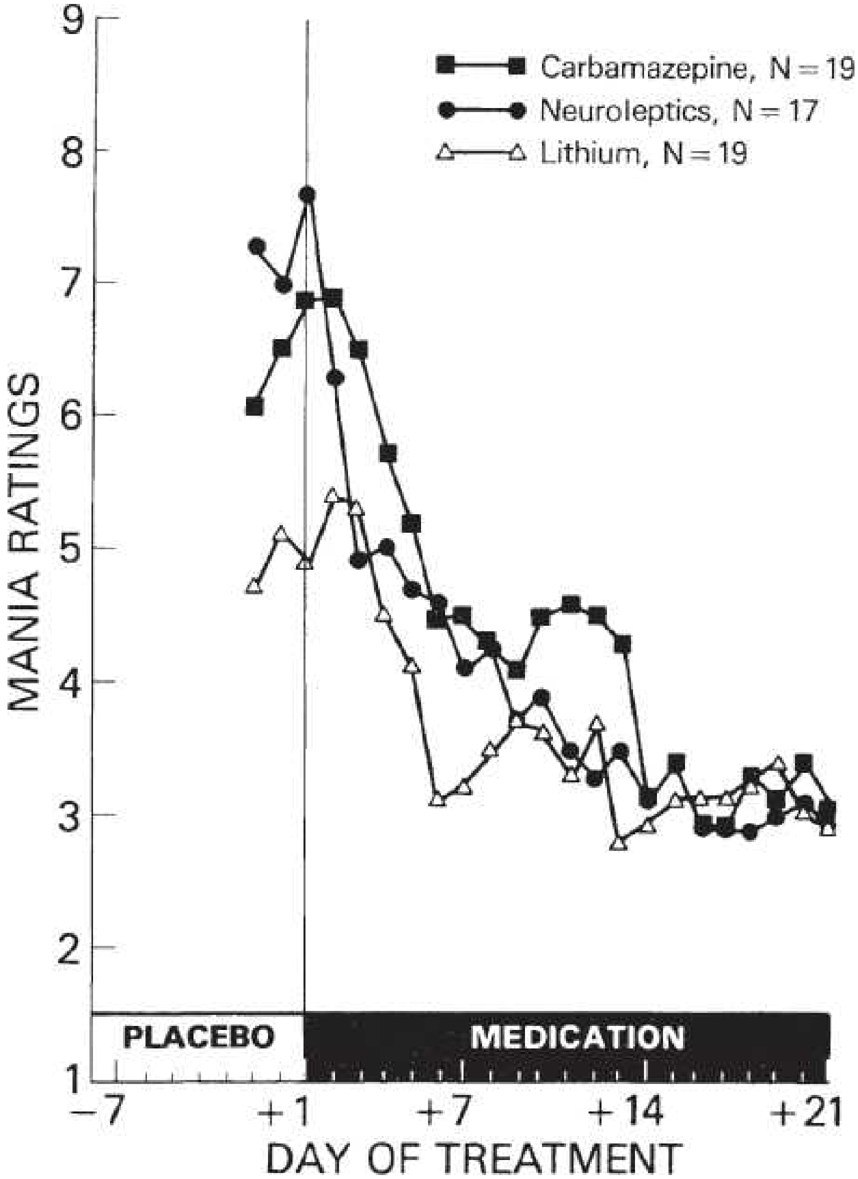

FIGURE 33.10c–6. Time course of double-blind acute antimanic effects of carbamazepine compared to lithium and neuroleptics. The incidence and time course of antimanic effects of carbamazepine appear comparable with those achieved by neuroleptics, although several studies have suggested a slightly faster onset of efficacy of neuroleptics in the first 3 days of treatment, a difference that was gone by 7 days. Even patients requiring seclusion for acute, fulminant, psychotic manic episodes may rapidly improve after initiation of treatment to carbamazepine alone.

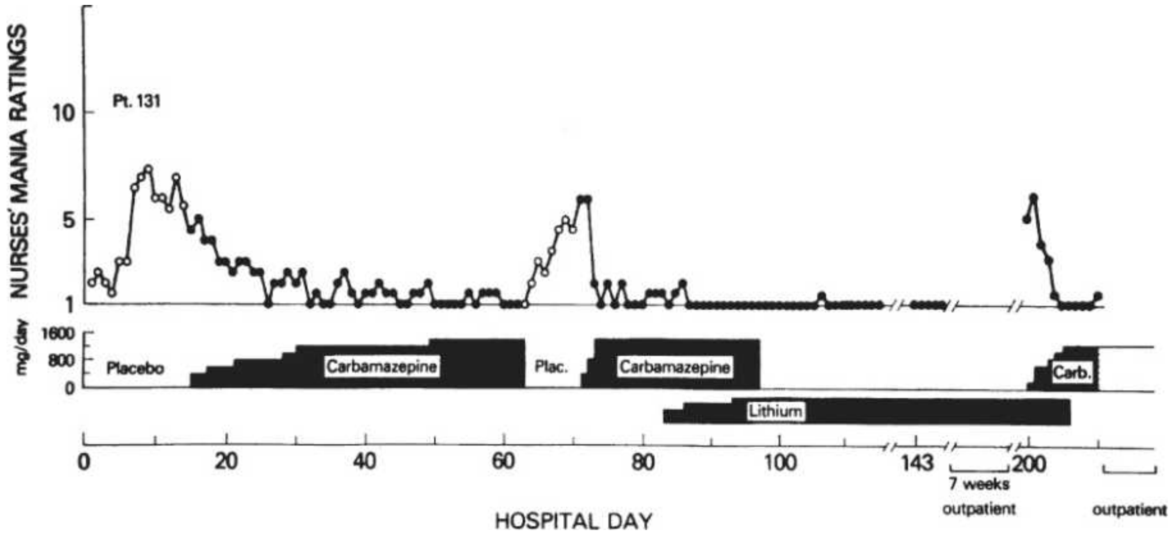

FIGURE 33.10c–7. Unequivocal antimanic response to carbamazepine in a double-blind, off-on–off-on clinical trial, a subsequent manic episode on lithium, and a third "on" to carbamazepine.

Moreover, the authors have observed that a group of 10 patients at the National Institute of Mental Health (NIMH) who were initial good acute antidepressant responders to carbamazepine on a double-blind basis subsequently relapsed on placebo and then re-responded during a second blind treatment trial with carbamazepine (Fig. 33.10c–9). This off-on-off–on documentation of responsivity indicates that carbamazepine has unequivocal antidepressant effects in a subgroup of highly treatment-refractory depressed patients. While good acute antidepressant effects occurred in about one-third of patients exposed to carbamazepine, the percentage of antidepressant response to this agent and the particular characteristics and predictors of response remains to be further delineated.

Initial data summarized in Table 33.10c–5 suggest that those with more severe episodic and less chronic depressions were among the best responders to the drug, as were those with low baseline CSF HVA, the major metabolite of dopamine. Carbamazepine responders also showed a pattern of baseline hypermetabolism on PET scans that is unusual and contrasts with the more typical hypofrontality of major depression. Some data also suggest that those with a history of depression in association with prior alcoholism are among those who respond well to the drug. This is of considerable interest because carbamazepine can block the effects of alcohol withdrawal in experimental animals, and the drug is widely used in the acute and long-term treatment of those with alcohol-related dysphoria in Scandinavian countries.

Prophylaxis

More than a dozen partially controlled studies (involving either randomization or double-blind comparison with other agents such as lithium) reveal that carbamazepine is approximately as effective as lithium in the prevention of affective episodes, although several caveats remain. In these controlled studies of carbamazepine prophylaxis, 224 of 382 (59%) showed a moderate to marked response to carbamazepine. Similarly, lithium response in these same studies occurred in 241 of 395 patients (61%). However, in several studies, there was better antimanic efficacy of lithium compared with carbamazepine.

The German collaborative study indicated several different predictors of response to these two agents. Lithium was substantially more effective than carbamazepine in those with a classic bipolar I diagnosis, with euphoric mania, no thought disorder or comorbid substance abuse, as well as (in other studies) a positive family history of affective disorder. Conversely, there was a trend toward better prophylactic efficacy of carbamazepine in those with bipolar II illness, schizoaffective diagnosis, dysphoric mania, and substance abuse comorbidity (current or prior) as well as (in other studies) a negative family history of bipolar disorder in first-degree relatives.

Case studies performed in a double-blind fashion have also documented that some patients respond to carbamazepine, and they fail to respond to divalproex sodium (Depakote) (Fig. 33.10c–8B) or vice versa. These observations are consistent with the notion that response to the anticonvulsants does not occur as a class effect and that further elucidation of the clinical and biologic predictors of response to carbamazepine would be of great clinical importance.

It is noteworthy that within individual patients, there appears to be dose-related antimanic and antipsychotic responsiveness (Fig. 33.10c–8C). However, there is little evidence of a relationship between blood levels and the degree of clinical antidepressant or antimanic response across individuals (Fig. 33.10c–10).

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System

Typical of many anticonvulsant drugs, carbamazepine can exert a variety of untoward effects on CNS function. Most commonly, these include dizziness, ataxia, and diplopia (characteristically occurring approximately 2 hours after a given dose of the regular immediate-release formulation). These common side effects can largely be avoided with slow upward titration of the dose to just below a patient's side-effects threshold, which can vary greatly, as illustrated in Figure 33.10c–10. Given this wide range of individual proclivity to side effects (Fig. 33.10c–11) and the lack of a clear anticonvulsant dose–response relationship, the importance of individualizing dose titration is emphasized as preferable to attempting to achieve a set blood level within the conventional 4 to 12 μg/mL "therapeutic" window.

In overdose, carbamazepine produces drowsiness, stupor, coma, sinus tachycardia, atrial ventricular conduction blocks, hypotension or hypertension, seizures, nystagmus, and hyporeflexia or hyperreflexia. Hypothermia, oral dyskinesias, and respiratory depression can also occur, yet few fatalities have been reported even after ingestion of as high as 10 to 20 g of carbamazepine.

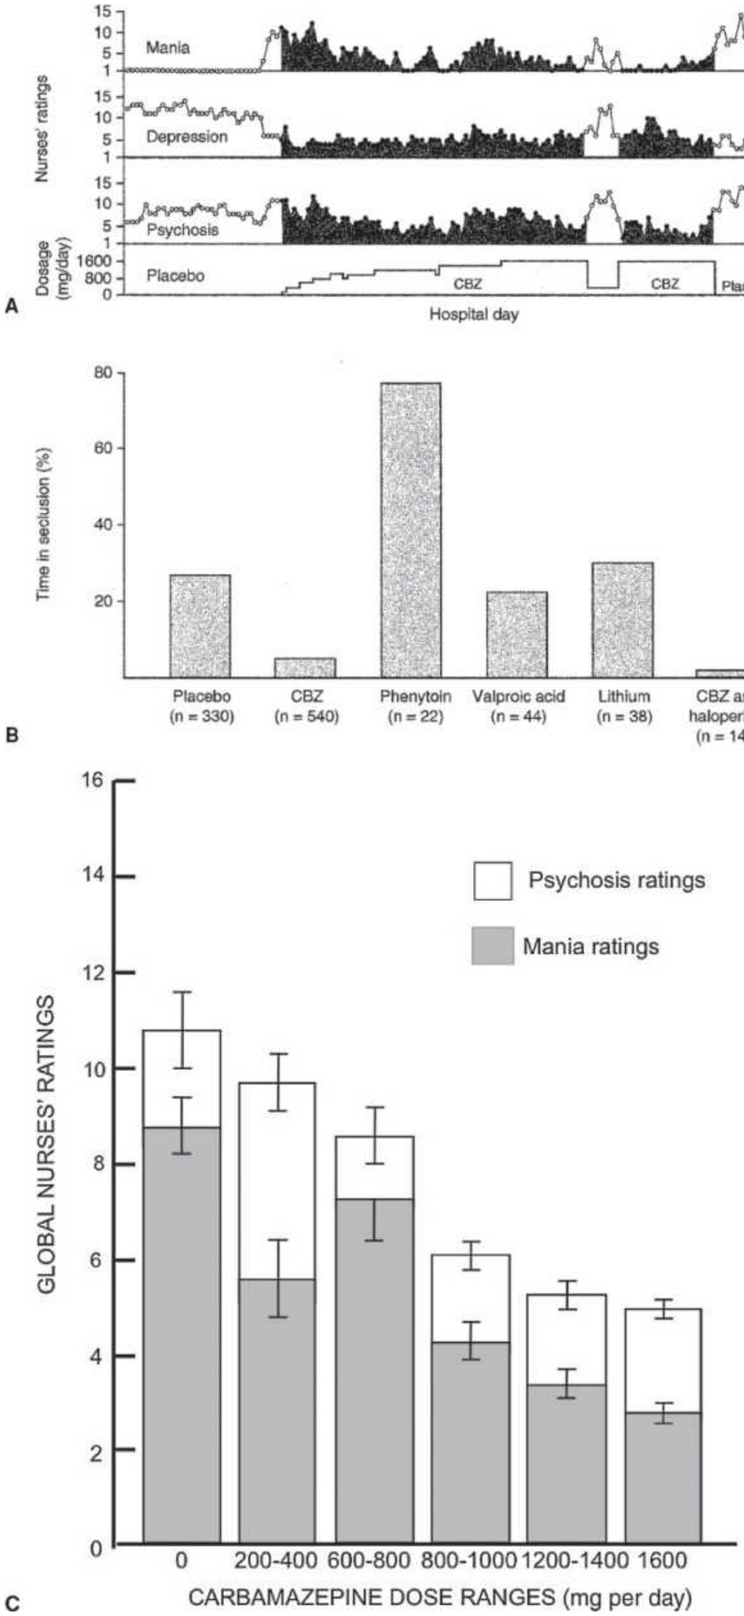

FIGURE 33.10c–8. Efficacy of carbamazepine (CBZ) in preventing manic and depressive episodes in a patient whose symptoms were previously refractory to lithium and antipsychotic treatment **(A).** CBZ administered on a blind basis

acutely suppressed manic and psychotic symptoms. During periods of CBZ dose reduction or placebo substitution, exacerbation of manic and psychotic symptoms was consistently noted and reinstitution of active CBZ treatment led to improvement on three different occasions. Each rating circle is one hospital day **(B).** The prophylactic effect of CBZ during double-blind, clinical trials in a treatment-refractory, rapidly cycling patient who required seclusion 26% of the time (based on each 24-hour day) while taking placebo or 30% of the time while taking lithium, but only 4% of the time while taking CBZ (*n* = 540 days) at doses greater than 800 mg per day. The patient was not responsive to two other antiepileptic drugs, phenytoin (seclusion 77%) or valproic acid (seclusion 22%), but did exceptionally well and rarely required seclusion (1.6%) while treated with the combination of CBZ and haloperidol. *n,* number of days in treatment. **C:** Dose-dependent therapeutic effects of carbamazepine during a prolonged manic episode in the same patient.

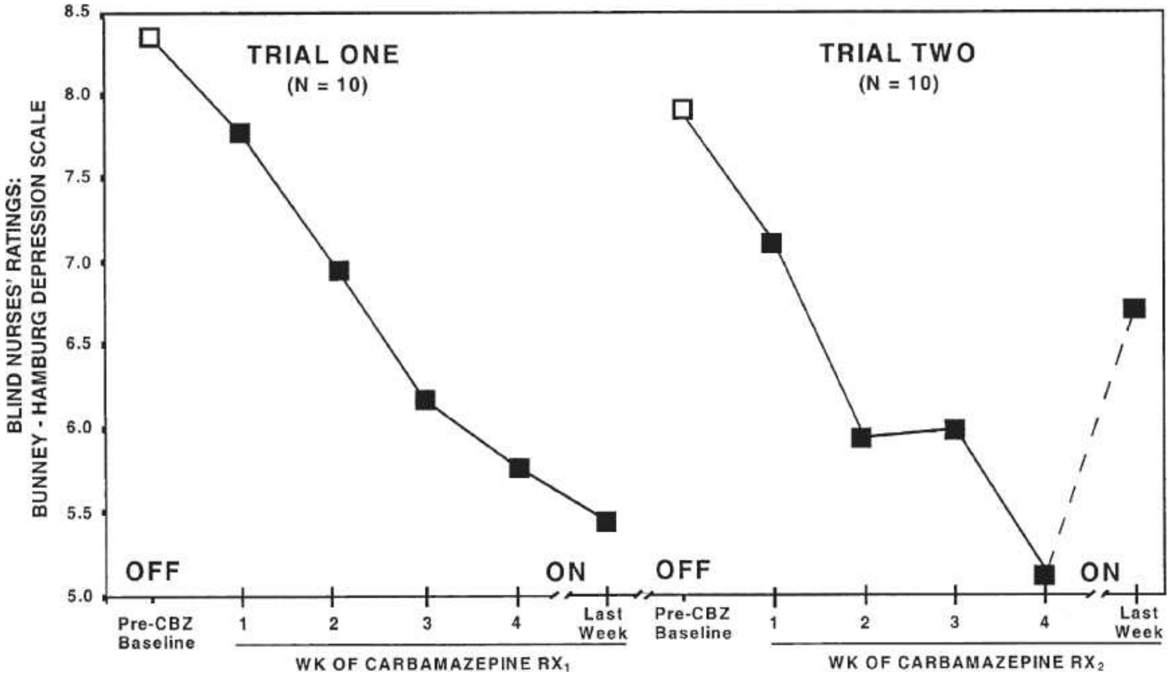

FIGURE 33.10c–9. Confirmation of antidepressant response to carbamazepine (CBZ) in an off-on–off-on design in a subgroup of ten treatment-refractory patients. Seventeen of the 54 depressed patients studied in a blind fashion (31.5%) showed an initial good response (≥2 points on the Bunney–Hamberg Depression scale).

In overdose, supportive techniques include gastric lavage and instillation of activated charcoal (10 to 100 g and then 12.5 g per hour) until the patient is symptom-free. Consideration of charcoal hemoperfusion before the patient becomes hypotensive has also been recommended. Although flumazenil (Ro 15–1788) has been recommended by some, the preclinical pharmacology noted above would not support such a suggestion. Instead, the GABA_A receptor partial inverse agonist Ro 15–4513, which has been shown to reverse alcohol intoxication and is also effective in reducing the sedation and lethality of carbamazepine overdose in rodents, should be considered.

Carbamazepine's effects on memory and psychomotor performance have generally been minor, and improvement in a few indices has even been reported during treatment. However, higher doses or those that exceed an individual's threshold for neurotoxicity can be associated with impairment. A similar range of side effects can occur with oxcarbazepine, although it is generally better tolerated than carbamazepine, with the exception of an increased incidence of hyponatremia (Fig. 33.10c–1).

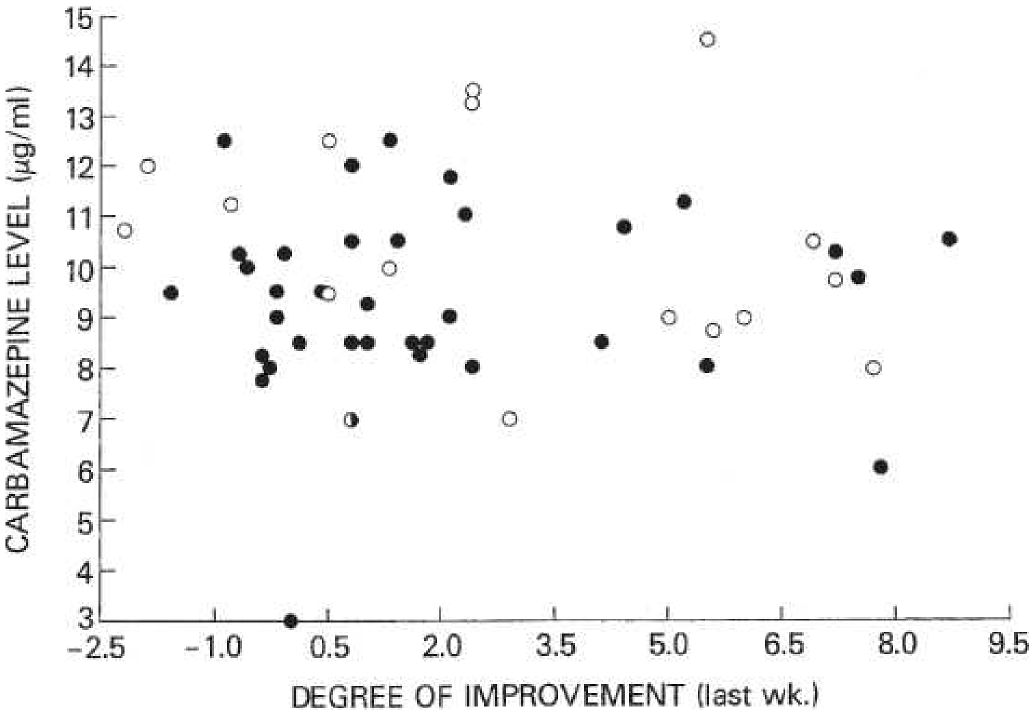

FIGURE 33.10c–10. The lack of relationship between plasma levels and degree of clinical improvement across patients in mania (*open circles*) or depression (*filled circles*).

Table 33.10c–5.
Possible Correlates of Carbamazepine Response to Treatment in the Affective Disorders

Depression

Greater acuity and severity

Low homovanillic acid levels in CSF

Higher epoxide/carbamazepine ratio

Greater decreases in thyroxine and free thyroxine decrease during carbamazepine treatment

Frontal and paralimbic (especially left insula) hypermetabolism on positron emission tomography

History of alcoholism

Comorbid posttraumatic stress disorder

Prophylaxis

Lack of family history of bipolar illness in first-degree relatives

Lack of prior rapid cycling

Nonclassical presentations:

Bipolar II, non-euphoric mania

Schizoaffective (especially depressive with mood incongruent delusions)

Substance abuse comorbidities

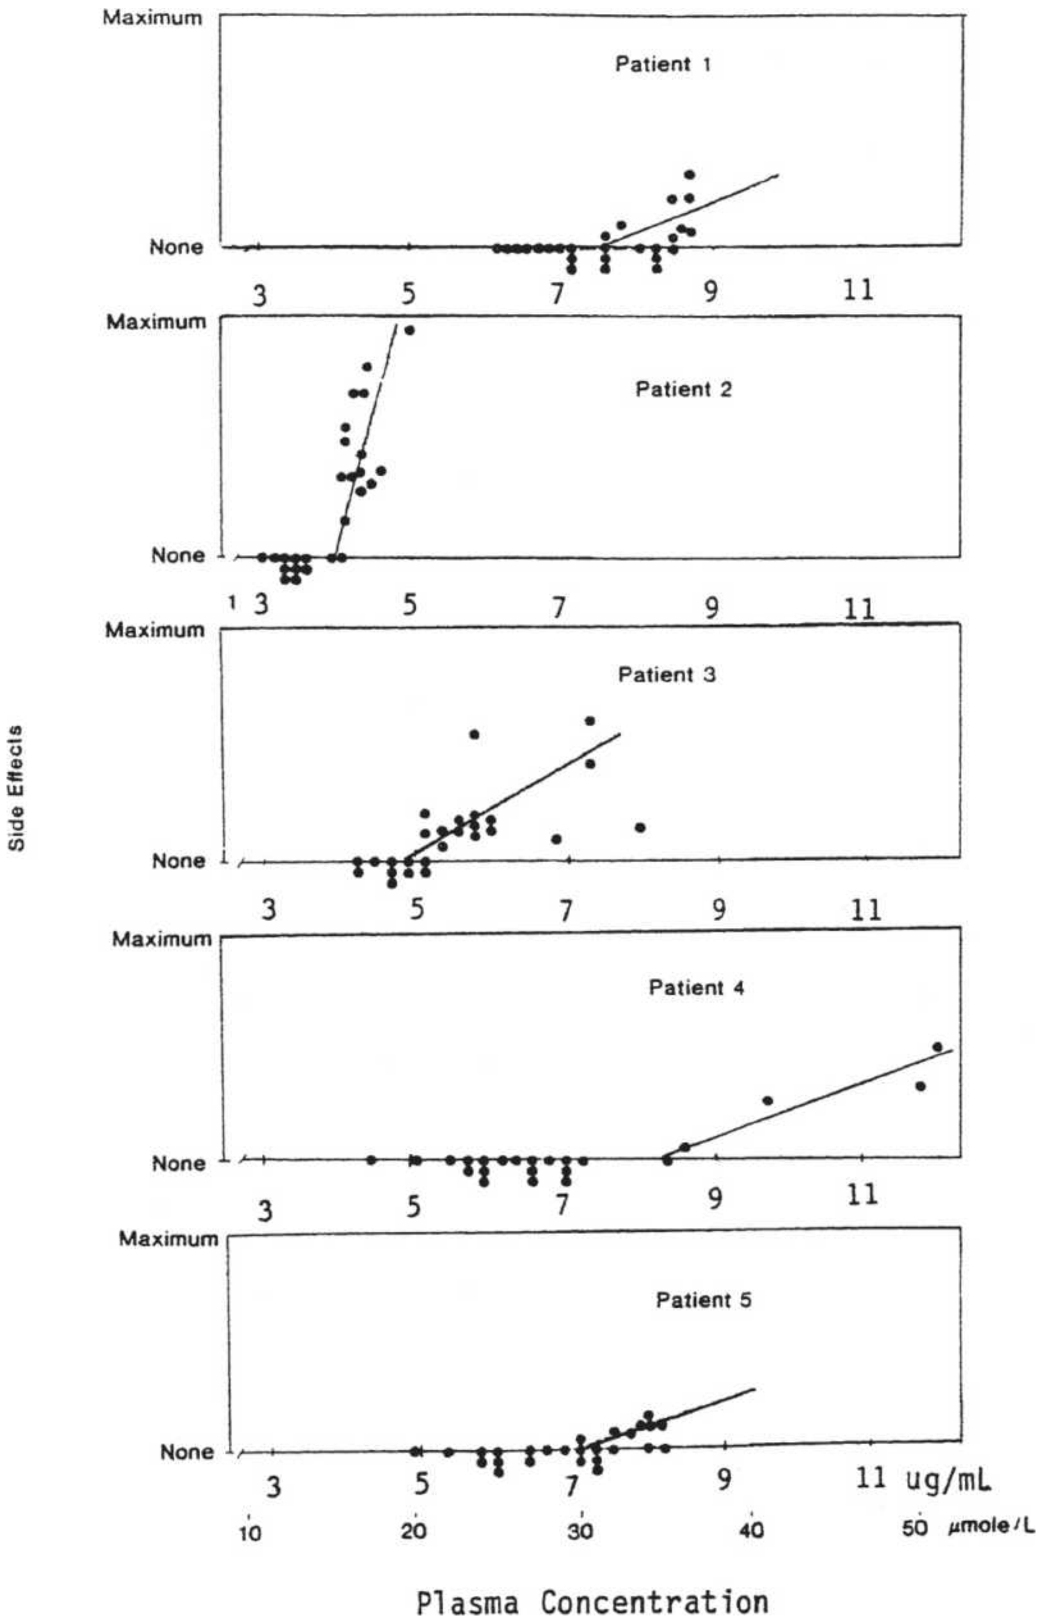

FIGURE 33.10c–11. The lack of relationship between carbamazepine concentrations and adverse effects emergence (i.e., highly individualized blood concentration to adverse-effects relationships exist within different

patients). (Adapted from Tomson T. Interdosage fluctuations in plasma concentration determine intermittent adverse effects. *Arch Neurol*. 1984;41(8):830–834. Copyright 1984, the American Medical Association.)

Table 33.10c–6.

Some Side Effects of Carbamazepine and Their Possible Management

Side Effect (Frequency, Type)	**Possible Approach (Strength of Evidence or Practice)**	**Comment**
Dizziness, ataxia, diplopia (C, D)	Reduce peak dose effects by ↓ dose (+ + +); switch to all HS sustained-release formulation (+)	Will occur 2–3 hours after IR dose if patient is near their side effects threshold (+ + +)
Fatigue, sedation (C, D)	Switch more of IR dose to HS (+ + +) or all of ER dose to HS (+); ↓ Dose or wait for adaptation or autoinduction (+ +)	Start with low HS dose; given wide individual variability in side effects threshold, titrate slowly to clinical effect or to side effects limitation (+ + +)
Benign rash (VC, I)	Discontinue drug (+); antihistamines (+); steroids (+)	Possible switch to oxcarbazepine, 2/3 no rash (+ +); or can restart CBZ slowly under coverage of prednisone (+ +)
Severe rash (R, I, S)	Discontinue drug (+ + +)	Obtain medical/dermatologic consultation (+ + +); re-challenge not recommended (even with steroids)
Benign WBC suppression (VC, D) vs. Agranulocytosis Aplastic anemia	Lower dose (+); add lithium (+ + +) Discontinue drug (+ + +) Discontinue drug (+ + +)	Lithium increases CSF (+ + +), whereas CBZ suppresses CSF (+ + +); 2,500–3,000 WBC lower limit of tolerability (±) Medical support and consultation required

		(+ + +) Medical support and consultation required (+ + +)
Weight gain (UC, I)	Consider topiramate or zonisamide augmentation (+ +) or switch to weight-neutral drug such as LTG, OXC (+)	Rarely a problem
Hyponatremia (O, D)	↓ Dose (+ +); add lithium (+ +); add demeclocycline (+ +)	Women, older age, and use of higher doses are vulnerability factors (+ + +)
Thyroid hormone suppression (VC, D)	None needed as ↓ T_4 may correlate with better response (+ +)	No ↑ TSH; no change BMR with CBZ (+); thyroid supplements rarely needed (+ + +); ↓ T_4 and ↓ T_3 may be addictive with lithium (+ +)
Tremor (R, D)	↓ Dose (+)	Check ammonia levels when combined with VPA if tremor is coarse or flapping (±)
Teratogenic (O, D) Spina bifida ≈1% Cranial facial abnormality	Pretreat with ↑ folate (+)	Avoid combination Rx if possible, especially with VPA (+); minor developmental delays do not persist
Hepatitis (R, I)	Discontinue if enzymes ↑ to three times normal (+ +) Discontinue if patient is symptomatic (+ + +)	
Memory disturbance	↓ Dose (+); switch to all	CBZ potentiation of

	HS with long-acting preparation (±)	vasopressin receptors may prevent memory loss (+/−)
High cholesterol	Treat with statins (+)	Switch to non-enzyme inducer (±)

C, common; CSF, colony stimulating factor; D, dose related; hs, at night; I, idiosyncratic; O, occasional; R, rare; S, sensitivity may cross to other antiepileptic drugs; T_3, triiodothyronine (liothyronine); T_4, thyroxine; UC, uncommon; VC, very common; WBC, white blood cell; ↑, indicates increase; ↓, indicates decrease; (+) likely works; (+ +) many case reports; (+ + +) well supported, controlled data; (±) questionable or hypothetical.

Blood

As summarized in Table 33.10c–6, the hematopoietic system is a major target of carbamazepine's benign and serious adverse actions. A statistically significant but usually clinically insignificant suppression of the white blood cell (WBC) count occurs in a substantial proportion of patients and is thought to be based on the drug's ability to inhibit colony-stimulating factor. Lithium enhances colony-stimulating factor and will reverse the benign WBC suppression of carbamazepine.

In contrast, the potentially life-threatening occurrence of agranulocytosis, pancytopenia, or aplastic anemia is a rare phenomenon and thought to occur in approximately 1 in 25,000 to 100,000 patients. Because of the rarity of these idiosyncratic events, many authorities recognize the inadequacy of routine blood count monitoring and suggest advising patients that, in the face of clinical signs of potential hematologic dysfunction (such as fever, sore throat, rash, petechiae, bruising, or overt bleeding), they should immediately contact their physician and obtain a complete blood cell count (CBC). It may be wise to monitor the CBC during the initial phases of carbamazepine administration so as to assess the degree of benign white count suppression or any evidence of more problematic changes, such as drops in platelet or red cell counts which deserve closer monitoring and attention.

In contrast to carbamazepine, the routine benign suppression of the WBC has not been reported with oxcarbazepine, and the incidence of more serious blood dyscrasias does not appear elevated over baseline.

Hormonal Effects

Carbamazepine increases the 24-hour excretion of urinary-free cortisol and notably induces a robust escape from dexamethasone suppression. These effects are thought to be not entirely related to heightened metabolism of steroid compounds (such as lowering of dexamethasone levels) and may suggest actions of carbamazepine that are contrary to those of more traditional antidepressants that downregulate the hypothalamic–pituitary–adrenal axis and increase glucocorticoid hormone receptors upon chronic administration. Whether this side effect of increasing cortisol could be clinically useful in the treatment of patients with PTSD who have abnormally low basal secretion of urinary free cortisol and show enhanced sensitivity to dexamethasone suppression compared with normal or depressed patients remains to be systematically explored.

Carbamazepine decreases circulating levels of thyroxine (T_4), free T_4, and triiodothyronine (T_3) without substantially altering thyroid-stimulating hormone. Studies indicate that it does not affect basal metabolic rate and that thyroid replacement is almost never required. In fact, patients with the largest decrements in T_4 or free T_4 showed the greatest degree of antidepressant response to carbamazepine in one series. For example, the degree of improvement in depression with carbamazepine was inversely related to the degree of decrease in free T_4 from baseline ($r = -0.56$; $N = 36$; $P = .0004$).

Renal Effects (Hyponatremia)

Carbamazepine has direct or indirect agonist-like effects at the vasopressin receptor, accounting for its occasional use in the treatment of diabetes insipidus. It will not reverse the lithium-induced variety of this syndrome, however. This carbamazepine-increased resorption of water predisposes patients to the development of hyponatremia and, in rare instances, water intoxication. Older adult patients, women, and those treated with high doses are more prone to this side effect. Several small case series suggest that carbamazepine-related hyponatremia can be prevented or reversed by the administration of lithium or demeclocycline (Declomycin).

Hyponatremia is the one area in which oxcarbazepine has a higher incidence of side effects than carbamazepine. Approximately 3% to 5% of patients treated with oxcarbazepine develop hyponatremia, and whether lithium or demeclocycline would be effective treatments is not known. The elimination half-life of oxcarbazepine is prolonged in those with renal impairment.

Skin

Carbamazepine can induce a variety of dermatologic syndromes—from a common benign macular papular pruritic rash typically emerging in the first 9 to 23 days after drug initiation to more serious conditions. Drug cessation usually results in regression of the rash, but, in rare instances, it can progress to exfoliative dermatitis, erythema multiforme, Stevens–Johnson syndrome (SJS), or toxic epidermal necrolysis (TEN). Given the inability to distinguish which rashes might evolve toward these serious endpoints, most clinicians recommend stopping the drug in the face of even the benign presentation of a carbamazepine-related rash, which can be expected to occur in some 5% to 15% of individuals. However, a substantial group of patients re-exposed to carbamazepine will not have a re-emergence of the rash. The rash rate may be lower with the new extended-release preparations.

In those individuals who appear to respond well to carbamazepine but no other agents, one can attempt to suppress the benign dermatologic reaction with prednisone (Cordrol) (40 mg per day). However, several case reports have indicated that, in the face of evidence of more serious systemic allergy (such as fever, lymphadenopathy, and pneumonitis), such steroid co-treatment may not be successful.

Oxcarbazepine appears to have a reduced frequency of inducing both the benign and serious forms of rash. Moreover, the majority of patients who have a rash on carbamazepine will not show a recurrence on oxcarbazepine, but approximately 25% to 30% will show such a cross-sensitivity.

Considerable progress has been made in studying the pharmacogenomics of serious rash (SJS/TEN) on carbamazepine. The human lymphocyte antigen (HLA-B*1502 has been associated with this syndrome in patients of Asian descent (including Han Chinese, Thai, Malaysian, Filipino, and Taiwan), where the frequency of HLA-B*1502 is about 10% to 15% in the general population. If one has this antigen, the odds ratio (OR) is 79.8. A direct interaction of HLA-B*1502 with cytotoxic T lymphocytes has been reported.

In contrast, in those of northern European descent, the risk of SJS/TEN is lower and of the order of 1 to 6 per 10,000 and is associated with HLA-A*3101 (which occurs in 2% to 5% of Europeans) with an OR of 25.9. Nine percent of Japanese have the HLA-A*3101, and it is associated with SJS/TEN OR = 10.8. In addition, preliminary evidence links HLA-B*1511 to severe rash in Japanese. There is some controversy about the clinical utility of doing these genetic screens for potential carbamazepine-treated patients, but the consensus is emerging that it would be worthwhile for those of Asian descent. In Thailand, the positive predictive value (PPV) was 1.92, while the negative predictive value (NPV) was 99.96.

There is another hypersensitivity syndrome (also called DRESS for drug reaction with eosinophilia and systemic symptoms) which occurs with a maculopapular rash (77%), increased liver enzymes (71%), eosinophilia (64.3%), fever (61%), lymphadenopathy (55%), and increased WBC (43%). Treatment with *N*-acetylcysteine (NAC) and/or intravenous immunoglobulin (IVIG) has anecdotally been reported effective, as has treatment without the use of steroids. In those with the CBZ-induced hypersensitivity syndrome, CBZ-specific CD4(+) and CD8(+) T cells have been shown to persist some years after the resolution of the syndrome.

Liver

Like other anticonvulsants, carbamazepine has been associated with enzyme elevations. However, the outright appearance of hepatitis is extremely rare. As with oxcarbazepine, routine monitoring does not appear indicated.

Carbamazepine increases total serum cholesterol by an average of 20 points. It increases both high- and low-density lipoproteins, such that deleterious cardiovascular effects have not been unambiguously demonstrated. However, in those at high risk, preventive treatment with statins may be indicated. Homocysteine increases and folate decreases have been reported, so treatment with folate may also be helpful. Vitamin D levels may also decrease on carbamazepine with or without associated increases in osteoporosis.

Weight

In epilepsy patients, long-term treatment with carbamazepine is associated with small degrees of weight gain, which are significantly less than those observed on valproate. Oxcarbazepine is reported to be weight neutral. Carbamazepine decreases plasma levels of ghrelin, which also decreases with obesity.

Heart

The cardiac effects of carbamazepine are generally not prominent, although the drug does decrease atrial-ventricular conduction and is relatively contraindicated in patients with heart block. Carbamazepine has been used to treat digitalis-induced arrhythmias, including ventricular tachycardia. Bradycardia and syncopal episodes have been reported in rare instances, with older adult women apparently at increased risk. Effects on blood pressure are typically minimal, and orthostatic hypotension is not a common accompaniment (as it is with several structurally related tricyclic antidepressants).

THERAPEUTIC INDICATIONS

Bipolar Disorder

Carbamazepine has been approved by the FDA for use in seizure disorders and trigeminal neuralgia. Like many treatments of bipolar disorder, carbamazepine is widely used in the treatment of acute mania and in long-term prophylaxis but is only FDA-approved as the long-acting preparation Equetro in acute mania. Carbamazepine is approved in many European countries, Japan, and Canada, however. It is considered a first- or second-line treatment in many guidelines and can be used as a substitute for lithium or as an adjunct to it for the partial responder (Table 33.10c–4). Use in combination with lithium appears especially helpful in rapid cyclers.

Oxcarbazepine is thought to have effects similar to carbamazepine, but these have not yet been documented in large placebo studies, and the drug is not FDA approved for bipolar illness. One study reported that overall, oxcarbazepine was no more effective than placebo in children with mania, although it did exceed placebo in the younger subgroup of children, but not in those with later adolescent-onset acute mania.

Carbamazepine can also be used in conjunction with unimodal antidepressants and antipsychotic agents, although several instances of drug–drug interactions are of some importance—for example, blood levels of nefazodone (Serzone), haloperidol, aripiprazole (Abilify), lurasidone

(Latuda), and quetiapine (Seroquel) and lamotrigine are substantially reduced. This would also occur with several of the newer atypical antipsychotics, including brexpiprazole (Rexulti), cariprazine (Vraylar), and lumateperone (Caplyta). Carbamazepine is not recommended for use in conjunction with the atypical antipsychotic clozapine (Clozaril) for fear of an additive risk of agranulocytosis, although the mechanisms for WBC suppression appear to differ. The use of carbamazepine in conjunction with valproate has not been as systematically explored in refractory mood disorders as it has in seizure disorders. The combination usually requires a decrease in the dose of carbamazepine (because valproate displaces carbamazepine from its protein-binding sites and also increases the levels of the 10,11-epoxide by virtue of its inhibition of the epoxide hydroxylase). Case reports show the efficacy of the combination of carbamazepine and valproate when either drug alone was not efficacious.

As antimanic effects are often observed within the first several days of treatment with carbamazepine, a several weeks trial in acute mania is usually sufficient to ascertain whether the patient is going to be a responder. Longer periods of evaluation may be required to assess its potential antidepressant efficacy, however. Exploration of its potential efficacy in long-term prophylaxis requires the observation of a consistent reduction of episode severity or the prevention of episodes for a duration several times longer than the previous usual “well interval.” Thus, the faster the cycling at baseline, the more rapid can be the assessment of prophylactic effectiveness.

Although 4 to 12 μg/mL has been identified as a therapeutic range for anticonvulsant effects, there is no relationship between blood levels to the degree of anticonvulsant, antimanic or antidepressant response. One study suggested that 1,200 mg per day was associated with an antimanic response, although trough serum levels of 8 to 12 μg/mL are generally associated with good anticonvulsant and antimanic effects (Fig. 33.10c–10).

However, there is very considerable variability in the relationship of blood levels to an individual’s threshold for and slope of the rate of rise of side effects. That is, some patients may begin to have considerable side effects at low blood levels of 4 ug/mL, while others may have no side effects at levels of 12 ug/mL. This indicates that in most instances, upward dose titration can be pursued as a function of clinical responsiveness and an absence of emergence of side effects rather than with close attention to blood level monitoring. If fact, most patients can be very well managed without blood level monitoring except in instances of unexpected toxicity, absence of effectiveness at high doses, or suspicion of noncompliance.

Schizophrenia and Schizoaffective Disorder

A series of double-blind studies with few exceptions have indicated that the addition of carbamazepine to antipsychotics is more effective than placebo, particularly in those patients with more florid positive symptoms and problems with aggression and dyscontrol. It does not appear useful as an adjunct in chronic, negative, symptom-prominent schizophrenia. Carbamazepine is helpful in schizoaffective disorder, particularly in depressed phases. One study suggested that, in contrast to carbamazepine, oxcarbazepine was less effective in those with more fulminant psychotic manic symptoms.

Impulse Control Disorders

A very substantial case series literature indicates that carbamazepine is highly effective in a wide range of aggressive syndromes and impulse-dyscontrol disorders that can manifest in those with diagnoses of borderline and other personality disorders, affective disorders, and schizophrenia. Its efficacy in these dyscontrol syndromes appears independent of the presence or absence of an associated EEG abnormality.

Other Disorders

Carbamazepine is as effective in acute alcohol withdrawal syndromes as diazepam, and it does not have the abuse liability of benzodiazepines. Greater anxiolytic and global distress decreases have also been reported in withdrawing alcoholics treated with carbamazepine compared with benzodiazepines. In addition, placebo-controlled prophylactic studies of alcohol dependence have suggested greater relapse prevention of heavy drinking with carbamazepine. Although carbamazepine inhibits the development of cocaine-kindled seizures and their associated lethality in rodents, controlled clinical studies in cocaine abusers did not indicate that it is more successful in maintaining abstinence or drug-free urine than placebo, except in a subgroup with a concomitant mood disorder.

Open studies suggest the potential use of carbamazepine in the treatment of PTSD, particularly the paroxysmal recurrent components and the associated sleep disorder. Isolated case reports, but no controlled clinical trials, indicate its adjunctive use in other anxiety disorders and in OCD.

PRECAUTIONS AND ADVERSE REACTIONS

The *Physicians' Desk Reference* indicates that aplastic anemia and agranulocytosis occur in conjunction with the use of carbamazepine at a rate five to eight times greater than that in the general population. That incidence is approximately 6 patients per 1,000,000 of the population per year for agranulocytosis and 2 patients per 1,000,000 population per year for aplastic anemia. If, in the course of treatment, a patient exhibits low or decreased WBC or platelet counts, that individual should be monitored closely in the face of stable, benign WBC suppression; the usual minimum safe total WBC count is approximately 3,000 and absolute neutrophil count approximately 1,000 to 1,500 neutrophils/mm^3. The addition of lithium may be sufficient to reverse the benign WBC suppression of carbamazepine based on their opposite effects on stimulating or inhibiting colony-stimulating factor. However, if there is a concomitant suppression of the red cell or platelet series or other indications of bone marrow depression, carbamazepine should be stopped immediately.

Carbamazepine will increase the metabolism of estrogen in birth control formulations, resulting in occasional unwanted pregnancies. Therefore, a higher dosage form of the estrogen component or other contraceptive devices should be used.

FIGURE 33.10c–12. Carbamazepine (CBZ) metabolism. *Bottom left:* Drugs that inhibit cytochrome P450 increase CBZ. ++, drugs that decrease the level of the active metabolite carbamazepine through induction of its oxidative metabolic pathway cytochrome P450; +, drugs that decrease the level of the active metabolite carbamazepine-10, 11-epoxide (CBZ-E) through induction of the epoxide hydroxylase and production of the inactive dihydroxy metabolite (CBZ-D); −, drugs that increase the level of carbamazepine-10,11-epoxide through blockade of the epoxide catabolism. Drug names in capital letters indicate common or more important interactions.

Carbamazepine is a category D drug and should be avoided during pregnancy. There is a several percentage risk of spina bifida with the use of carbamazepine, and this appears to increase with anticonvulsant combination treatment. In one series, carbamazepine was reported to decrease the head size and body length, although the developmental lag was completely compensated for after a period of several months. Although carbamazepine and its epoxide metabolite are transferred to breast milk during lactation, their concentrations are approximately 50% of those in maternal plasma. There are no adequate studies of the clinical effects of oxcarbazepine in pregnant women; given its similar structure to carbamazepine and evidence of problems in animal studies, one might consider it to be teratogenic in humans until more systematic data to the contrary are acquired.

DRUG INTERACTIONS

In contrast to oxcarbazepine, carbamazepine is a potent inducer of cytochrome P450 oxidase enzymes, particularly of the 3A4 category. This leads to its own autoinduction after 2 to 3 weeks, as well as a reduction in the levels of a variety of other compounds listed in Table 33.10c–2.

If a patient is switched from carbamazepine to oxcarbazepine, deinduction of the 3A4 enzyme should be expected, and substances that had their levels reduced by carbamazepine may show increases. This is particularly important for lamotrigine, as carbamazepine approximately halves lamotrigine levels, and substantial increases in lamotrigine levels would occur with carbamazepine discontinuation. This could also occur with dicumarol and warfarin (Coumadin), increasing proclivity for excess anticoagulant activity and increased bleeding.

Of potential importance for the generation of carbamazepine's toxicity are a series of agents that inhibit either cytochrome oxidase 3A4 or the epoxide hydroxylase, as schematized in Figure 33.10c–12. Many commonly used agents markedly increase blood levels of carbamazepine (Table 33.10c–7). These include the antibiotic erythromycin and all of its related congeners, as well as the calcium channel blockers verapamil (Verelan) and diltiazem (Cardizem), but not nifedipine (Adalat), nimodipine, or amlodipine (Norvasc). The antituberculosis drug isoniazid (Nydrazid) will also markedly increase carbamazepine levels, but more minor effects are observed with dextropropoxyphene (Darvon), fluoxetine (Prozac), and nicotinamide (Nicomide), and minimal effects occur with cimetidine (Tagamet).

Table 33.10c–7.
Drugs That Increase Concentrations of Carbamazepine

Drug Class	Drug
Antidepressants	Fluoxetine, flavoxamine, nefazodone[a,b]
Antiepileptics	Valproate (increases CBZ-10, 11-epoxide[c])
Antimicrobials	Isoniazid[d], quinupristin/dalfopristin
Ca^+ channel blockers	Diltiazem[c], verapamil[c,d], (but not nifedipine or nimodipine)
Lipid active	Gemfibrozila, nicotinamide[a]
Macrolide antibiotics	Clarithromycin[c,d], erythromycin[c,d], flurimycin[c,d], josamycin[c,d], midecamycin acetate, ponsinomycin[c,d], troleandromycin, triacetyleandronyion[c,d]
Anti-HIV	Delavirdine[c,d], ritonavir[c,d]
Others	Acetazolamide[a], cimetidine[a], danazol, delavirdine[c,d], dextropropoxyphene[a], gestodene[b], mifepristone, omeprazole[a], ticlopidine[a]

[a] Weak effect.

[b] Mild to moderate.

[c] Potential for toxicity.

[d] Important or severe.

Table 33.10c–8.
CBZ in Bipolar Illness: A Brief Users Guide

Start with low (200 mg) H.S. doses in depression, euthymia; higher doses (600–800 mg/day in nighttime and divided doses) in manic inpatients.
All H.S. dosing is reasonable with CBZ ER (Equetro) preparation.
Titrate slowly to an individual's response or side effects threshold (as there is no correlation with blood levels and degree of response).
Hepatic enzyme CYP 450 (3-A-4) induction and autoinduction occurs in 2–3 weeks; slightly higher doses of CBZ may be needed/tolerated at that time.
Employ adequate birth control methods, including higher-dosage forms of estrogen (as CBZ will lower estrogen levels).
Major increases in CBZ blood levels and potential toxicity are caused by erythromycin, verapamil, isradipine.
Warn regarding benign rash 5–10%; rare progression to severe rash, so drug should be discontinued. HLA-A*3101 predicts severe rash in northern Europeans and Japanese. HLA-B-1502 predicts in those of Asian descent.
Benign WBC decreases occurs regularly (and are usually inconsequential). Lithium will prevent or reverse these.
Rare agranulocytosis and aplastic anemia (several per million new exposures); warn regarding appearance of fever, sore throat, petechiae, bleeding gums, and to check with physician to obtain immediate CBC.
Avoid CBZ in pregnancy: Spina bifida 0.5%; other adverse outcomes about 8%.
Some people will response well to CBZ and no other mood stabilizers (lithium) or anticonvulsants (VPA).
Combination treatment often required to maintain remission and prevent loss of effect via tolerance.

H.S., nighttime or hours of sleep.

There are fewer drug–drug interactions of importance for oxcarbazepine. However, strong inducers of cytochrome P450 enzymes (such as carbamazepine) decrease plasma levels of the monohydroxy derivative metabolite by 29% to 40%. As noted in Table 33.10c–1, there is no autoinduction, and few major drug–drug interactions have been reported. However, oxcarbazepine reduces estrogen levels in oral contraceptives, and its use, as with carbamazepine, will necessitate higher dosage forms or alternative contraceptive devices.

The use of carbamazepine fell off in the 1990s after a decade of considerable use in the 1980s. One reason was the advent of valproate and the notion that it was easier to use. However, now that it is clear that some patients are relatively selective responders to carbamazepine, it becomes increasingly important to demystify some of the important details about its use. A primer employing a dozen key principles is included in Table 33.10c–8.

33.10d Lamotrigine

ROBERT M. POST, M.D.

Neuroscience-Based Nomenclature (NbN)	
Glutamate channel blocker	
Pharmacologic Domain	Glutamate
Mechanism of Action	Voltage-gated sodium channel blocker

HISTORY

Lamotrigine (Lamictal) was developed as a result of screening folate antagonists as anticonvulsants. The observations that folates could produce seizures in animals and some anticonvulsants such as phenytoin (Dilantin) and phenobarbital (Solfoton) could impair folate metabolism led to the hypothesis that folate antagonists could be anticonvulsants. Further research has failed to establish antifolate as a treatment for epilepsy in humans, and lamotrigine also appears to lack clinically significant antifolate effects in humans. Nevertheless, lamotrigine did prove effective in several animal models of epilepsy. Burroughs Wellcome (later Glaxo Wellcome and currently GlaxoSmithKline) developed lamotrigine as an antiepileptic drug, and it was marketed for the adjunctive treatment of partial seizures in the United States in 1995.

Initial, postmarketing, open, clinical experience suggested efficacy, coupled with generally good tolerability (aside from the risk of rash), in a variety of neurologic and psychiatric conditions. Later double-blind, placebo-controlled studies revealed that lamotrigine was useful for some of the neurologic and psychiatric conditions suggested in open studies. Lamotrigine demonstrated efficacy and was approved for maintenance treatment of bipolar I disorder in 2003, with effects more robust in preventing depression than mania. Lamotrigine also had some efficacy in acute bipolar depression, but the magnitude of the effect was only modest. Limited data also suggested lamotrigine had potential utility in rapid cycling bipolar disorder. However, lamotrigine did *not* receive approval for the treatment of acute bipolar depression or rapid cycling bipolar disorder. Lamotrigine was *not* effective as the main intervention in acute mania. In summary, lamotrigine emerged as an agent that appears to “stabilize mood from below,” such that it may maximally impact the depressive component of bipolar disorders and have some mood-stabilizing effects as well.

CHEMISTRY

Lamotrigine, 3,5-diamino-6-(2,3-dichlorophenyl)-*as*-triazine, is a structurally novel phenyltriazine anticonvulsant (Fig. 33.10d–1). Three oral lamotrigine preparations are currently available in the United States: 25-, 100-, 150-, and 200-mg immediate- or extended-release tablets; 50-, 250-, and 300-mg extended-release tablets; and 2-, 5-, 25-, 50-, 100-, and 200-mg chewable dispersible tablets. By mid-2016, generic formulations of all of the above (with the exception of the 2- and 5-mg chewable dispersible tablets) were available.

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Lamotrigine has an oral bioavailability of about 98% and linear kinetics that are not significantly altered by food. Lamotrigine is 55% bound to plasma proteins and has a moderate volume of distribution of about 1 L/kg. A large percentage (approximately 85%) of lamotrigine is conjugated to yield inactive glucuronide metabolites, with only about 10% excreted unchanged in the urine. In monotherapy, its half-life is around 28 hours and clearance is about 40 mL per minute.

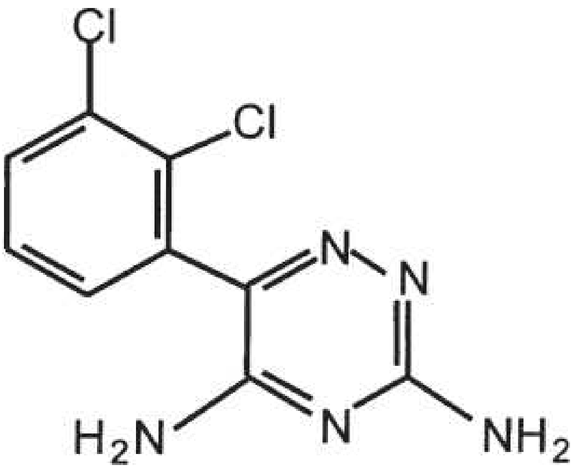

FIGURE 33.10d–1. Molecular structure of lamotrigine.

Combined with hepatic enzyme inducers such as carbamazepine (Tegretol, Equetro) or phenytoin (Dilantin), lamotrigine's half-life falls about 50% to approximately 14 hours and clearance doubles to approximately 80 mL per minute. Estrogen-containing hormonal contraceptives also induce lamotrigine metabolism.

Combined with the enzyme inhibitor valproate (Depakote), lamotrigine's half-life doubles to approximately 56 hours and clearance falls approximately 50% to around 20 mL per minute. Thus, in patients with epilepsy, immediate-release lamotrigine is given in two divided doses unless valproate is present, which may allow single daily dosing. In bipolar disorder patients where stable blood levels are less critical, single daily dosing of immediate-release lamotrigine is used unless an enzyme inducer (such as carbamazepine [Tegretol]) is present in which case two divided doses are recommended. An extended-release formulation of lamotrigine has been approved for once-daily administration in patients with epilepsy but not bipolar disorder. Lamotrigine clearance is decreased with hepatic insufficiency, which may necessitate decreased dosage. Clearance is decreased to a lesser extent with renal insufficiency, but dosage decreases may still be needed.

Pharmacodynamics

Like other anticonvulsants, lamotrigine has multiple biochemical actions, and the relationships between these and clinical effects remain to be established. Lamotrigine blocks voltage-sensitive sodium channels, modulating the release of the excitatory amino acids glutamate and aspartate, and may have more limited effects on calcium channels.

Lamotrigine also weakly blocks 5-HT_3 serotonergic receptors, has weak effects at σ-opioid receptors, and modestly inhibits serotonin uptake in human platelets and rat brain synaptosomes and noradrenaline and dopamine uptake in rat brain synaptosomes. In contrast, lamotrigine does not bind with high affinity to GABAergic, NMDA, glutamatergic, adrenergic, 5-HT_2 serotonergic, dopaminergic, cholinergic, histaminergic, adenosinergic, or κ-opiate–binding sites, and does not affect dihydropyridine calcium channels. Although lamotrigine inhibits dihydrofolate reductase in vitro, it does not appear to have clinically significant antifolate effects in humans.

Lamotrigine has antiseizure activity in maximal electroshock, pentylenetetrazol, amygdala-kindled, and other animal models of seizures; cerebroprotective actions in several animal models of ischemia; analgesic effects in animal models of neuropathic pain; and activity in the conflict animal model of anxiety. It is noteworthy that lamotrigine, like carbamazepine, does not block the initial stages of the development of amygdala-kindled seizures, while it is highly effective in inhibiting the middle phase of fully developed kindled seizures. Like carbamazepine, repeated administration of lamotrigine against fully kindled seizure results in tolerance development. This contingent tolerance phenomenon depends on the drug being present at the time of amygdala stimulation and can be reversed by a period of time when seizures are induced in the absence of the drug. There are some clinical observations that a similar tolerance process could develop in the long-term prevention of affective episodes.

Lamotrigine blood concentrations are not systematically related to antiseizure effects or efficacy in bipolar disorders.

CLINICAL DRUG STUDIES

Seizure Disorders

Immediate-release lamotrigine monotherapy appeared effective in a multicenter, double-blind controlled study of converting adults with partial seizures taking carbamazepine, phenytoin, phenobarbital, or primidone monotherapy to lamotrigine monotherapy. In a single study with a less rigorous methodology, extended-release lamotrigine monotherapy also appeared effective for conversion to monotherapy in adolescents and adults with partial seizures. Adjunctive immediate-release lamotrigine appeared more effective than adjunctive placebo in three multicenter, double-blind, placebo-controlled trials in adults with refractory partial seizures; in one multicenter, double-blind, placebo-controlled trial in pediatric (age 2 to 16 years) partial seizure disorder patients; another in adult and pediatric (age 3 to 25 years) patients with Lennox–Gastaut syndrome; and in pediatric and adult patients with primary generalized tonic–clonic seizures. Extended-release adjunctive lamotrigine appeared effective for primary generalized tonic–clonic seizures and partial-onset seizures in adolescents (age ≥13 years) and adults.

Pain Syndromes

Lamotrigine may have analgesic effects, as it was effective in placebo-controlled studies of post-transurethral prostatectomy pain, central poststroke pain, and HIV painful distal sensory polyneuropathy. However, in placebo-controlled studies, lamotrigine had inconsistent efficacy in diabetic neuropathy and was ineffective in neuropathic pain and spinal cord injury pain.

Other Neurologic Disorders

Although open reports were encouraging, a double-blind, placebo-controlled study failed to show benefits for migraine. Lamotrigine was also ineffective in placebo-controlled studies in amyotrophic lateral sclerosis, Huntington disease, and Parkinson disease.

Bipolar Disorders

In two 18-month multicenter, randomized, double-blind, placebo-controlled trials (one after depressive episodes, one after manic, or hypomanic episodes), both lamotrigine and lithium, compared with placebo, delayed time to intervention for any mood episode in bipolar I patients. Lamotrigine mood prophylaxis effect was driven by a more robust delay of depression, so lamotrigine was predominantly effective against depressive relapse. Lithium mood prophylaxis was driven by a more robust delay of mania, so lithium was predominantly effective against mania.

Although an early double-blind, placebo-controlled study suggested that lamotrigine monotherapy had some efficacy in the acute treatment of bipolar depression (based on a secondary outcome measure), four subsequent trials were negative. However, a meta-analysis including all five controlled trials suggested a statistically significant but only clinically modest efficacy in acute bipolar depression. One double-blind, placebo-controlled, industry-sponsored study suggested that the olanzapine (Zyprexa) plus fluoxetine (Prozac) combination compared to lamotrigine monotherapy had modestly superior efficacy for acute bipolar depression but also more adverse effects. A small controlled trial suggested that adjunctive lamotrigine compared to adjunctive risperidone (Risperdal) might have utility in bipolar disorder patients who remained depressed despite taking a mood stabilizer plus an antidepressant.

In treatment-resistant (primarily rapid cycling bipolar) mood disorder inpatients, about 50% responded to lamotrigine monotherapy, compared to only about 25% with gabapentin (Neurontin) monotherapy or placebo. Moreover, in patients who were responsive to lamotrigine in the first randomized phase, the response was again confirmed in a blind re-exposure to lamotrigine, such that antidepressant effects were affirmed by the initial increased percent response and by a renewed response to a second exposure.

In a less treatment-resistant community sample of patients with bipolar disorder and a rapid cycling course of illness, lamotrigine monotherapy appeared more effective than placebo bipolar II disorder, but not bipolar I disorder. Added to lithium, adjunctive lamotrigine was superior to placebo in acute bipolar depression and also appeared to provide continued benefit in longer-term treatment. Adding lamotrigine to quetiapine also yielded acute and longer-term benefits in patients with quetiapine-resistant bipolar depression. However, in that study, a subgroup that was treated with adjunctive folate surprisingly did not show a significant effect compared to those not treated with folate. Lamotrigine monotherapy has not been shown efficacious in controlled studies of acute mania. In summary, these controlled studies support the notion that lamotrigine may “stabilize mood from below” in the sense that it may impact the depressive more than the manic component of bipolar disorders. Although lamotrigine is not FDA-approved for acute bipolar depression, the meta-analysis of the four RCTs, the superiority of gabapentin and placebo, and its efficacy as an adjunct to both lithium and quetiapine provide substantial evidence of its efficacy for acute as well as a preventive treatment of bipolar depression.

Family history may offer hints to the effectiveness of the mood stabilizers. While lithium is more effective in those with a positive family history of mood disorder, carbamazepine appears more effective in those without a positive family history of bipolar disorder. In contrast, lamotrigine appears to have good responses in those with a family and personal history of anxiety disorders. As comorbid anxiety disorders are a consistent predictor of a poor response to lithium, lamotrigine, and other mood-stabilizing anticonvulsants valproate and carbamazepine may offer better effects in this large subgroup of patients with bipolar disorders.

Major Depressive and Other Disorders

There are fewer studies with mixed results suggesting lamotrigine efficacy in (unipolar) major depressive disorders. In controlled studies, chronic lamotrigine was no better than placebo in children with autism or adults with depersonalization disorder and was only numerically but not statistically superior to placebo in adults with PTSD. In hospitalized treatment-resistant schizophrenia patients on clozapine (Clozaril), adding lamotrigine compared to placebo reduced general psychopathologic and positive (but not negative) symptoms. A subsequent similar trial of adding lamotrigine to antipsychotics failed to replicate this in the primary (last observation carried forward) analysis but was positive in a post hoc observed case analysis. Interestingly, in a small controlled trial, lamotrigine appeared superior to placebo in the treatment of anger in women with borderline personality disorder. Lamotrigine was also superior to adding a placebo to SSRI treatment for obsessive-compulsive disorder. A small controlled study in patients with obesity suggested that lamotrigine compared to a placebo might yield modestly greater decreases in BMI, but not weight.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Lamotrigine has been associated with common benign rashes, uncommon serious rashes, and rare hypersensitivity reactions (see Precautions below). Lamotrigine binds to melanin-containing tissues and thus has the potential to accumulate in the eyes. However, to date, lamotrigine has not been associated with ocular problems.

THERAPEUTIC INDICATIONS

Seizure Disorders

Immediate-release lamotrigine is indicated as an adjunctive treatment for adults and children over age 2 years with partial seizures and for pediatric (over age 2 years) and adult patients with Lennox–Gastaut syndrome. It is also approved for conversion to monotherapy in adults with partial seizures who are receiving valproate or a single enzyme-inducing antiepileptic drug such as carbamazepine, phenytoin, phenobarbital, or primidone in patients ≥16 years old. Extended-release lamotrigine is indicated in adolescents and adults as adjunctive therapy for primary generalized tonic–clonic seizures and partial-onset seizures, as well as for conversion to monotherapy in patients with partial seizures who are taking a single anticonvulsant.

Bipolar Disorders

Lamotrigine is indicated for the maintenance treatment of bipolar I disorder to delay the time to occurrence of mood episodes in patients treated for acute mood episodes with standard therapy. Limited controlled data suggested lamotrigine might have at least some efficacy in the acute treatment of bipolar depression and in rapid cycling bipolar disorder. In view of such data, lamotrigine was considered to be an important treatment option for bipolar maintenance treatment and acute bipolar depression in the 2013 revision of the Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders' update of the CANMAT guidelines for the management of patients with bipolar disorder. However, as of late 2021, lamotrigine continued to lack FDA approval for the treatment of acute bipolar depression or for bipolar II prophylaxis, where its spectrum of greater efficacy in depression and mania prevention would suggest utility for this condition.

PRECAUTIONS AND ADVERSE REACTIONS

The prescribing information for lamotrigine includes a boxed warning due to the risk of serious rashes (including Stevens–Johnson syndrome) requiring hospitalization and discontinuation of treatment. The incidence of serious rashes was estimated in 1997 to be 1% in prospectively monitored pediatric (age less than 16 years) and 0.3% in premarketing clinical trials of adult patients. Rare cases of toxic epidermal necrolysis and rash-related death have been reported, but numbers are too few to allow precise estimates of rates.

Other than age, possible factors increasing the risk of serious rash include increasing lamotrigine doses too quickly, concurrent administration of valproate (which doubles lamotrigine blood concentrations), and exceeding the recommended initial lamotrigine dose or the rate of lamotrigine dose escalation. Nearly all life-threatening rashes have occurred between 2 and 8 weeks after lamotrigine initiation, but isolated cases have been reported after prolonged treatment. If patients do not take lamotrigine for 5 days or more (approximately five times the half-life of lamotrigine), the drug needs to be reintroduced according to the gradual initial escalation regimen, as serious rashes can occur with rapidly restarting the medication.

Benign rashes can occur in as many as 10% of patients taking lamotrigine, and the prescribing information recommends that lamotrigine be ordinarily discontinued at the first sign of rash unless the rash is clearly not drug related. Thus, any rash in a patient on lamotrigine requires immediate evaluation. Some clinicians report that “dermatology precautions” and initial titration even slower than that described in the prescribing information may decrease the rate of benign rash.

Dermatology precautions include not starting lamotrigine within 2 weeks of having a rash, viral syndrome, or vaccination. It is advised during the first 3 months on lamotrigine to avoid ingesting other new medicines or new foods or utilizing new cosmetics, conditioners, deodorants, detergents, or fabric softeners or developing sunburn or poison ivy/oak exposure. However, the utility of these dermatology precautions was not confirmed in a controlled study. The utility of initial titration, even slower than that described in the prescribing information, is widely practiced but remains to be established in a controlled study.

Any patient developing a rash accompanied by eye, mouth, or bladder discomfort, fever, or lymphadenopathy should go immediately to the emergency room for dermatologic assessment as such symptoms could herald the onset of a serious rash. Rashes with more benign presentations require medical evaluation as soon as possible (and before taking the next dose of lamotrigine) for assessment of the risk of continuing lamotrigine treatment. Rare hypersensitivity reactions with multiorgan failure/dysfunction have been reported so that patients who develop fever or lymphadenopathy require emergent evaluation. Rare blood dyscrasias have been reported. In view of the potential risk of withdrawal seizures in patients with epilepsy, lamotrigine should be tapered over a period of at least 2 weeks unless safety concerns require more rapid lamotrigine discontinuation. Stopping lamotrigine immediately for a rash in patients with affective disorders would appear prudent.

With the exception of the risk of rash, lamotrigine is generally well tolerated. Although transient difficulties with headache may be encountered during the initiation phase, other difficulties such as sedation, neurocognitive adverse effects, sexual problems, or weight gain are not typically seen.

The most common lamotrigine adverse effects during dose escalation (added to standard therapy) phase in adult bipolar disorder patients were headache, rash, dizziness, diarrhea, dream abnormality, and pruritus. In the lamotrigine monotherapy phase in maintenance treatment studies in adult bipolar disorder patients, the most common adverse effects were nausea, insomnia, somnolence, back pain, fatigue, rash, and rhinitis, and the adverse effects most commonly leading to discontinuation were rash and manic/hypomanic/mixed mood symptoms.

In late 2008, the FDA announced a class warning regarding increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders for lamotrigine as well as 10 other anticonvulsants (carbamazepine, felbamate [Felbatol], gabapentin [Neurontin], levetiracetam [Keppra], oxcarbazepine [Trileptal], pregabalin [Lyrica], tiagabine [Gabitril], topiramate [Topamax], valproate, and zonisamide [Zonegran]). In the FDA’s analysis, anticonvulsants compared to placebo yielded approximately twice the risk of suicidality (0.43% vs. 0.22%). The relative risk for suicidality was higher in the patients with epilepsy compared to psychiatric disorders, suggesting that the risk in psychiatric patients was quite small. Acute oral overdoses of lamotrigine up to 15 g have caused central nervous system and cardiac adverse effects, and some have been fatal.

Lamotrigine was classified as pregnancy category C. Limited initial data suggested the possibility of a modest association between lamotrigine and cleft lip or palate, but this has not been replicated in later studies. Specifically, the North American Antiepileptic Drug Registry found a higher risk of oral cleft, which was not found in other pregnancy registries. Lamotrigine is excreted in breast milk, considered “unsafe” for lactation, and thus is contraindicated with breastfeeding.

DRUG INTERACTIONS

Lamotrigine is mainly metabolized by glucuronidation with minimal involvement of oxidative metabolism and is primarily a target rather than an instigator of drug–drug interactions. Thus, enzyme inducers such as carbamazepine, phenytoin, phenobarbital, primidone (Mysoline), rifampin (Rifadin), and estrogen-containing (but not progesterone) hormonal contraceptives can decrease blood lamotrigine concentrations by 40% to 50%. The carbamazepine derivatives, oxcarbazepine (Trileptal), and eslicarbazepine acetate (Aptiom) appear to less robustly decrease lamotrigine levels (so that dosage adjustment of lamotrigine administered with these agents is not recommended). The enzyme inhibitor valproate approximately doubles blood lamotrigine concentrations. Also, sertraline (Zoloft) may increase lamotrigine levels.

Lamotrigine appears to have at most modest effects on the pharmacokinetics of other drugs. For example, lamotrigine can yield modest (25%) decreases in valproate levels. Although lamotrigine can exacerbate the neurotoxic effects of carbamazepine, this may be due to a pharmacodynamic interaction, as only equivocal evidence suggests that lamotrigine could increase levels of the epoxide metabolite of carbamazepine. Lamotrigine does not alter lithium pharmacokinetics, which is important, given lamotrigine’s utility in bipolar disorders. Lamotrigine does not appear to have clinically significant drug interactions with clozapine, olanzapine, risperidone, or aripiprazole, although a therapeutic drug monitoring database study suggested that lamotrigine might decrease quetiapine concentrations. Lamotrigine does not appear to have clinically significant antifolate effects in humans, although folate may interfere with the benefit of adding lamotrigine to quetiapine.

LABORATORY INTERFERENCES

Lamotrigine has not been associated with interference with laboratory tests.

DOSAGE AND ADMINISTRATION

It is crucial to gradually introduce lamotrigine in order to attenuate the risk of rash.

Because valproate increases and enzyme inducers (such as carbamazepine, phenytoin, phenobarbital, primidone, and rifampin) decrease lamotrigine blood concentration, the lamotrigine prescribing information includes detailed instructions for gradual lamotrigine introduction (Table 33.10d–1).

Table 33.10d–1.
Gradual Introduction of Lamotrigine in Adults With Bipolar Disorders

	Lamotrigine With Valproate (mg/day)	Lamotrigine With Enzyme Inducers (mg/day)	Lamotrigine With Neither Valproate Nor Enzyme Inducers (mg/day)
Weeks 1 and 2 dose	12.5	50	25
Weeks 3 and 4 dose	25	100	50
Week 5 dose	50	200	100
Week 6 dose	100	300	200
Week 7 and thereafter (FDA target dose)	100	400	200
Typical final dose range	100–200	400–800	200–400

Adapted from FDA, U.S. Food and Drug Administration.

In maintenance treatment of adults with bipolar I disorder, when given without valproate or enzyme-inducing anticonvulsants, lamotrigine is started at 25 mg per day for weeks 1 and 2, increased to 50 mg per day for weeks 3 and 4, increased to 100 mg per day for week 5, and then increased to the 200 mg per day target dose. It may be wise, as some clinicians do, to use even more gradual initial titration in efforts to further decrease the risk of rash, starting with 25 mg per day for the first 2 weeks, increasing to 50 mg per day for the next 2 weeks, and thereafter increasing by 25 mg per day on a weekly basis.

When added to valproate, lamotrigine is started at lower doses and titrated upward more slowly. It is started at 25 mg every *other* day (or 12.5 mg per day) for weeks 1 and 2, increased to 25 mg per day for weeks 3 and 4, increased to 50 mg per day for week 5, and then increased to 100 mg per day target dose. Many clinicians use even more gradual initial titration in efforts to further decrease the risk of rash, starting with 12.5 mg per day for the first 2 weeks, increasing to 25 mg per day for the next 2 weeks, and thereafter increasing by 12.5 mg per day on a weekly basis.

When added to enzyme-inducing anticonvulsants (such as carbamazepine), lamotrigine is started at 50 mg per day for weeks 1 and 2, increased to 100 mg per day in divided doses for weeks 3 and 4, increased to 200 mg per day in divided doses for week 5, increased to 300 mg per day in divided doses for week 6, and then increased to 400 mg per day in divided doses to the target dose. Again, clinicians who wish to be more conservative use even more gradual initial titration in efforts to further decrease the risk of rash, starting with 50 mg per day for the first 2 weeks, increasing to 100 mg per day for the next 2 weeks, and thereafter increasing by 50 mg per day on a weekly basis.

Based on controlled trials, the prescribing information describes target doses of lamotrigine as 200 mg/day in monotherapy, 100 mg per day (with valproate), and 400 mg per day (with enzyme inducers). However, many clinicians choose to gradually titrate lamotrigine to a good clinical response rather than continuing to a presumed target dose. In the absence of a good response once target doses are achieved, some clinicians will further increase doses as necessary and tolerated to about twice the target figures. Although a therapeutic plasma concentration range has not been established for lamotrigine for bipolar disorder or for epilepsy, if patients attain high doses (e.g., 400 mg per day without inducers), it may be helpful to assess a 12-hour trough lamotrigine level to determine if there is a pharmacokinetic cause to apparent nonresponse.

While lamotrigine use in bipolar disorders had generally been limited in patients under the age of 16 years, due to the lack of an FDA indication and the potential for increased risk of rash, this has begun to change with the appreciation of the use of lamotrigine instead of antidepressants in adolescents with or at high risk for bipolar depression. Treatment with lamotrigine of young children with bipolar not otherwise specified (BP-NOS) and related comorbidities is increasingly also being considered given early evidence of effectiveness and the fact that the drug is used in pediatric epilepsy patients aged 2 to 12. Starting lower doses and slower rates of titration than even used in adult patients on valproate is advisable.

The prescribing information describes weight-proportional gradual adjunctive lamotrigine introduction in pediatric (age 2 to 12 years) epilepsy patients, with maintenance doses of 1 to 5 mg/kg per day (maximum 200 mg per day in one or two divided doses) in patients taking valproate, and 5 to 15 mg/kg per day (maximum 400 mg per day in two divided doses) in patients on enzyme-inducing anticonvulsants.

Although estrogen-containing hormonal contraceptives can decrease blood lamotrigine concentrations by as much as 50%, no adjustment to the lamotrigine dose-escalation guidelines is recommended solely based on the use of estrogen-containing hormonal contraceptives. However, the maintenance dose of lamotrigine may need to be increased as much as twofold.

When estrogen-containing hormonal contraceptives are added to lamotrigine, lamotrigine doses may be increased by 50 to 100 mg per day on a weekly basis. If adverse effects related to increased lamotrigine concentrations such as dizziness, ataxia, and diplopia consistently occur during the week of inactive hormonal preparation (i.e., the “pill-free” week), it may be necessary to decrease the overall lamotrigine maintenance dosage, but dose adjustments confined to the “pill-free” week are not recommended.

When estrogen-containing hormonal contraceptives are discontinued, lamotrigine doses may be decreased by 25% in the first week and by another 25% in the second week.

In patients with hepatic impairment, lamotrigine doses may need to be decreased by 25% in patients with moderate to severe hepatic impairment without ascites and 50% in patients with severe hepatic impairment with ascites. Lamotrigine dosage may need to be decreased in patients with impaired renal function.

If patients do not take lamotrigine for 5 days or more (i.e., for five times the half-life of lamotrigine or more), the drug needs to be reintroduced according to the gradual initial escalation regimen as serious rashes can occur with rapidly restarting the medication.

In conditions other than seizure disorders, lamotrigine is commonly given in one or two divided doses. Single daily dosing is convenient, enhances adherence, and in contrast to epilepsy, breakthrough symptoms due to the resulting lower trough blood concentrations are less of a concern. In some (nonepilepsy) applications, clinicians may administer most or all of the dosage in the morning or at bedtime if individual patients find the drug activating or sedating, respectively.

33.10e Valproate

ROBERT M. POST, M.D., AND MARK A. FRYE, M.D.

Neuroscience-Based Nomenclature (NbN)	
Glutamate Modulator	
Pharmacologic Domain	Glutamate
Mechanism of Action	Yet to be determined

Valproic acid (Depakene), and its formulation derivatives divalproex sodium (Depakote), extended-release (ER), divalproex sodium (Depakote ER), and valproate sodium injection (Depacon), represent one of several first-generation mood-stabilizing anticonvulsants.

Valproate is currently approved for seizure disorders by the U.S. Food and Drug Administration (FDA) as (1) monotherapy or adjunctive therapy for complex partial seizures that occur in isolation or in conjunction with other types of seizures, (2) monotherapy and adjunctive therapy of simple and complex absence seizures, and (3) adjunctive therapy for patients with multiple seizures that include absence seizures.

Divalproex has an FDA indication in these same epilepsy syndromes but additionally has indications for (4) prophylaxis of migraine and (5) treatment of acute manic episodes associated with bipolar disorder. Intravenous (IV) valproate sodium is currently FDA approved as an alternative in patients for whom oral administration is temporarily not feasible (i.e., unresponsive or otherwise on nothing-by-mouth [NPO] status). ER divalproex sodium is currently FDA approved for migraine prophylaxis, monotherapy, and adjunctive therapy in complex partial seizures and acute mania.

HISTORY

The first clinical observations of valproate's anticonvulsant activity were in Europe in the 1970s. Shortly thereafter, the first reported evaluation of valpromide (the prodrug of valproate) in bipolar disorder was that of O. Lambert in France. Since then, valproate has been extensively evaluated in bipolar disorder (particularly the manic phase as exemplified by the 1995 indication for acute mania). Valproate has been studied to a much lesser extent in other psychiatric conditions and has not been approved for indications such as schizophrenia, schizoaffective disorder, bipolar depression, panic disorder, post-traumatic stress disorder (PTSD), alcohol withdrawal, and target symptoms of impulsivity, agitation, and mood lability.

CHEMISTRY

Valproic acid (*N*-dipropylacetic acid) is a simple-chain branched-chain carboxylic acid (Fig. 33.10e–1).

The commercial formulation derivatives available include valproic acid, which is available in syrup and capsules; valpromide (amide prodrug of valproic acid used in Europe); valproate sodium injection; divalproex sodium, which is an enteric-coated delayed-release complex of valproic acid and sodium valproate in a 1 to 1 ratio that is available in tablet and sprinkle formulation (can be opened and spread on food); and an ER formulation of divalproex sodium.

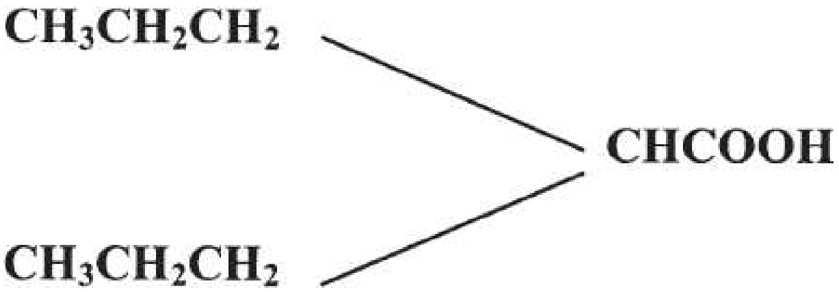

FIGURE 33.10e–1. Molecular structure of valproate.

PHARMACOLOGIC ACTIONS

Pharmacokinetics

All formulations of valproate are rapidly absorbed, with peak plasma concentrations obtained 3 to 4 hours after oral administration. The plasma half-life of valproate is 10 to 16 hours. However, when dosed in combination with drugs that induce cytochrome P450 enzymes (i.e., carbamazepine [Tegretol]), the half-life is shorter.

The ER formulation of divalproex sodium was designed for once-daily dosing, thereby maintaining lower maximum drug concentration (C_{max}) and higher minimum drug concentration (C_{min}) between dosing intervals. The ER formulation has 80% bioavailability of direct release (DR) divalproex sodium, and increasing the DR dose by 20% to an approximately equivalent ER dose with clinical monitoring would be a reasonable switch strategy.

Valproate is highly protein bound, primarily to albumin. It is generally thought that at serum levels less than 45 to 50 μg/mL, these binding sites are unsaturated, while at higher serum levels, these binding sites become saturated, with the unbound valproate level increasing. The unbound portion of valproate is considered to be pharmacologically active and can cross the blood–brain barrier. When used in combination with other psychotropic agents, valproate has a higher degree of plasma protein binding such that it can displace these drugs and increase their free levels (i.e., lamotrigine [Lamictal] and carbamazepine).

Valproate is metabolized primarily by hepatic glucuronidation and mitochondrial β-oxidation. Several of valproate's metabolites, 2-propyl-2-pentenoic acid and 2-propyl-3-oxopentanoic acid, have potent anticonvulsant activity.

Pharmacodynamics

Valproate's anticonvulsant and mood-stabilization mechanisms of action have not been specifically identified and may not necessarily be the same. Its anticonvulsant effects are rapid in onset, while antimanic and antidepressant effects are slower in onset and appear to require chronic administration. Several hypotheses for its mechanisms of action include: enhancement of brain γ-aminobutyric acid (GABA) levels via multiple actions of increased synthesis and decreased degradation; modulation of other neurotransmitters; blockade of voltage-sensitive Na^+ channels; and effects on extra hypothalamic neuropeptides, secondary messenger systems, and neuroprotection. Comparative effects with two other antimanic mood stabilizers, carbamazepine and lithium (Eskalith), are listed in Table 33.10e–1.

Preclinical studies have shown that valproate enhances GABAergic function in specific regions of the brain by a variety of presynaptic or postsynaptic mechanisms, or both, such as enhancement of GABA synthesis through activation of glutamate decarboxylase, prevention of GABA catabolism through inhibition of GABA transaminase, DR of GABA in response to calcium influx, reversal of the GABA transporter, and postsynaptic GABA type A ($GABA_A$) receptor activation effects. However, whether GABA enhancement is directly related to the antimanic effects of valproate remains controversial, and indirect inferences from the effects of other potent anticonvulsants that enhance brain GABA further suggest that this is unlikely. For example, other potent GABAergic drugs, tiagabine (Gabitril Filmtabs), gabapentin (Neurontin), and topiramate (Topamax), are not effective antimanic treatments.

Table 33.10e–1.

Common and Differential Effects of Valproate (VPA) Compared to Carbamazepine (CBZ) or Lithium (Li)

	CBZ	VPA	Li
Common Effects			
GABA turnover	↓	↓	↓
$GABA_B$ receptors in hippocampus (chronic)	↑	↑	↑
GABA levels	(↑)	↑	(↑)
↓ GSK-3B	+	+	+
Brain tryptophan and 5-HT	↑	↑	↑
Dopamine turnover	↓	↓	↓
NMDA-mediated Ca^{++} currents	↓	↓	↓
Arachidonic acid turnover	↓	↓	↓
Myoinositol transport (SMIT)	↓	↓	↓
Stroke neuroprotection	+	+	+
BDNF	↑	↑	↑
Lithium-Shared Effects			
Inhibition of ERK MAP kinase path	−	+	+
↓ PKC	−	+	+
↓ MARCKS levels	−	+	+
↑ Bcl-2	−	+	+
↑ Neurogenesis	−	+	+
↓ β-Catenin	−	+	+
↑ AP-1 Binding	−	+	+
Carbamazepine-Shared Effects			
Na_i+ block	+	(+)	−
K efflux	↑	↑	−
[^{3}H] picrotoxinin binding	↓	↓	−
Release of aspartate, glutamate	↓	↓	−
Somatostatin levels	↓	↓	−

Histone, deacetylase inhibition	+	+	−
Block completed kindled seizures	+	+	−
Unique Effects of Each Drug			
Inositol Monophosphatases	−	↓	↑
Absence seizures	↑	↓	−
Blocks kindling development	−	+	−
Inhibit after-discharge spread in	−	+	−
hippocampus in cortex	+	−	−
Potential anticancer effects (AML)	−	+	−
Forms ester with coenzyme A	−	+	−
↑ PPARs	−	+	−

GABA, γ-aminobutyric acid; GSK, glycogen synthase kinase; 5-HT, serotonin; NMDA, *N*-methyl-d-aspartate; SMIT, *myo*-inositol transport system; BDNF, brain-derived neurotrophic factor; ERK, extracellular-signal-regulated kinases; PKC, protein kinase C; MARCKS, myristoylated alanine-rich C kinase substrate; AP, activator protein; AML, acute myelogenous leukemia; PPARs, peroxisome proliferator-activated receptors.

In addition, GABA deficits, as measured in cerebrospinal fluid (CSF) by magnetic resonance spectroscopy (MRS), or plasma analysis, have not been consistently reported in clinical studies of affectively ill patients. GABA assessments after drug treatment have also produced inconsistent results. Valproate treatment increased GABA in the CSF of 31 pediatric epileptic patients and 6 schizophrenic patients; by MRS analysis, valproate increased occipital GABA in 6 euthymic bipolar patients. However, no increase in GABA, as measured by CSF analysis in six schizophrenic patients or by MRS analysis in five refractory epileptic patients treated with valproate, has also been reported.

The discordance between the CSF, MRS, and plasma studies remains unresolved; different study populations, collection and storage times of samples, lengths of treatment, and methodologies of GABA assay need to be standardized to better elucidate the role of GABAergic mechanisms in the therapeutic effects of valproate.

Valproate's effect on less well-studied neurotransmitters and neuropeptides has included glutamate (increased release in mouse brain), serotonin (increased extracellular level in rat hippocampus and striatum), dopamine (increased extracellular level in rat), somatostatin (decreased CSF level), and corticotropin-releasing factor (CRF) (decreased CRF in the median eminence, raphe nuclei, and decreased CRF messenger ribonucleic acid [mRNA] in the central nucleus of the amygdala and paraventricular nucleus of the hypothalamus). Although these neurotransmitters and neuropeptides have all been implicated in the pathophysiology of mania, depression, or psychosis, it is not known whether valproate’s modulation of these neurotransmitters and neuropeptides contributes to its mood-stabilizing properties.

Intracellular signaling systems similar to those of lithium have also been observed with valproate. Like lithium, valproate stimulates glutamate release and, through activation of the *N*-methyl-D-aspartate (NMDA) receptor, has been shown to increase inositol-1,4,5-triphosphate. Additionally, lithium, valproate, and carbamazepine, but not amitriptyline (Elavil), have been shown to inhibit the high-affinity *myo*-inositol transport system in astrocytes; this inhibition of inositol and subsequent reduced intraneuronal level of inositol (*inositol depletion*) may be related to the mood-stabilization mechanism of valproate. However, although lithium decreases inositol monophosphatase activity, valproate increases it.

Similar actions have also been observed with lithium and valproate in the downregulation of protein kinase C (PKC) activity and downregulation of myristoylated alanine-rich C kinase substrate (MARCKS) activity (a major substrate of PKC) and increased level of Bcl-2 (a neuroprotective protein). PKC inhibition is a likely contributor to antimanic efficacy. In one open and two double-blind, placebo-controlled studies, the potent PKC inhibitor tamoxifen (Nolvadex), which also has antiestrogen receptor effects, has shown antimanic efficacy.

Like lithium, valproate increases Bcl-2, brain-derived neurotrophic factor (BDNF), and neurogenesis, but the increases in hippocampal volume and cortical gray matter seen with lithium have not been consistently observed with valproate. However, patients on valproate had increased volumes of their cingulate cortices and increased *N*-acetyl-aspartate (NAA) to creatine (Cre) or choline (Cho) ratios in the hippocampus compared with those not treated with valproate. Since BDNF decreases during episodes of depression and mania, valproate’s ability to increase BDNF could be important to some of its clinical actions.

Valproate is also positive in animal models of stroke and, surprisingly, is effective not only when given before middle cerebral artery ligation but (like lithium) when given shortly after the ligation as well. In contrast to lithium, valproate inhibits histone deacetylase, which could account for many of its effects on gene transcription. It is also possible that this effect contributes to valproate's teratogenicity (as described below) or to its possible therapeutic actions in conjunction with hydralazine (an inhibitor of DNA methylation) in reversing treatment resistance to chemotherapy of malignancies. In contrast to valproate, valpromide does not inhibit histone deacetylase, such that a role for this mechanism could be revealed in comparative studies.

CLINICAL DRUG STUDIES

Acute Mania

The early uncontrolled studies of valproate (divalproex or valpromide) in acute mania suggested efficacy. Subsequent controlled studies of valproate in acute mania confirmed this view; these studies are reviewed in Table 33.10e–2.

Table 33.10e–2.
Controlled Studies of Valproate or Divalproex in Acute Mania

Study	Design (N)	Primary Outcome Variable	Results	Comment
Pope et al., 1991	3-week, randomized, db, pc, DSM-III-R mania, unresponsive to Li ($N = 36$)	% ↓ YMRS	VAL 54% ↓ vs. PLC 5% ↓ ($P = .003$), ITT ($P = .013$)	Response 1–4 days after achieving serum VAL >50 μg/mL
Bowden et al., 1994	3-week, multisite, randomized, db, pc, RDC confirmed mania ($N = 179$) DVPX vs. Li vs. PLC in 2:1:2 ratio. Dosage titrated to DVPX (150 μg/mL) and Li (1.5 mmol/L), except if adverse event was present	50% ↓ MRS	Mean dose/level DVPX: 2,000 mg/93.2 μg/mL) Li: 1,950 mg/1.2 mmol/L ITT: DVPX, 46% ($P = .004$ vs. PLC); Li, 49% ($P = .025$ vs. PLC); PLC 25%	All rapid-cycling patients ($N = 8$) randomized to DVPX; therefore, no comparative analysis possible 48% of current Li responders reported past Li inefficacy or intolerance
Freeman et al., 1992	3-week, randomized, db, DSM-III-R mania ($N = 27$) DVPX (titrated to 3,000 mg—lower dose for response or side effect) vs. Li (titrated to response, side effect, 1,800 mg q.d., or level 1.5 mmol/L)	50% ↓ SADS-C mania	Li levels (0.8–1.4 mmol/L), mean DVPX level (98 ± 17 μg/mL) Li 12/13 (92%) vs. DVPX 9/14 (64%)	Pretreatment depression significantly higher in DVPX responders vs. nonresponders ($P < .05$) Post-treatment mania scores higher in mixed vs. nonmixed manics treated with Li ($P < .05$)
McElroy et al., 1996	1-week, randomized, sb, psychotic mania, rapid load DVPX ($N = 21$, 20 mg/kg/day) vs. HAL ($N = 15$, 0.2 mg/kg/day)	Mean change YMRS	DVPX 43% YMRS ↓; HAL 35% YMRS ↓	Equal efficacy Greater use of benztropine in HAL group
Hirschfeld et al., 1999	10-day, multisite, randomized, db, DSM-IV acute mania (YMRS ≥ 14) DVPX load ($N = 20$, 30 mg/kg/day on days 1–2, 20 mg/kg/day on days 3–10) vs. DVPX nonload ($N = 20$) vs. Li ($N = 19$)	Safety and tolerability DVPX load	84% DVPX load had level >50 μg/mL by day 3 vs. 30% DVPX nonload	No difference in adverse event or YMRS change
Muller-Oerlinghausen et al., 2000	3-week, multisite, randomized, db, pc adjunct VAL (20 mg/kg/day) vs. PLC to neuroleptic ($N = 136$) Step-wise dose reduction of neuroleptic	Mean dose ↓ neuroleptic at study end	Day 21 VAL level (80.3 ± 22.3 μg/mL) 43% ↓ of neuroleptic in adjunct VAL vs. 14% ↓ in adjunct PLC ($P = .0007$)	Decreased neuroleptic burden in VAL patients
Vasudev et al., 2000	4-week, randomized, db, CBZ vs. VAL ($N = 30$)	Mean change in YMRS	VAL (75.4 μg/mL) greater YMRS ↓ vs. CBZ (6.2 μg/mL) ($P = .023$)	Correlation between VAL level and ↓ YMRS at week 2
Tohen et al., 2002	3-week, multisite, randomized, db, parallel DSM-IV mania (YMRS ≥ 20) ($N = 251$) DVPX ($N = 125$, flexible dose of 500–2,500 mg q.d.) vs. OLZ ($N = 123$, 5–20 mg q.d.)	Mean change YMRS Response (50% ↓ YMRS) Remission (YMRS ≤ 12)	DVPX (mean dose 1,401 mg q.d., serum level 79.4 μg/mL), OLZ (mean dose 17.4 mg) YMRS ↓ DVPX 10.4 points vs. OLZ 13.4 points ($P =$ N.S.) Response and remission: DVPX 42.3% and 34.1% vs. OLZ 54.4% and 47.2% ($P = .058$; $P = .039$)	Weight gain 2.5 kg OLZ vs. 0.9 kg DVPX Somnolence, dry mouth, ↑ appetite, tremor, neck rigidity more common with OLZ Nausea, diarrhea more common with DVPX
Zajecka et al., 2002	3-week, multisite, randomized, db, parallel DSM-IV mania (MRS ≥ 25) ($N = 120$) DVPX ($N = 43$; loading 20 mg/kg/day) vs. OLZ ($N = 57$; start dose 10 mg with ↑ for persistent symptoms)	Mean MRS change Response (50% ↓ MRS)	DVPX, mean dose of 2,115 mg; OLZ mean dose of 15 mg MRS ↓ DVPX 14.8 points vs. OLZ 17.2 points ($P =$ N.S.) ITT: Response (DVPX 53%, OLZ 62%, $P =$ N.S.)	Weight gain, somnolence, rhinitis, edema, ↑ cholesterol more common with OLZ ↑ Monocytes, ↑ eosinophils, ↓ neutrophils, ↓ platelets more common with DVPX
Bowden et al., 2006	3-week, multisite, randomized db, pc, DSM-IV acute mania DVPX started at 25 mg/kg day 1 ↑ 500 mg on day 3 → 85–125 μg/mL (Dosing once daily in AM)	Response (50% ↓ YMRS)	ITT: Response DVPX 48% PLC 34% ($P = .02$) Mean final dose 3,057 mg per day (35.4 mg/kg) → mean serum level 95.9 μg/mL	On DVPX: somnolence, dizziness, complaints; weight gain: 1.8 kg DVPX 0.3 kg PLC Total cholesterol −13.5 mg/dL DVPX +2.5 mg/dL PLC

CBZ, carbamazepine (Tegretol); db, double blind; DVPX, divalproex sodium (Depakote); HAL, haloperidol (Haldol); HAMD, Hamilton Depression Scale; ITT, intent-to-treat analysis; Li, lithium (Eskalith); MRS, Mania Rating Scale; N.S., not significant; OLZ, olanzapine (Zyprexa); pc, placebo controlled; PLC, placebo; RDC, Research Diagnostic Criteria; SADS-C, Schedule for Affective Disorders and Schizophrenia-Change; sb, single blind; VAL, valproate; YMRS, Young Mania Rating Scale.

The first placebo-controlled studies by Pope and colleagues (1991) and Bowden et al. (1994) were pivotal in receiving an FDA indication for acute mania. Post hoc analyses of the Bowden study have suggested that, although there was no difference from lithium in the response rate for patients with euphoric mania, patients with concomitant depressive symptoms (i.e., dysphoric mania) or a cumulative lifetime episode burden of greater than 4 prior depressive episodes or 11 prior manic episodes responded more poorly to lithium. Furthermore, four distinct manic subtypes (anxious-depressed, psychotic, classic, and irritable) based on pretreatment symptom cluster analyses confirmed that the classic manic subtype responded similarly to divalproex and lithium, but the irritable manic subtype responded significantly better to divalproex than lithium ($P < .004$) or placebo ($P < .04$). The three treatments did not differ in response rates to depressive or psychotic subtypes.

Two studies have suggested that a serum valproate level of greater than 45 to 50 μg/mL is associated with an antimanic response. A multicenter study of the divalproex ER preparation in acute mania was again highly positive compared with placebo for both mania and mixed patients and in those with and without psychosis. Starting dose and rate of titration may have been too high because the side-effect profile was not diminished compared with the acute release studies. Serum levels of 71.3 to 85 μg/mL or higher appeared to be the therapeutic target since those under this concentration show fewer good responses (smaller effect sizes [0.4 to 0.8]) compared with those at higher blood levels (effect sizes 0.9 to 1.1). The ER preparation was dosed on a once-daily basis in the morning, but clinically, one would recommend single bedtime dosing to enhance sleep and reduce side effects during awake time and increase compliance. Many clinicians would similarly recommend that the IR preparation could be given all at night.

Because of valproate's robust effects in acute mania in adults, it was surprising that it failed to separate from placebo in a study of childhood- and adolescent-onset mania. Concomitant stimulant medication was allowed in that study, which may have confounded the results. In another study on childhood mania, response to valproate was inferior to that of risperidone.

Given that there are many FDA-approved conventional mood-stabilizing agents for the treatment of acute mania (lithium, valproate, long-acting carbamazepine [Equetro], olanzapine [Zyprexa], risperidone [Risperdal], quetiapine [Seroquel], aripiprazole [Abilify], ziprasidone [Geodon], and cariprazine [Vraylar]), the few controlled comparison studies provide only preliminary information regarding the selection of an antimanic agent. Side-effect profile and long-term tolerability would appear to provide an important rationale for the choice of antimanic agents.

Although the typical antipsychotic agents have been extensively used for the treatment of acute mania in the past, they represent a somewhat outmoded treatment because they are associated with more postmanic depressive symptom severity and breakthrough episodes of depression (vs. lithium) and an adverse side-effect profile. Typical antipsychotics are associated with considerable side-effect liabilities, including neuroleptic-induced dysphoria, acute dystonia, extrapyramidal side effects, and, most importantly, long-term risk of tardive dyskinesia in some 20% to 40% of bipolar patients (even those treated intermittently).

As reviewed previously, the post hoc analyses of comparison studies of lithium versus divalproex would suggest that depressive or irritable symptoms in mania are more effectively treated with divalproex. Other possible correlates of a relatively positive response are listed in Table 33.10e–3. There is one large open trial in rapid-cycling patients of valproate prophylaxis as monotherapy in lithium-refractory patients (N = 43) or as add-on therapy (N = 101) with a greater than 70% antimanic or nonmixed response. The only comparison study of valproate and carbamazepine suggested greater efficacy and dose-dependent antimanic response with valproate.

Table 33.10e–3.

Potential Correlates of Response to Valproate

	Strength of Association
Diagnosis-Related Factors	
Diagnosis of bipolar disorder (vs. schizoaffective or schizophrenia disorder)	+++
Dysphoric (or mixed mania)	+++
Bipolar II disorder	++
Clinical Course Variables	
Presence of rapid cycling	+
Decreasing or stable episode frequency	++
Later age of onset of illness (but see Fig. 33.10e–2A,B)	+
Shorter duration of illness	+
Long and severe course of illness (see Figs. 33.10e–2 and 33.10e–3)	++
Comorbid Psychiatric Diagnosis	
Comorbid alcohol abuse	+++
Comorbid mental retardation	+
Comorbid anxiety and panic attacks	+++
Comorbid PTSD	+
Treated hypothyroidism	+
Marked sleep disturbance	+
Explosive dyscontrol and aggression	++
Associated Neurologic Factors	
Presence of nonparoxysmal EEG abnormalities (not subsequently replicated)	±
Organic affective disorder	±
History of closed head trauma	+
Comorbid migraine	+++
Family History	

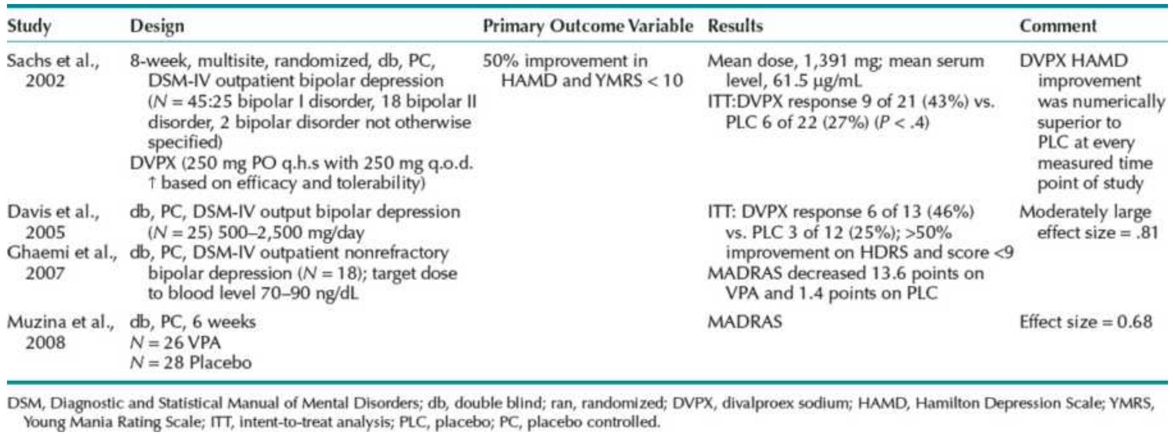
Positive family history of mood disorder	+
Treatment-related variables:	
Patients who are lithium naïve (especially BP-II)	+
Higher serum valproate concentrations at days 3–6 of treatment	
Higher serum valproate concentrations with more severe illness: cyclothymia < BP-II < BP-I	++
Brain Imaging	
Low activity in the frontal and anterior cingulate and medial frontal gyrus	+
Plasma GABA	
Not low (near normal)	+

PTSD, post-traumatic stress disorder; EEG, electroencephalogram; BP, bipolar; GABA, γ-aminobutyric acid; +++, well documented in several open studies or one controlled study; ++, good support in literature; +, fair support; ±, weak support or equivocal.

Data from West SA, Strakowski SM, Sax KW, McElroy SL, Keck PE Jr, McConville BJ. Phenomenology and comorbidity of adolescents hospitalized for the treatment of acute mania. *Biol Psychiatry*. 1996;39(6):458–460 and Post RM, Speer AM, Obrocea GV, Leverich GS. Acute and prophylactic effects of anticonvulsants in bipolar depression. *Clin Neuroscience Res*. 2002;2(3–4):228–251.

Two comparative studies of divalproex versus olanzapine were similar in design, with the exception of dose and titration. In one smaller study that started with a rapid loading dose of divalproex (mean dose of 2,115 mg vs. olanzapine mean dose of 15 mg), the mean reduction in manic symptoms and response rates were not statistically different. In the larger-powered study that started with a nonloading and lower divalproex dose (mean dose of 1,401 mg vs. olanzapine mean dose of 17.4 mg), response and remission rates were significantly in favor of olanzapine. A 12-week comparative study in acute mania suggested the superiority of quetiapine to valproate for efficacy but with a higher side-effect burden.

Table 33.10e–4.
Controlled Studies of Valproate and Divalproex Sodium in Bipolar Disorder (Acute Depression)



Study	Design	Primary Outcome Variable	Results	Comment
Sachs et al., 2002	8-week, multisite, randomized, db, PC, DSM-IV outpatient bipolar depression (*N* = 45:25 bipolar I disorder, 18 bipolar II disorder, 2 bipolar disorder not otherwise specified) DVPX (250 mg PO q.h.s with 250 mg q.o.d. ↑ based on efficacy and tolerability)	50% improvement in HAMD and YMRS < 10	Mean dose, 1,391 mg; mean serum level, 61.5 μg/mL ITT:DVPX response 9 of 21 (43%) vs. PLC 6 of 22 (27%) (*P* < .4)	DVPX HAMD improvement was numerically superior to PLC at every measured time point of study
Davis et al., 2005	db, PC, DSM-IV output bipolar depression (*N* = 25) 500–2,500 mg/day		ITT: DVPX response 6 of 13 (46%) vs. PLC 3 of 12 (25%); >50% improvement on HDRS and score <9	Moderately large effect size = .81
Ghaemi et al., 2007	db, PC, DSM-IV outpatient nonrefractory bipolar depression (*N* = 18); target dose to blood level 70–90 ng/dL		MADRAS decreased 13.6 points on VPA and 1.4 points on PLC	
Muzina et al., 2008	db, PC, 6 weeks *N* = 26 VPA *N* = 28 Placebo		MADRAS	Effect size = 0.68

DSM, Diagnostic and Statistical Manual of Mental Disorders; db, double blind; ran, randomized; DVPX, divalproex sodium; HAMD, Hamilton Depression Scale; YMRS, Young Mania Rating Scale; ITT, intent-to-treat analysis; PLC, placebo; PC, placebo controlled.

Acute Bipolar Depression

Conventional mood stabilizers have been less well studied in the depressive phase of bipolar disorder. Several open trials have clearly suggested antidepressant properties with valproate, generally at lower doses than studies in acute mania. In a 12-week open trial of 19 patients with bipolar II depression, divalproex sodium monotherapy (with a mean dose of 882 mg every night and a mean level of 80.7 μg/mL), 63% of the cohort responded to treatment as defined by a 50% reduction in the Hamilton Rating Scale for Depression.

As presented in Table 33.10e–4, a controlled study of divalproex monotherapy in acute bipolar I or II depression did not statistically separate from placebo at the 8-week study endpoint. The small sample size (*N* = 45) does not allow definitive conclusions about the acute antidepressant efficacy of divalproex. However, in another small randomized-controlled trial including 25 patients, valproate not only showed superior antidepressant effects compared with placebo but showed even more clinically and statistically robust antianxiety effects in monotherapy of bipolar depression. A more recent double-blind placebo-controlled study showed marked superiority of valproate over placebo with a moderately large effect size of 0.81.

Current guidelines emphasize the importance of maximizing mood stabilizer or atypical antipsychotic treatment and revising these agents if needed before starting treatment with conventional unimodal antidepressant therapy.

Prophylactic Mood Stabilization

There are six controlled studies that have evaluated the efficacy of valproate or divalproex in long-term mood stabilization (Table 33.10e–5). These studies include one open randomization comparing valpromide versus lithium monotherapy; one open randomization comparing valproate versus lithium monotherapy in a child, adolescent, and young adult population; one placebo-controlled, adjunctive divalproex trial to lithium-maintained bipolar I patients; one 52-week, parallel design comparing lithium, divalproex, and placebo monotherapy in recently recovered manic patients; and one controlled comparison study between divalproex and olanzapine monotherapy in those patients who had presented in an acute manic episode.

Several conclusions can be drawn regarding these studies. First, one study suggested that valproate had better prophylaxis against mania compared to depressive episodes. Conversely, the largest controlled study to date did not find any difference between divalproex, lithium, or placebo in time to recurrence of a mood episode or, specifically, a manic episode. However, almost 200 patients, who were initially enrolled as acutely manic, were unable to fully recover and thus were not randomized into the prophylactic phase; this methodologic limitation may have yielded a type II error in a cohort of only randomized mildly ill patients, thereby making it more difficult to show differences between active drugs and the low rate of manic relapse even on placebo. A secondary outcome measure, however, suggested greater depression prophylaxis with divalproex than placebo in the monotherapy analysis and in a subgroup of patients who were subsequently treated with adjunctive antidepressant therapy (i.e., sertraline [Zoloft] or paroxetine [Paxil]) added to divalproex versus placebo.

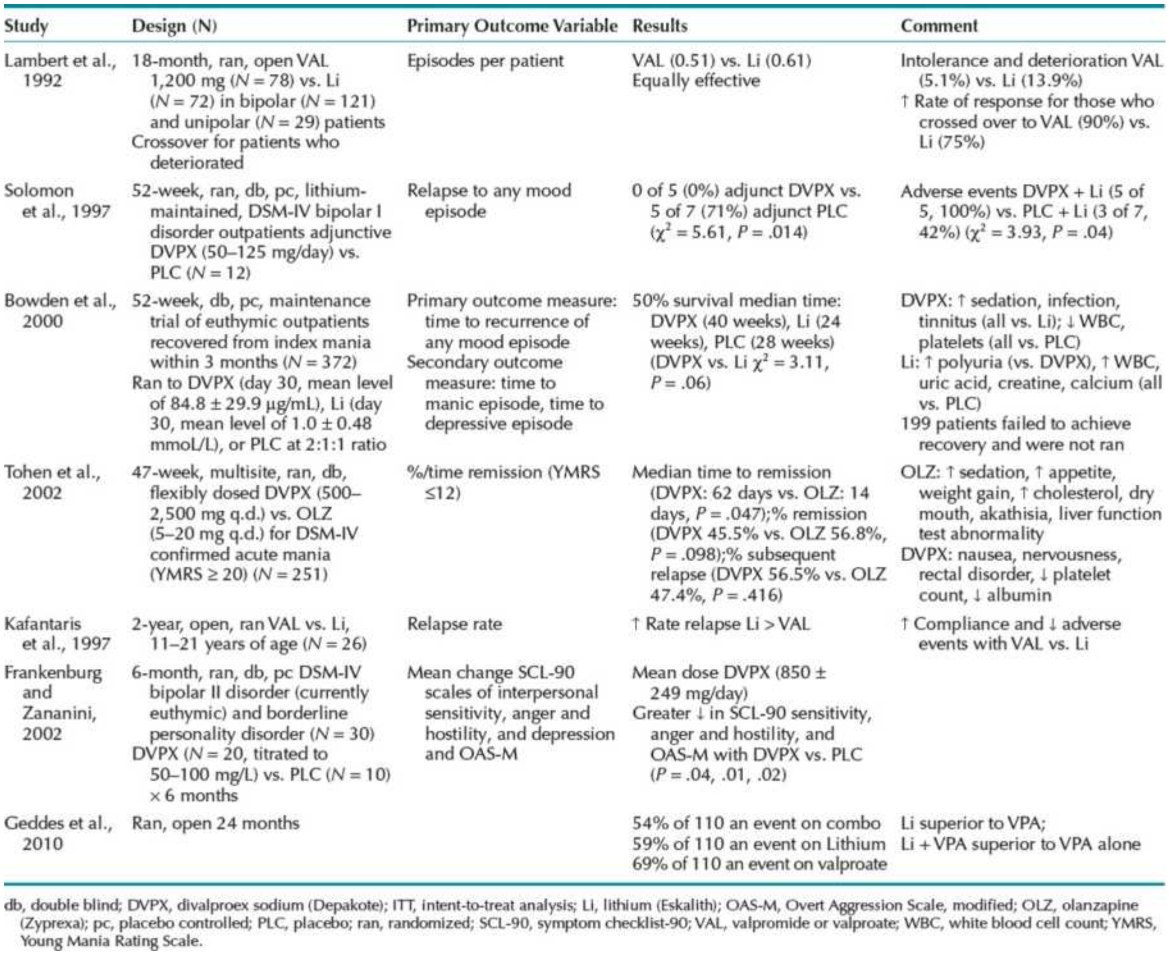
In the 47-week acute mania comparison study of divalproex versus olanzapine, the median time to remission (YMRS ≤12) took significantly longer for divalproex (62 days) than for olanzapine (14 days, $P = .047$). Similarly, there was greater improvement in the YMRS with olanzapine versus divalproex at weeks 2 to 15 and week 23; however, from weeks 30 to 47, there was no difference in the two groups. Once remitted, there was no difference in relapse rates between the two groups.

In a second 18-month maintenance study of lithium versus valproate, those patients who had deteriorated or who were intolerant of lithium treatment had a higher response rate with a subsequent crossover to valproate in comparison to those patients who were initially treated with valproate with a subsequent crossover to lithium.

In a maintenance study comparing lithium plus valproate versus lithium alone, the combination was more effective than lithium alone; however, the adverse event profile was higher with the combination treatment. In the largest practical clinical trial (using a randomized open design of x months duration), Geddes and colleagues found clear superiority of lithium compared to valproate, with the combination marginally better than lithium alone. Despite an indication only in acute mania and some evidence of inferiority compared to lithium, there is wider use of valproate than lithium in the United States in the maintenance phase of bipolar disorder, case examples of which are illustrated in Figures 33.10e–2A,B and 33.10e–3. The latest Cochrane analysis in 2013 concluded that limited evidence supported the efficacy of valproate in the maintenance treatment of bipolar disorder.

Valproate in combination with lithium was evaluated in adults with rapid-cycling disorder in preparation for a blind randomization to monotherapy. Disappointingly, only 25% of the evaluable sample responded to the combination acutely, and only 19% of the intact to treat (ITT) sample responded. After randomization, relapses were about 50% on either lithium or valproate monotherapy, suggesting a very low valproate monotherapy response rate (about 12%) in this difficult-to-treat but common subtype of rapid cycling (which makes up 40% to 60% of outpatients in some series). A return to the combination of lithium plus valproate produced a high reresponse rate.

Table 33.10e–5. Controlled Long-Term Evaluation of Divalproex Sodium in Bipolar Disorder



Study	Design (N)	Primary Outcome Variable	Results	Comment
Lambert et al., 1992	18-month, ran, open VAL 1,200 mg ($N = 78$) vs. Li ($N = 72$) in bipolar ($N = 121$) and unipolar ($N = 29$) patients Crossover for patients who deteriorated	Episodes per patient	VAL (0.51) vs. Li (0.61) Equally effective	Intolerance and deterioration VAL (5.1%) vs. Li (13.9%) ↑ Rate of response for those who crossed over to VAL (90%) vs. Li (75%)
Solomon et al., 1997	52-week, ran, db, pc, lithium-maintained, DSM-IV bipolar I disorder outpatients adjunctive DVPX (50–125 mg/day) vs. PLC ($N = 12$)	Relapse to any mood episode	0 of 5 (0%) adjunct DVPX vs. 5 of 7 (71%) adjunct PLC ($\chi^2 = 5.61$, $P = .014$)	Adverse events DVPX + Li (5 of 5, 100%) vs. PLC + Li (3 of 7, 42%) ($\chi^2 = 3.93$, $P = .04$)
Bowden et al., 2000	52-week, db, pc, maintenance trial of euthymic outpatients recovered from index mania within 3 months ($N = 372$) Ran to DVPX (day 30, mean level of 84.8 ± 29.9 μg/mL), Li (day 30, mean level of 1.0 ± 0.48 mmol/L), or PLC at 2:1:1 ratio	Primary outcome measure: time to recurrence of any mood episode Secondary outcome measure: time to manic episode, time to depressive episode	50% survival median time: DVPX (40 weeks), Li (24 weeks), PLC (28 weeks) (DVPX vs. Li $\chi^2 = 3.11$, $P = .06$)	DVPX: ↑ sedation, infection, tinnitus (all vs. Li); ↓ WBC, platelets (all vs. PLC) Li: ↑ polyuria (vs. DVPX), ↑ WBC, uric acid, creatine, calcium (all vs. PLC) 199 patients failed to achieve recovery and were not ran
Tohen et al., 2002	47-week, multisite, ran, db, flexibly dosed DVPX (500–2,500 mg q.d.) vs. OLZ (5–20 mg q.d.) for DSM-IV confirmed acute mania (YMRS ≥ 20) ($N = 251$)	%/time remission (YMRS ≤12)	Median time to remission (DVPX: 62 days vs. OLZ: 14 days, $P = .047$);% remission (DVPX 45.5% vs. OLZ 56.8%, $P = .098$);% subsequent relapse (DVPX 56.5% vs. OLZ 47.4%, $P = .416$)	OLZ: ↑ sedation, ↑ appetite, weight gain, ↑ cholesterol, dry mouth, akathisia, liver function test abnormality DVPX: nausea, nervousness, rectal disorder, ↓ platelet count, ↓ albumin
Kafantaris et al., 1997	2-year, open, ran VAL vs. Li, 11–21 years of age ($N = 26$)	Relapse rate	↑ Rate relapse Li > VAL	↑ Compliance and ↓ adverse events with VAL vs. Li
Frankenburg and Zananini, 2002	6-month, ran, db, pc DSM-IV bipolar II disorder (currently euthymic) and borderline personality disorder ($N = 30$) DVPX ($N = 20$, titrated to 50–100 mg/L) vs. PLC ($N = 10$) × 6 months	Mean change SCL-90 scales of interpersonal sensitivity, anger and hostility, and depression and OAS-M	Mean dose DVPX (850 ± 249 mg/day) Greater ↓ in SCL-90 sensitivity, anger and hostility, and OAS-M with DVPX vs. PLC ($P = .04, .01, .02$)	
Geddes et al., 2010	Ran, open 24 months		54% of 110 an event on combo 59% of 110 an event on Lithium 69% of 110 an event on valproate	Li superior to VPA; Li + VPA superior to VPA alone

db, double blind; DVPX, divalproex sodium (Depakote); ITT, intent-to-treat analysis; Li, lithium (Eskalith); OAS-M, Overt Aggression Scale, modified; OLZ, olanzapine (Zyprexa); pc, placebo controlled; PLC, placebo; ran, randomized; SCL-90, symptom checklist-90; VAL, valpromide or valproate; WBC, white blood cell count; YMRS, Young Mania Rating Scale.

In a parallel study in children and adolescents with mania, some 43% responded acutely to the lithium plus valproate combination, but upon randomization to either monotherapy, some two-thirds failed to maintain their improvement. However, the great majority reresponded to the combination when it was reintroduced. Most of these youngsters also required stimulant comedication, and several required an atypical antipsychotic as well. These systematic prospective data in a double-blind maintenance study suggest that as in many adult patients, valproate monotherapy is very often insufficient, and combination treatment with lithium or an atypical antipsychotic is typically required in children for sustained mood stabilization and in adults with rapid cycling bipolar disorder.

A recent randomized multicenter study of childhood mania, comparing valproate, lithium, or the atypical antipsychotic risperidone, supported this viewpoint. Geller and colleagues found that risperidone was superior to both lithium and valproate. The percentages with CGI-BP improvement of 2 (much improved) or less (very much improved) were risperidone, 68.5%; lithium, 35.6%; and valproate, 24.0%. However, risperidone had more side effects, such as weight gain and prolactin increases. When nonresponders were rerandomized to the addition of one of the other two treatments, those receiving risperidone as part of the regimen again fared the best.

In a secondary prevention study of children at high risk for bipolar I illness by virtue of both the presence of (1) subthreshold symptoms or a bipolar not otherwise specified presentation and (2) a positive parental history of bipolar illness, valproate was no more effective than placebo. Whether other monotherapies would fare better in this early attempt at secondary prevention remains to be established. Thus, because of the documented inefficacy of valproate monotherapy in a large double-blind study in childhood and adolescent acute mania, its inferiority to risperidone in another study, and its lack of prevention of the disorder in children at high risk, the combination of valproate with lithium or with an atypical such as risperidone may be of critical importance in the management of these children. The role of valproate in conjunction with the better tolerated atypical antipsychotics in long-term treatment also needs to be further explored.

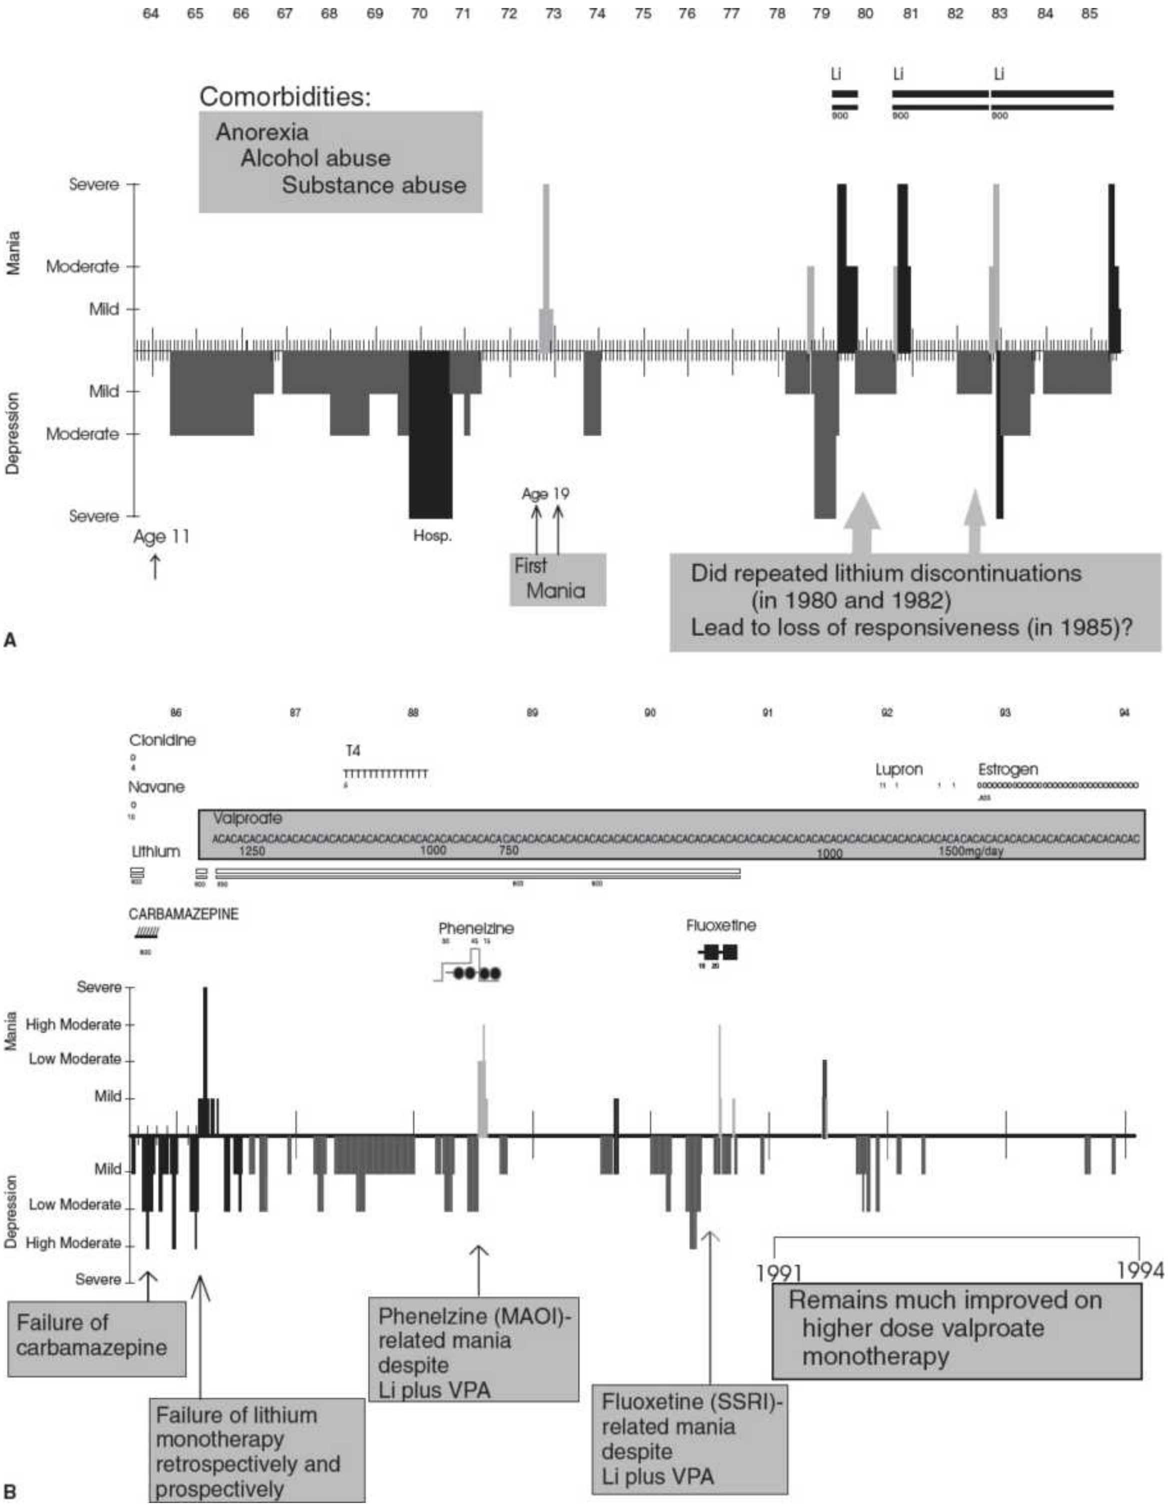


FIGURE 33.10e–2. **A:** Early-onset illness (at age 11) with depression and multiple comorbidities and ultimate failure to respond to lithium in 1985. **B:** Good prophylactic response to valproate in this lithium and carbamazepine-nonresponder. She did well on the combination of lithium and valproate and then on valproate monotherapy since 1990. She had no further hospitalizations for mania (from 1986 to the present), but had occasional

depressive recurrences. Note shift in time scale from (A). (From Post RM, Leverich GS. *Treatment of Bipolar Illness: A Casebook for Clinicians and Patients. Treatment of Bipolar Illness*. W.W. Norton & Co.; 2008:198–200.)

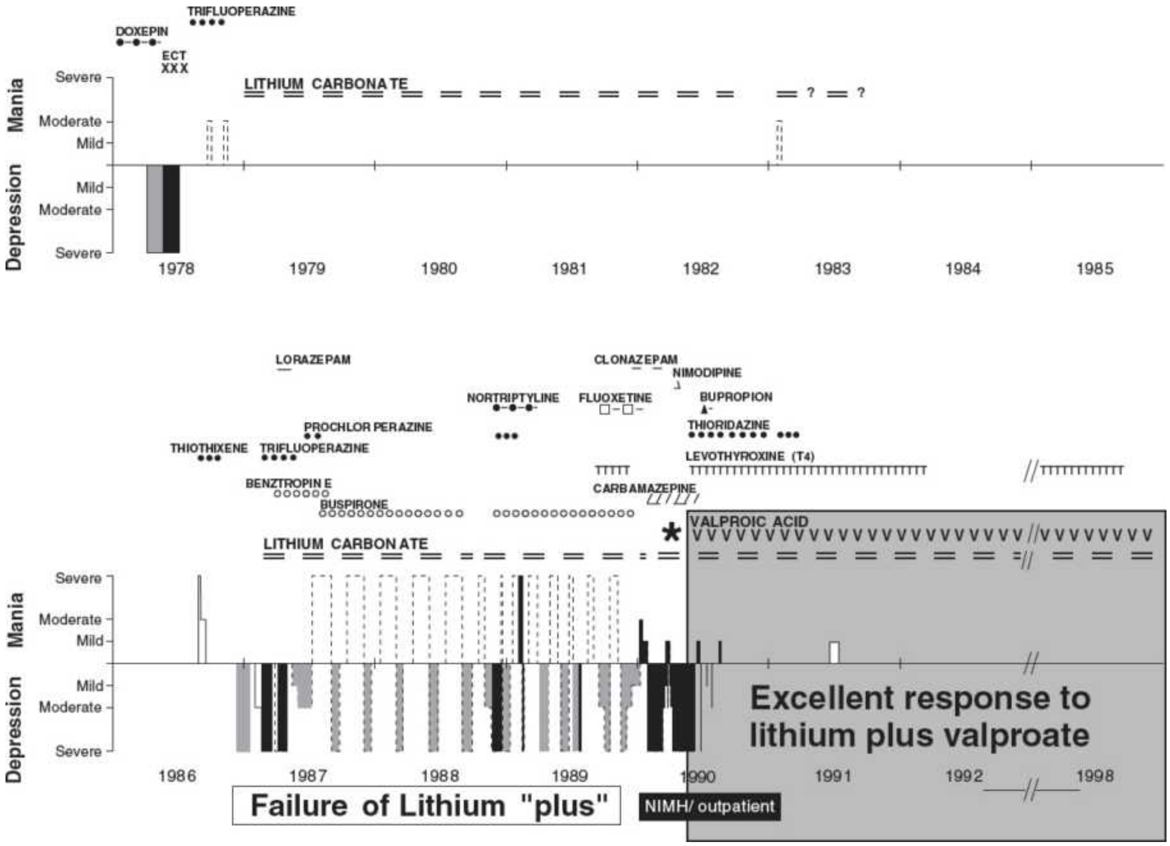

FIGURE 33.10e–3. Valproate augmentation in a lithium-refractory bipolar patient with profound recurrent psychotic depression. Reemergence of the illness in 1986 was unresponsive to the reinstitution of lithium, buspirone, a variety of antidepressants, adjunctive antipsychotics, and minor tranquillizers. Carbamazepine, alone and in combination with lithium, was effective in reducing the amplitude of the manias, but had no impact on the patient's severe psychotic, delusional depressions. When carbamazepine was discontinued and valproate was added to lithium, the patient soon started to improve and reached a complete and sustained remission for the first time in 5 years. Her remission, illustrated in the figure from 1990 to 1998, persisted through 2008. ECT, electroconvulsive therapy.

Schizophrenia and Schizoaffective Disorder

There are no controlled studies of valproate in the treatment of schizoaffective disorder. Clinically, the treatment regimen of schizoaffective disorder usually includes a mood stabilizer, such as valproate, carbamazepine, or lithium, and an atypical antipsychotic.

Recent prevalence data have suggested that the use of valproate alone and in combination with atypical antipsychotics has substantially increased, and the use of lithium has decreased, but whether these trends reflect relative effectiveness or some other variable is not known.

Although mood stabilizers are not identified as first-line agents in the treatment of schizophrenia, valproate may be useful as an accelerating agent to antipsychotic therapy. In a 28-day, double-blind, parallel-group, multicenter trial of 249 patients who were hospitalized with an acute psychotic exacerbation of schizophrenia, subjects were randomized to one of four treatments: (1) olanzapine monotherapy (15-mg fixed dose by day 15), (2) risperidone monotherapy (6-mg fixed dose by day 15), (3) olanzapine plus divalproex (15 mg/kg/day on day 1, titrated as clinically indicated to a maximum dose of 30 mg/kg/day by day 12), or (4) risperidone plus divalproex. Statistically significant differences favoring the combination groups were noted as early as day 3 and maintained significance through day 21 in positive but not negative symptoms. Moreover, at the final day-28 visit, there was no significant difference in PANNS total score reduction in the monotherapy groups versus the combination groups. Weight gain was not significantly different between the olanzapine–divalproex group (8.3 lb) versus the olanzapine group (7.7 lb); however, there was significantly more weight gain in the risperidone–divalproex group (7.5 lb) versus the risperidone alone group (4.2 lb).

This study suggests that the time course of treatment response of antipsychotic therapy (specifically, positive symptom severity) can be accelerated with divalproex, but the potential pharmacoeconomic and the utility of the short-term benefits remain uncertain.

Alcohol Withdrawal and Relapse Prevention

Divalproex, carbamazepine, and gabapentin have all been studied in the treatment of alcohol withdrawal. Although the intermediate (diazepam [Valium]) and long-acting benzodiazepines (lorazepam [Ativan] and clonazepam [Klonopin]) are the standard established agents for alcohol detoxification, comparative studies have shown that carbamazepine decreases global distress more than oxazepam and anxiety more than lorazepam.

In an open-label, 5-day study involving patients undergoing a standard protocol for alcohol detoxification, as needed dosing of lorazepam, with or without divalproex (500 mg by mouth three times a day), was given based on a Clinical Institute Withdrawal Assessment for Alcoholism, revised (CIWA-A-R) score. Although the CIWA-A-R score reduction was not significantly different, the cumulative lorazepam dosage was lower in the group that received divalproex. The treatment was well tolerated without significant side effects or hepatocellular enzyme elevation. In a second study of 23 inpatients hospitalized for dysphoric mania complicated by substance use (primarily alcohol), treatment of the comorbidity with divalproex resulted in not only dysphoric symptom reduction (as measured by the YMRS and Hamilton Rating Scale for Depression) but also effective alcohol withdrawal and abstinence over the course of 20-week prospective follow-up. Mild hepatocellular enzyme elevation (not greater than three times normal) at the time of admission, presumably related to alcohol ingestion, decreased over the study period.

Alcohol relapse prevention (i.e., maintaining sobriety after alcohol detoxification) has also been evaluated with the mood-stabilizing anticonvulsants carbamazepine and valproate. In a 12-month, placebo-controlled study in 29 alcohol-dependent patients, carbamazepine treatment was associated with a decrease vs. increase in the time to return to heavy drinking and a decrease in the number of drinking measures at 2- and 4-month follow-up. Recent data have suggested similar effectiveness with divalproex. Twenty-nine outpatients with alcohol dependence participated in a 12-week, double-blind, placebo-controlled pilot trial of divalproex (mean divalproex level at week 12 was 88.2 μg/mL). There was a greater reduction in irritability in the divalproex treatment group, and a smaller percentage of divalproex-treated patients relapsed to heavy drinking (37%) compared with placebo-treated patients (63%; $P \le .05$). Given the extensive comorbidity of alcoholism with other axis I disorders, particularly bipolar I and II disorders, treatment with valproate may stabilize mood and help treat components of alcoholism (withdrawal and relapse prevention). These results have now been replicated and extended.

In a 24-week, double-blind, placebo-controlled study of bipolar patients with comorbid active alcoholism maintained on lithium and psychosocial treatment as usual, valproate showed greater effects than placebo on several measures of drinking. Of the 25 patients randomized to placebo, 68% returned to heavy drinking compared with 44% of the 27 randomized to divalproex ($P = .02$). Liver function tests, ALT, and AST did not differ, while GTP (γ-67P) was higher in those on placebo and was correlated with the amount of alcohol consumed per week. Of those who did return to heavy drinking (four or more drinks per day for women; five or more drinks per day for men), time to relapse was also significantly delayed for those on divalproex (93 days) compared with 62 days on placebo ($P = .02$).

Although other agents are effective in primary alcohol dependence (i.e., naltrexone [ReVia] and acamprosate [Campral] [which are FDA approved], and now effectiveness is seen with topiramate in two large randomized controlled trials and also gabapentin), none have been specifically studied in bipolar patients with comorbid alcoholism with the exception of valproate, making it a particularly good agent for such dual diagnosis patients. It is noteworthy that in patients with bipolar illness, women are 7.35 times and men 2.8 times more likely than those in the general population to have problems with alcohol use and abuse. Greater amounts of depression and anxiety were correlated with the women who abused alcohol, suggesting that it was a form of self-medication and that earlier and more effective intervention on these target symptoms potentially could have lessened the incidence of alcohol comorbidity.

Panic Disorder

Several open-label studies suggest that valproate may be effective in treating panic attacks. In one open-label study of lactate-induced panic attacks, valproate effectively blocked the reintroduction of panic attacks on lactate rechallenge in 10 of 12 patients; furthermore, 71% of patients had a greater than 50% reduction in panic attack frequency, with 43% achieving complete remission. These data are consistent with the marked decreases in anxiety when valproate is used in the treatment of bipolar depression. However, in a double-blind, placebo-controlled, crossover study, 35 patients with panic disorder responded equally well to valproate and placebo.

Post-Traumatic Stress Disorder

Valproate has been investigated in several open trials (total $N = 53$) of patients with combat-related PTSD. The first open trial noted a decrease in avoidance and hyperarousal but no change in intrusive symptoms. In the first 8-week study, adjunctive valproate (mean dose of 1,365 mg, mean serum level of 80 μg/mL) was associated with a significant decrease in intrusion and hyperarousal but no change in avoidant symptoms. In the second 8-week open trial, which included a 2-week washout with a majority of patients on monotherapy, valproate (mean dose of 1,840 mg ± 270 mg, the mean level of 69 μg/mL ± 29 μg/mL) was associated with a significant reduction in all symptom clusters of intrusion, avoidance, and hyperarousal.

Further clinical studies of valproate in the extinction of conditioned fear would appear appropriate in light of preclinical data that valproate specifically increases the promotor of a BDNF variant that is involved in the new learning that is necessary for the extinction of conditioned fear. It is likely that the effects of valproate as a histone deacetylase inhibitor are involved in this effect.

Impulse Control Disorder

Several impulse control disorders, such as intermittent explosive disorder, pathologic gambling, and kleptomania share some clinical features with mania. Valproate has been investigated in several case reports and open trials with generally positive results, particularly if manic or mixed symptoms were present. One hundred and sixteen patients with intermittent explosive disorder were part of a 12-week, randomized, placebo-controlled study evaluating valproate in the treatment of impulsive aggression; in this study, only patients with impulsive aggression associated with borderline personality disorder responded to valproate. A second controlled, single-blind study randomized patients with pathologic gambling, those taking lithium or valproate showed significant improvement.

Highly significant effects of valproate compared with placebo in a crossover design were seen in children and adolescents with an explosive temper and a disruptive behavioral disorder (oppositional defiant disorder or conduct disorder). These children were also severely mood-dysregulated, and some may have met criteria for bipolar not otherwise specified, but they were not bipolar II or bipolar I and did not have a high incidence of a family history of bipolar disorder in first-degree relatives.

These findings are of considerable importance because they suggest the utility of valproate in children with explosive aggression (86% response on valproate vs. 25% on placebo), even in those who do not meet the criteria for bipolar disorder. The fact that these irritable, hostile, and aggressive children show marked improvement over placebo and that in another study of children with more classic bipolar presentations meeting DSM-IV criteria, valproate did not separate from placebo suggests the usefulness of valproate in just this area of greatest diagnostic controversy, that is in those who are the highly impaired by their irritability and dyscontrol but may or may not end up in the bipolar diagnostic spectrum.

Further concerted study in this area and in those with conduct disorder would be of great clinical importance.

Borderline Personality Disorder

Several open trials have suggested valproate's effectiveness in some symptom domains in patients with borderline personality disorder (i.e., mood lability, irritability). In one 10-week, placebo-controlled study, 12 patients treated with valproate (mean dose of 750 mg) had nonsignificant improvement in global symptom severity and functioning compared to patients treated with placebo. A second, 6-month, placebo-controlled study of 30 euthymic bipolar II disorder patients who also met the criteria for borderline personality disorder were randomized to divalproex (mean dose of 850 mg) versus placebo. The primary outcome variable was the mean change in symptom checklist-90 (SCL-90) scales of interpersonal sensitivity, anger and hostility, and depression and the Overt Aggression Scale, modified (OAS-M). In a last-observation-carried-forward analysis, controlling for baseline severity, divalproex was more effective than placebo in reducing interpersonal sensitivity, anger and hostility, and aggression.

Another 12-week, randomized, placebo-controlled study evaluated the effectiveness of divalproex in the treatment of impulsive aggression in patients with borderline personality disorder ($N = 96$), intermittent explosive disorder ($N = 116$), and PTSD ($N = 34$). The primary outcome variable, the mean score reduction in the OAS-M obtained during the last 4 weeks of treatment, did not show a significant treatment difference in those patients treated with divalproex versus those treated with placebo. However, when the data were analyzed by the diagnostic subgroup, there were significant treatment differences in patients with borderline personality disorder ($\chi^2 = 3.95$; $P = .047$) but not in those with an intermittent explosive disorder or PTSD, in measures of aggression, verbal assault, assault against objects, and assault against others but not in an assault against self. There was a significant reduction in irritability, as measured by the OAS-M Irritability score, and severity of illness, as measured by the Clinical Global Impression (CGI) Scale. The mean dose of divalproex was 1,404 mg (with a range between 500 and 2,250 mg), with a corresponding serum level of 65.5 μg/mL (with a range between 0 and 147 μg/mL).

Behavioral Agitation of Dementia

Several open-trial investigations had suggested valproate's effectiveness in reducing behavioral agitation associated with dementia. The dose was generally lower than that used in other conditions, most likely reflecting an older patient population and a pharmacokinetic profile characterized by decreased protein-binding capacity. However, the one double-blind, placebo-controlled, 6-week study of higher doses of divalproex in the treatment of manic symptoms in older adult demented patients was suspended prematurely because of a disproportionate rate of adverse events (primarily sedation and thrombocytopenia) and dropouts (noncompliance) reported with divalproex compared to placebo. At the time of study suspension, 85 patients had been randomized to placebo, and 87 had been randomized to divalproex (median dose of 1,000 mg daily or 18 mg/kg/day, mean weekly serum valproate levels ranging from 55.3 to 68.9 μg/mL). Although there was no significant difference in the primary outcome as measured by the Bech–Rafaelsen Mania Scale, there was a greater reduction in the Cohen–Mansfield Agitation total score (noted as early as week 2 and maintained throughout the 6-week period) and the verbal agitation subscale score at week 6. This study suggests that, although agitation can be reduced with valproate, many older adult patients may not be able to tolerate an aggressive dosing strategy (18 mg/kg/day).

THERAPEUTIC INDICATIONS

Neurologic Conditions

Valproate is currently approved by the FDA for (1) monotherapy or adjunctive therapy of complex partial seizures that occur in isolation or in conjunction with other types of seizures, (2) monotherapy and adjunctive therapy of simple and complex absence seizures, and (3) adjunctive therapy for patients with multiple seizures that include absence seizures. Divalproex has an FDA indication in these same epilepsy syndromes but additionally has indications for (4) prophylaxis of migraine. The ER preparation is approved for seizures, acute mania, and migraine.

Psychiatric Conditions

Valproate and carbamazepine ER are currently the only mood-stabilizing anticonvulsants that are FDA approved for the treatment of acute mania associated with bipolar disorder. Based on open studies and case series in treatment-refractory and rapid-cycling patients, valproate has also been widely used in the prophylactic treatment of recurrent mania and depression, although the database for this is meager. Moreover, caution is urged in the use of valproate in women of childbearing age, as emphasized below.

Valproate has been shown to be particularly effective in acute mania with depressive, dysphoric, and mixed symptoms, acute mania associated with a rapid-cycling course of illness specifier (four or more episodes in a 12-month period), and acute dysphoric mania complicated by substance abuse, particularly alcohol abuse and dependence (Table 33.10e–3). Given its current neurologic FDA indications, valproate may be particularly useful in bipolar disorder complicated by seizure disorder, electroencephalogram (EEG) abnormalities, head trauma, and migraine. Outside of formal DSM-IV-TR diagnoses, valproate appears to be effective on target symptoms of irritability, aggressiveness, mood lability, and impulsivity.

PRECAUTIONS

Serious Adverse Reactions

Rare serious side effects—as noted in the FDA black box warnings—include hepatic failure, pancreatitis, and hyperammonemic encephalopathy associated with patients with urea cycle disorders. However, baseline or serial laboratory monitoring does not necessarily predict severe hepatotoxicity or pancreatitis, and close clinical observation appears superior to routine clinical monitoring in this regard. Additional warnings include sedation in older adults and thrombocytopenia.

Valproate is rated pregnancy category rating D, as noted by increased risk (1% to 4%) of neural tube defects, such as spina bifida (Table 33.10e–6). Recent studies have also highlighted the notable occurrence of other teratologic effects. The rate of any adverse outcome (a major congenital malformation or fetal death) was higher with valproate (20.3%) than with phenytoin (Dilantin) (10.7%), carbamazepine (8.2%), or lamotrigine (1.0%), and, the adverse events with valproate were dose-related.

Table 33.10e–6.
Black Box Warnings and Other Warnings

More Serious Side Effect	Management Considerations
Hepatotoxicity	Rare, idiosyncratic event Estimated risk 1:118,000 (adults) Greatest risk profile (polypharmacy, younger than 2 years of age, mental retardation) → 1:800
Pancreatitis	Rare, similar pattern to hepatotoxicity Incidence in clinical trials data is 2 of 2,416 (0.0008%) Postmarketing surveillance shows no increased incidence Relapse occurs with rechallenge Asymptomatic amylase not predictive
Hyperammonemia	Rare—more common in combination with carbamazepine (Tegretol) Associated with coarse (flapping) tremor and may respond to L-carnitine administration
Associated with urea cycle disorders	Discontinue valproate and protein intake Assess underlying urea cycle disorder Divalproex is contraindicated in patients with urea cycle disorders
Teratogenicity	Neural tube defect: 1–4% with valproate; high incidence of other congenital anomalies; developmental delay substantial and IQ decreases prominent, averaging 10 IQ points. Abnormalities may be more frequent in women with epilepsy than those treated for bipolar disorder. Preconception education and folate plus vitamin B complex supplementation and relative avoidance of valproate for women of childbearing potential
Somnolence in older	Slower titration than conventional doses

adults	Regular monitoring of fluid and nutritional intake
Thrombocytopenia	Decrease dose if clinically symptomatic (i.e., bruising, bleeding gums) Thrombocytopenia more likely with valproate levels ≥110 μg/mL (women) and ≥135 μg/mL (men)

Adapted from *Physician's Desk Reference.* Medical Economics Company; 2002.

In a cohort study of 913,302 Danish children, prenatal valproate exposure was associated with 4.5-fold increased risk of intellectual disability and a 6-fold increased risk of combined outcome of intellectual disability and delayed childhood milestones compared with children with no prenatal valproate exposure. Other antiepileptic drugs, including carbamazepine, clonazepam, and oxcarbazepine, but not lamotrigine, were also found to be associated with an increased risk of intellectual disability. Of note, however, in the small number of women exposed to valproate who did not have an epilepsy diagnosis, the risks were not increased and were equal to those of unexposed controls.

In addition, behavioral teratologic effects have also been reported. A syndrome of moderate to severe developmental delay has been identified, with a small percentage having severe retardation and an intelligence quotient (IQ) below 70. Thus, it would appear that avoiding pregnancy during valproate treatment or switching to other less problematic agents when planning for pregnancy is of very great importance. However, two studies have suggested that women with epilepsy are particularly vulnerable to these adverse outcomes, and the magnitude of the relationship to women with other diagnoses exposed to valproate remains uncertain.

Although neural tube defects can be monitored for and detected with modern techniques (i.e., fetal ultrasound in weeks 18 to 20; α-fetoprotein; and, if needed, amniotic fluid at 16 weeks), there is currently no way of predicting the behavioral deficits which, upon follow up of children exposed to valproate in utero, appear substantially more severe than with other anticonvulsants. For example, in those exposed to valproate, the IQ measured at 3 years of age averaged 9 points lower than those exposed to lamotrigine. Valproate's use in combination with other agents also appears to be an additional risk factor.

Valproate has also been associated with a many-fold increased risk for autism of childhood or lifetime onset. This increased clinical risk has been validated in animal models of fetal exposure to valproate.

Given the evidence of a highly elevated risk for neural tube and other teratologic defects and for lower IQ, most neurologists attempt to avoid the use of valproate in women with epilepsy who wish to become pregnant. If the use of valproate is unavoidable because of failure of other agents, most would recommend the use of folic acid and vitamins B_6 and B_{12} in the hope of ameliorating the known risks to the fetus, in addition to careful attention to the optimal forms of birth control.

These cautions would also appear appropriate to women of childbearing age who have bipolar disorder. The characteristics of mania itself, such as hypersexuality and poor judgment, make the risk of an unplanned or unwanted pregnancy even more likely. Thus avoidance of the use of valproate in these women would appear indicated, and in the absence of other alternative treatments, special emphasis on the importance of birth control and adjunctive use of folate, B_6 and B_{12}. It is noteworthy, however, that the high risks for birth defects and developmental delay appear to be more prominent in women with epilepsy than in those with bipolar disorder. It has been suggested that the analog of valproate valnoctamide has both anticonvulsant and antimanic efficacy and may have a lesser likelihood of congenital malformations based on studies in laboratory animals. This drug may have lesser potency as a histone deacetylase inhibitor which some have posited as the mechanism of valproate's teratogenic effects.

Valproate has been classified as compatible with breastfeeding, as case reports have consistently reported low concentrations (1% to 10% of the mother's serum level) of valproate in breast milk.

Several preclinical studies have suggested that valproate can stimulate human immunodeficiency virus 1 (HIV-1) and hepatitis C virus (HCV) replication. Although small clinical studies in HIV-1–infected and HCV-infected patients do not confirm these preclinical observations, close clinical monitoring is recommended.

In long-term toxicity studies in rats, valproate was associated with an increase in pulmonary adenomas and fibrosarcomas. There is no evidence to suggest a carcinogenic effect in humans, and on the contrary, there is considerable evidence of an antineoplastic effect in several tumor types, including chronic myelogenous leukemia (CML).

On the side of possible benefit in the future, valproate can reopen critical periods of synaptic plasticity, rendering the possibility of allowing new input in adulthood to reverse some effects of earlier experience.

Minor Adverse Reactions

Common side effects include gastrointestinal (GI) distress, tremor, sedation, benign hepatic transaminase elevation, leukopenia, thrombocytopenia, hair loss, increased appetite, and weight gain (Table 33.10e–7). Despite weight gain, there are no increases in triglycerides or total cholesterol. Generally, most of the common side effects are dose-related and can often be minimized by dose reduction, dose consolidation, or adjunctive pharmacotherapy.

Table 33.10e–7.

Some Valproate Side Effects and Their Potential Management

Side Effect (Frequency)	**Potential Treatments**	**Support**	**Comment**
GI distress (O)	Switch to enteric coated preparation Add H_2 blocker Give with meals or all H.S.	++ + +	Effect may be additive with lithium
Tremor (O)	↓ dose Switch to ER formulation Add Propanolol	+ + ±	Additive with lithium?
Weight gain (O)	Early diet and exercise instructions Augment with topiramate, zonisamide	++ ++ ++	Additive with lithium?
Alopecia (hair loss) (UC)	Prophylaxis with zinc and selenium supplements	+	Straight hair may grow back curly
Thrombocytopenia (low platelets) (UC)	Discontinue valproate	++	Monitor for bleeding
PCO syndrome (UC)	Treatment with oral contraceptives will prevent PCOs Switch to lamotrigine	++ ++	Menstrual irregularities may precede use of VPA and may increase on VPA Testosterone not ↑ in 4 of 5 studies Hirsutism rare

Avoid pregnancy

O, occasional; UC, uncommon; VR, very rare; C, common; D, dose related; PCO, polycystic ovaries; PCOs, polycystic ovarian syndrome; H_2, histamine; ER, extended release; VPA, valproate; RUQ, right upper quadrant; GI, gastrointestinal; EEG, electroencephalogram; ?, ambiguous or uncertain.

Valproate causes dose-related increases in homocysteine, and for this reason, most clinicians would recommend routine cotreatment with folate to reduce this risk.

The relationship between valproate, polycystic ovaries, and polycystic ovarian syndrome (menstrual irregularity and clinical evidence of hyperandrogenism) remains controversial because patients with epilepsy and obesity appear to be at increased risk for the syndrome. Studies in women with bipolar disorder taking valproate or lithium have reported conflicting results. In one study of 22 outpatients, most patients reported menstrual irregularity, but none of them had evidence of significant hirsutism on physical examination or hormonal evidence consistent with polycystic ovarian syndrome. In another study of 32 bipolar outpatients, 7 patients currently on valproate and experiencing menstrual problems had evidence of hyperandrogenism (hirsutism and elevated testosterone).

Rasgon and colleagues again found a high incidence of menstrual irregularities in women with bipolar illness prior to treatment, and these increased further with valproate therapy. Hirsutism and significant elevation of serum testosterone were not observed, however.

In contrast, data from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) group did find statistically significant testosterone increases in valproate and, rarely, hirsutism. Thus, it would appear that there is a clear pretreatment increased risk of polycystic ovarian syndrome (menstrual irregularities, weight gain, increases in testosterone, even without polycystic ovaries themselves) and polycystic ovaries in women with epilepsy, which is further exacerbated by valproate. However, in women with bipolar disorder, polycystic ovarian syndrome at baseline pretreatment is relatively uncommon, and exacerbation by valproate is less apparent and more inconsistent.

Previous studies in epilepsy have been unable to fully assess baseline endocrine profile before valproate treatment, the impact of nonspecific weight gain as a risk factor for the development of polycystic ovarian syndrome, and the extent to which epilepsy and bipolar disorder are independent risk factors unrelated to medication exposure. All aspects of the syndrome are reversible in patients with epilepsy, especially if valproate is discontinued and lamotrigine is substituted. Menstrual history and weight should be followed carefully in women of reproductive potential who begin treatment with valproate. Since polycystic ovarian syndrome can be mitigated by birth control pills, this side effect should be discussed but should not preclude women with bipolar illness from treatment with valproate. More pressing is the need to inform women, particularly those with epilepsy, of the major risks to the fetus should they become pregnant, as discussed above.

DRUG INTERACTIONS

Valproate and Other Psychotropics

Lithium and valproate are often used in combination, and additive side effects of tremor or cognitive dulling can often be treated with dose reduction. Additive problems with weight gain can be more daunting. Recent use of the combination of bupropion ER 150 to 300 mg with naltrexone 50 mg has produced dramatic weight loss in many individuals, but this regimen has not been systematically studied for valproate or its combination with lithium. Additive GI problems and dyspepsia can be treated with adjunctive agents histamine 2 (H_2) antagonists.

More recently, atypical antipsychotics and valproate have been used together, with increased sedation (olanzapine) and weight gain (risperidone) reported as side effects. It is noteworthy, however, that valproate may prevent the increases in cholesterol induced by some atypical antipsychotics. This is thought to be attributable to valproate’s influence on peroxisome proliferator-activated receptors (P-PARs), which increase β-oxidation and are transcription factors in steroid–thyroid hormone–retinoic receptor superfamily.

Valproate has also been used as an adjunctive mood stabilizer and anticonvulsant in patients treated with clozapine. In fact, for patients who have had a seizure related to high-dose clozapine, valproate is the preferred agent over carbamazepine, given its risk of agranulocytosis. The combination is generally well tolerated, with the exception of sedation and weight gain.

There are clinical data to suggest greater efficacy and good tolerability of the lamotrigine–valproate combination for the treatment of complex-partial epilepsy compared with either drug alone. Given valproate's efficacy in acute mania and lamotrigine's efficacy in acute bipolar depression, it is likely that the two will be used together in psychiatric practice. Given valproate's plasma protein–binding capacity and its metabolic inhibition of lamotrigine, free levels of lamotrigine are doubled when used in combination with valproate; to reduce the risk of serious rash, the initial dose, rate of titration, and final dose of lamotrigine should be reduced by approximately 50% of the standard monotherapy recommendations when combined with valproate.

Two case series suggesting efficacy of the valproate–carbamazepine combination for refractory rapid-cycling bipolar disorder have been reported. The pharmacokinetics of this combination warrants clinical anticipation and monitoring, however. Adjunctive carbamazepine, as well as its cytochrome P450 3A4 autoinduction and heteroinduction, generally reduces levels of valproate, which are typically not consequential. However, valproate increases levels of free carbamazepine and its active metabolite by displacement from plasma protein. Valproate also increases levels of carbamazepine-10,11-epoxide by inhibiting its metabolism via epoxide hydroxylase to the inactive diol metabolite. Thus the increases in the carbamazepine-10,11 epoxide may not be evident if only carbamazepine levels alone are measured. Given these pharmacokinetic interactions, side effects of the combination generally are related to increased levels of carbamazepine and its active carbamazepine-10,11 epoxide, potentially yielding diplopia, ataxia, sedation, and confusion in those already near their carbamazepine side-effect threshold. Lowering the carbamazepine dose in anticipation of adding valproate will generally avoid this difficulty (Table 33.10e–8).

Antidepressants are often used in combination with valproate, although the efficacy of this approach has recently been questioned. There are case reports of the tricyclic antidepressant amitriptyline increasing valproate concentrations and, conversely, valproate increasing the levels of tricyclics. Additionally, adjunctive fluoxetine (Prozac) has been reported to increase serum levels of valproate.

Table 33.10e–8.
Pharmacokinetic Interactions of Valproate

Metabolic Interactions		
VPA → ↑ Drug	**Drug → ↑ VPA**	**Drug → ↓ VPA**

Valproate and Other Drugs

In contrast to carbamazepine, the primary pharmacokinetic liability of valproate is related to its plasma protein–binding capacity and the inhibition of other drugs metabolized by the liver. For example, valproate increases the free concentration of diazepam by plasma protein–binding site displacement and also has been shown to decrease the serum level of a diazepam metabolite *N*-desmethyldiazepam. Close clinical monitoring of this coadministration is indicated to avoid any potential for diazepam toxicity. Similar observations (i.e., binding displacement or inhibition of metabolism, or both) have been noted with ethosuximide (Zarontin), phenobarbital (Barbital), chlorpromazine, and aspirin.

Because valproate has been shown to inhibit the secondary phase of platelet aggregation, close clinical monitoring is indicated when using the drug with other drugs that affect coagulation, such as aspirin and warfarin (Coumadin).

VALPROATE AND LABORATORY INTERFERENCE

Valproate occasionally interferes with the results of laboratory tests. As a fatty acid, serum levels, if measured, reflect an increase. Valproate metabolites may produce a false-positive result in urine analysis for ketones.

DOSAGE AND ADMINISTRATION

In the outpatient setting, one should obtain a baseline hepatic panel and complete blood cell count before starting a patient on divalproex, although this can be ordered concomitantly with or after starting medications in more urgent treatment indications for hypomania or full-blown mania. An appropriate starting dose is 250 mg three times per day, with increases of 250 to 500 mg every several days to a therapeutic threshold (serum level greater than 50 mg/L). Once a steady-state dosage has been achieved, consolidating to bedtime dosing maximizes treatment adherence. The divalproex-ER preparation also lends itself well to single nighttime dosing. Rapid loading of divalproex (20 mg/kg/day) in acute mania has produced therapeutic serum levels more quickly than standard titration and has generally been well tolerated. However, high-dose IV valproate (20 mg/kg) over 30 minutes was not effective, and aggressive titration of the ER preparation was not more effective than less aggressive regimens. These findings add to the suggestion that actions induced by chronic administration of the drug are necessary for its antimanic and other psychotropic effects and suggest that more modest dosing strategies are likely to be as effective, produce fewer side effects, and be more clinically prudent.

33.10f Lithium

Robert H. Belmaker, M.D.

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Yet to be determined
Mechanism of Action	Enzyme interaction

The discovery of the use of lithium in medicine is usually attributed to John Cade in Australia in the late 1940s, whose work based on a theory that increased blood uric acid is the cause of mania. This theory is almost certainly false. However, historical records find that Hammond used lithium for acute mania in the mid-1800s in New York, and in the late 1800's Lange in Denmark used lithium for periodic depression. The message of this historical record for the clinical psychiatrist may be a more general truth about how ideas often have multiple sources and origins and can rarely be ascribed to a single individual. The finding that lithium salts are helpful in mania was developed into a concept that the lithium ion is a specific treatment for manic–depressive illness. This concept was highly heuristic but is not supported by the empirical clinical data available today (see below).

The use of lithium in mania was greatly delayed by the widespread toxicity of lithium chloride as a table salt substitute in congestive heart failure patients. Mogens Schou's classic controlled clinical trials of lithium in bipolar patients showed safety and efficacy in the prevention of both manic and depressive attacks in the disorder using monitoring of blood levels by flame photometry and led to the introduction of lithium treatment widely in Europe and then in the United States, the first limited treatment beginning in 1970. Sam Gershon described lithium as "the first salvo in the psychopharmacologic revolution."

Lithium was not and is not a patentable discovery, and no pharmaceutical company promoted its research, distribution, and marketing. Its development as a psychotropic compound was overshadowed by the introduction of chlorpromazine and the early neuroleptics in the 1950s, which were easier to use, did not require blood tests, and had a wider therapeutic index. However, the use of lithium salts in psychiatry developed a fascinating mystique: A simple ion, which is not metabolized anywhere in the body and is excreted the same way it is ingested, a compound that is mined as an ore in the earth rather than being synthesized in a factory, a compound that seemed so closely related to the body's natural physiologic mechanisms of electrical neurotransmission using sodium and potassium—these facts all created a scientific excitement around the hypothesis that lithium might be the key to understanding the basic biochemistry and neurophysiology of bipolar disorder (then known as manic–depressive illness). Moreover, the introduction of chlorpromazine and its congeners for the treatment of schizophrenia and imipramine and its congeners for the treatment of depression supported the concept that lithium is "specific" for bipolar disorder. This made the scientific opportunities for studying it even more tantalizing, and it also fits into the emerging desire for psychiatry in the second half of the 20th century to see itself as a medical discipline with specific illnesses and specific treatments. The goal of the current chapter is to provide necessary information to the clinical psychiatrist to choose and use lithium for the treatment of appropriate patients and not to subscribe to any ideology of treatment.

CHEMISTRY

Lithium is the third lightest element after hydrogen and helium and exists in the periodic table in the same column as sodium and potassium, which are physiologically critical substances for all life but particularly important in the propagation of the nerve signal. Lithium is a metal used in aeronautics, and its ion is extremely important in batteries as well (Fig. 33.10f–1). Most PubMed searches of lithium find far more articles about lithium in airplane wings and batteries than lithium in bipolar disorder. However, these uses are unrelated, and it should be clear that only the lithium ion is medically useful.

PHARMACOKINETICS AND PHARMACODYNAMICS

Lithium is completely absorbed from the gastrointestinal tract within a few hours of oral administration without regard to simultaneous food ingestion. It is absorbed into the bloodstream and is gradually eliminated by the kidney into the urine. It is water-soluble and lipophobic. It does not seem to interact directly with extracellular receptors but needs to cross the cell membrane into the cytoplasm in brain cells to have its effect. Lithium is absorbed equally well whether it is administered as the carbonate, orotate, sulfate, citrate, or chloride because these salts, of course, dissolve in the aqueous medium of the stomach. Preparations that have been commercially claimed to be “slow-release” with the aim of reducing the peak lithium level in the plasma and thereby reducing side effects are of questionable chemical validity as it is difficult to make a simple salt into a reliable slow-release preparation. It is far easier to tell a patient who has mild gastric acidity or nausea a few hours after ingestion to simply divide his lithium tablet into two half-doses and take them a few hours apart. At the other extreme are those who have advocated that patients take their whole daily dose as a single before-bed dose, the average dose being four tablets of 300 mg lithium carbonate each. Some small studies have found such administration to have equal clinical efficacy but fewer side effects. However, such administration leading to a single peak blood level with a long trough throughout most of the day is pharmacologically counterintuitive for a hydrophilic ion that must pass through a lipid cell membrane in order to achieve therapeutic levels in the cytoplasm. Most clinicians recommend giving lithium three times a day to minimize side effects and maximize the achievement of steady intracellular blood levels. Lithium salts should never be given intravenously as this can cause cardiac arrhythmias.

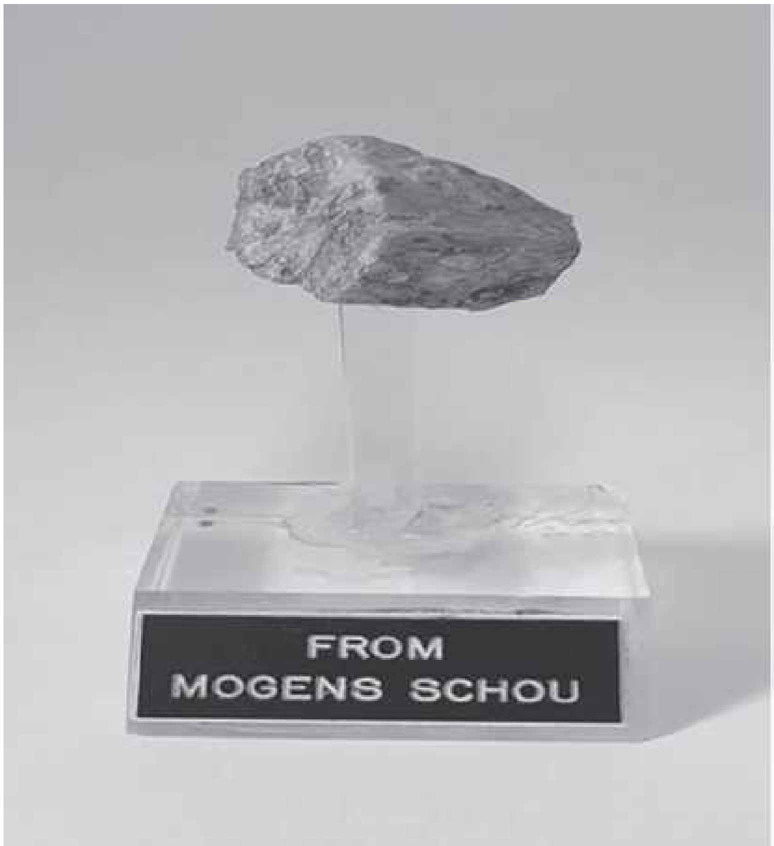

FIGURE 33.10f–1. Lithium ore, a gift from Mogens Schou to the author in 1976.

Lithium enters cells by complex mechanisms, including several distinct sodium channels. Intracellular lithium levels in the red blood cell are about two-thirds of those in plasma and were claimed at one point to be predictive of brain levels and clinical response. This seems not to be the case. Excitable cells (neurons) propagate the nerve signal by a successive opening of the voltage-activated sodium channel and an inrush of sodium ions. Some have claimed that lithium enters nerve cells in the brain by this mechanism, but the issue has not been decided. There may be differences in intracellular lithium blood levels between different areas of the brain, and this is currently being studied in the human brain, measuring lithium with advanced magnetic resonance imaging techniques.

Lithium, when started in acute mania at average doses of 300 mg lithium carbonate three or four times daily, accumulates gradually in plasma and distributes increasingly into the intracellular space reaching an equilibrium state after about 10 days. There is no metabolism of the lithium ion, which is excreted by the kidney with a half-life of about a day if renal filtration is normal. Dehydration, hyponatremia, and other conditions can decrease lithium excretion markedly. Blood levels should be determined in the morning before the first daily lithium dose of the day as these are felt to be most predictive of intracellular levels. Blood levels should be determined after 10 days of treatment at a specific dose. Blood levels taken earlier than this may deceive the clinician into thinking that the level is within the therapeutic window while the patient goes on over the coming days to accumulate lithium and go into toxicity. Thus, the pharmacokinetics of lithium is a very practical topic for every psychiatrist who uses it. Adjustment of dose should rarely be done at intervals of less than 10 days. The exception might be at the very beginning of lithium treatment when the first doses might be administered as one or two tablets to establish tolerance and patient acceptance.

The pharmacodynamic effect of lithium in the treatment of acute mania usually becomes apparent after 10 days, a somewhat shorter interval than the 3 weeks usually reported for the onset of treatment effects with monoamine enhancers or dopamine blockers. It has been speculated that the delay of 10 days in the case of lithium is related to the delay in achieving intracellular pharmacologically active cytoplasmic levels. Some clinicians have tried to give large loading doses of lithium in the first few days in order to speed up the response to treatment and drive the lithium ion into brain cells. This should be done only in carefully controlled conditions where daily blood levels are available and internal medicine consultation is accessible.

The pharmacodynamics of lithium in the prophylaxis of bipolar disorder suggest that a lithium-treated group shows fewer relapses compared to a control group by the end of the first period of measure, usually 2 weeks or 1 month. Upon lithium cessation after long prophylaxis, some rebound may occur where the lithium-treated group has increased relapse compared to the control group. Tapered discontinuation is advised, usually with overlapping initiation of a different mood stabilizer.

Overdose of lithium can be pharmacokinetically confusing. An overdose patient might arrive at the emergency room with a history of ingesting a large number of tablets and have a blood level in the emergency room of 10 mM, known to be highly toxic. He could be completely asymptomatic even at this blood level. However, if this patient is sent home, he will probably arrive the next morning comatose. The explanation is that the lithium in the stomach is absorbed into the blood but takes many hours, even at this high blood level, to get into the cells, where its pharmacologic effects then become apparent. The opposite case is that of the patient who has taken lithium chronically, sometimes for years, at stable blood levels and who neglects his follow-up and continues the same dose while he ages or starts a low sodium diet or increases his lithium dose because of low mood, without adequate blood level monitoring. He may gradually develop lithium toxicity with severe symptoms (see below), including diarrhea and seizures even at a blood level of 2.5 mM since the intracellular level is in full equilibrium with the blood level.

Therapeutic drug monitoring of blood levels is necessary with lithium because of the narrow therapeutic index and also the large variability of oral dose that leads to a given blood level because of differences in renal clearance. Target blood levels in lithium treatment are 0.5 to 1.0 mM. For prophylaxis, levels of 0.6 to 0.8 mM have been reported to be more effective than levels of 0.4 to 0.6 mM. However, levels of 0.4 to 0.6 have fewer side effects than levels of 0.6 to 0.8 mM. Thus, there is no right answer, only an individualized trade-off in clinical care. The rare case of monotherapy in mania can be treated for a few weeks with levels of 1.0 to 1.5 mM and may benefit more than with lower levels. Some have reported that in bipolar depression, where other options are limited, lithium levels of 1.0 to 1.5 mM may also be more antidepressant, but well-controlled data are lacking. Poor oral hydration and sodium depletion by undernutrition can complicate lithium treatment of bipolar depression.

THERAPEUTIC INDICATIONS

Efficacy in Bipolar Disorder

The findings of Schou's classic studies have been generally confirmed. Lithium is efficacious in acute mania, in the prophylaxis of mania and depression, and to a smaller extent in the treatment of acute bipolar depression. Early studies of lithium were carried out before the year 2000 without pharmaceutical company support. They could be and have been criticized by those who accept FDA-based standards for pharmaceutical research in terms of requiring large numbers of subjects, highly quantitative rating scales with predefined endpoints, and hard-core assurances of being double-blind. Such criticisms of the bedrock studies of lithium in bipolar disorder were useful in marketing newer drugs with efficacy in bipolar disorder. The first to be discovered was carbamazepine, originally an antiepileptic with chemical similarities to chlorpromazine and completely unrelated structurally to lithium.

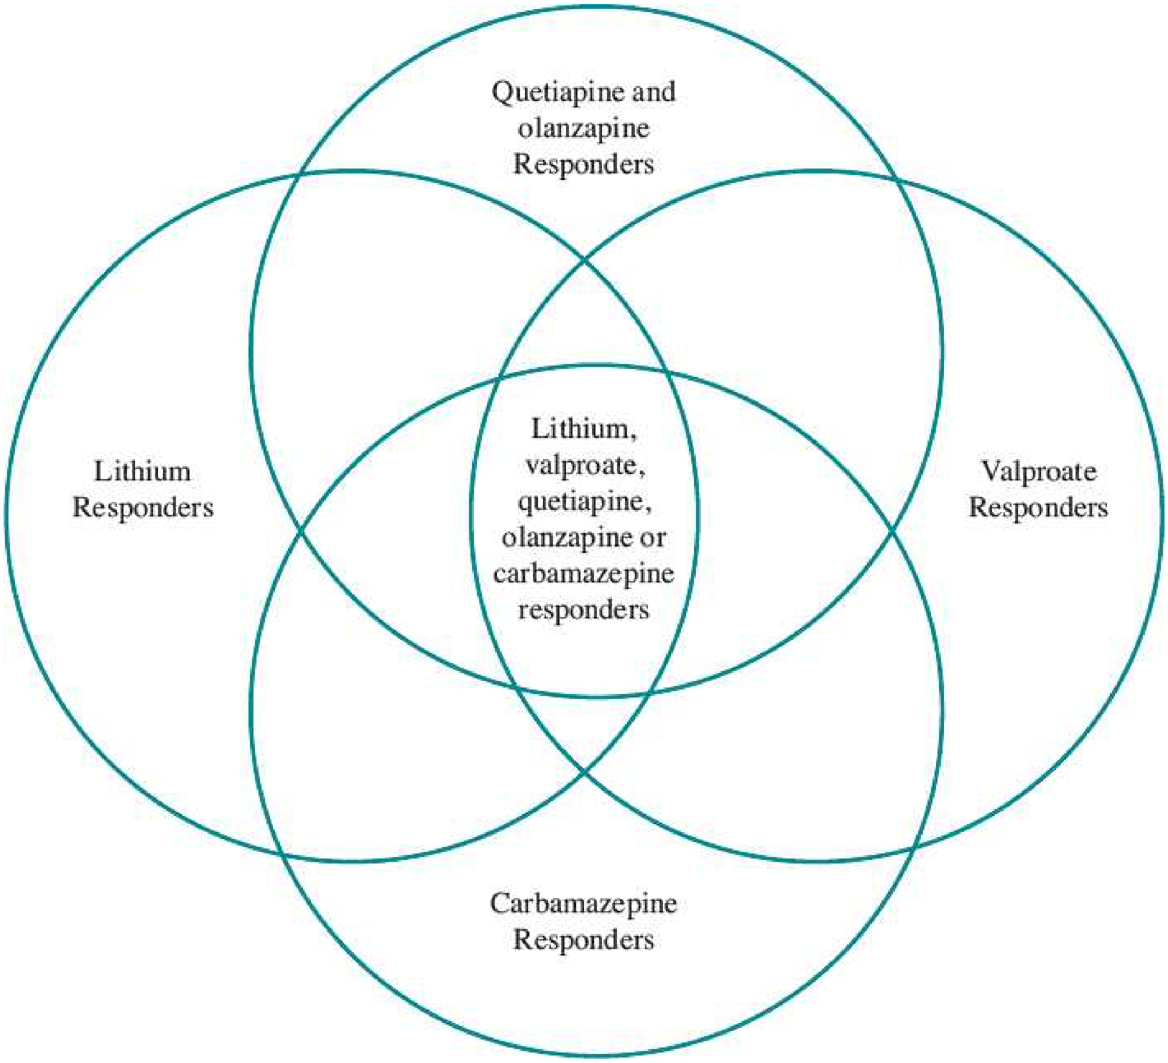
The original discovery of carbamazepine by Okuma in Japan was serendipitous but led to many further studies by Post and others postulating an epilepsy-like etiology of bipolar disorder and a kindling model of the course of bipolar disorder. These theories are still speculative, lithium itself is not antiepileptic at all, and not all antiepileptics are useful in bipolar disorder. The next drug discovered efficacious in bipolar disorder by Emrich in Germany was valproic acid, a 5-carbon branched-chain carboxylic acid whose only similarity to lithium is that it might be found naturally in geologic samples. Pharmaceutical support for valproic acid as a new drug for bipolar disorder was massive due to a special patent for divalproex sodium (which dissolves into valproate in the stomach).

Many of the key studies of valproic acid and carbamazepine in mania and the prophylaxis of bipolar disorder in the last 20 years used lithium as a positive control. These large, modern pharmaceutical company-funded studies provided good data for the use of lithium in bipolar disorder. They did not find a superiority of lithium over valproate or vice versa. Some clinical markers of specific Li responses were identified but are not generally replicable. These drugs, discussed in more detail elsewhere in this section, bear a clinical relationship to lithium roughly as described in Figure 33.10f–2.

That is, these drugs are also efficacious in acute mania and efficacious in the prophylaxis of both mania and depression in bipolar disorder but perhaps less efficacious in the treatment of bipolar depression. Some patients who have been lithium responders but must stop lithium because of side effects can be switched to carbamazepine and vice versa. The same is true of lithium and valproic acid or valproic acid and carbamazepine themselves. That is, it has not been possible to define patient groups who clearly respond only to lithium and not to valproic acid, and it is not possible to describe patients who respond both to valproic acid and to lithium and not to carbamazepine. Lamotrigine is again chemically unrelated to the other lithium-like medications we have described. Studies of lamotrigine using lithium as a positive control in large pharmaceutical company-sponsored multicenter trials again supported lithium’s efficacy in bipolar disorder.

The group of medications useful in bipolar disorder, including lithium, have been termed “mood stabilizers.” It is important to state immediately that this does not mean that they affect the range of normal human mood variability on a day-to-day or hour-to-hour basis. Moreover, all evidence suggests that they do not affect the mood instability of borderline personality disorder, and their effect on mood labile unipolar depressive disorder or dysthymic disorder is limited or nonexistent. The term “mood stabilizer” in psychiatric literature is often misleading to the public and to patient families. The key distinction should be that lithium and the other drugs in this class seem to be effective in preventing the pathologic mood disorders of mania and depression in bipolar disorder in a medical disease model. One can explain to patients that aspirin does not reduce body temperature unless there is a fever (but this does not make it specific to any particular cause of inflammation).

Partly because of the success of lithium in psychopharmacology and its popularity in psychopharmacology research in the 1970s and 1980s, manic–depressive illness has expanded as a clinical diagnosis. On the one hand, psychotic states with mood components have been included in the DSM-IV and 5 as psychotic mood disorders; on the other hand, recurrent depressions with occasional episodes of hypomania or some hypomanic symptoms have been included under bipolar disorders as bipolar II. This great expansion of the conceptual limits of bipolar disorder has also led to an expansion of the epidemiologic incidence and prevalence of bipolar disorder in population studies. However, lithium is not effective in most cases of bipolar II disorder, and as a treatment requiring blood level monitoring and risking short-term and long-term toxicity, its use should be carefully considered when used in cases unlike those in whom its efficacy has been clearly demonstrated.



Quetiapine and olanzapine Responders
Lithium Responders
Lithium, valproate, quetiapine, olanzapine or carbamazepine responders
Valproate Responders
Carbamazepine Responders

FIGURE 33.10f–2. The above illustrates roughly the fact that some people respond to lithium and another group responds to valproate, another group responds to carbamazepine, and another group responds to some dopamine blockers; many patients with bipolar disorder respond to any of these four classic mood stabilizer groups, and some respond to only one or two. There is good clinical data to call all of these treatments mood stabilizers, but each is distinct chemically and biochemically.

While controlled studies of lithium find it more effective than placebo in bipolar disorder, these studies represent the average result for large groups of patients. Many patients with clear bipolar disorder do not respond to lithium or respond with a reduction, but not elimination, in frequency and severity of episodes. For those who do not respond to lithium, other treatments are available, and continued physician follow-up and monitoring are essential. Conversely, lithium should be considered as an option in patients who fail to achieve good remission with other mood stabilizers.

Lithium is often called “the gold standard of treatment of bipolar disorders”: Some have called it a “first-line” treatment for bipolar disorder. However, these are misrepresentative statements. Not every newly diagnosed bipolar patient is put on lithium treatment, and no guideline suggests that to be the desirable situation. Rather than the gold standard of therapy, lithium should be called the classic therapy, but it is clearly not for every patient.

Is lithium underutilized? Those who study it and use it regularly often feel this, but they may have an understandable bias not dissimilar to that of a company selling its product. It is not reasonable to estimate 1% of the adult U.S. population as bipolar, accept lithium as the gold standard for bipolar treatment, and conclude that two million Americans should be benefitting from lithium treatment for their expensive and disabling illness. These estimates must be adjusted enormously for those who do not want blood tests, do not respond to lithium, have side effects with lithium, or have better prophylaxis or acceptability with carbamazepine, valproate, olanzapine, quetiapine or other mood stabilizers.

POLYPHARMACY AND ADMINISTRATION OF LITHIUM

The medical workup before beginning lithium therapy includes complete blood count and blood chemistry, including renal function and thyroid-stimulating hormone (TSH) and calcium, and physical and neurologic examination within the last 6 months, including electrocardiogram (EKG) in patients over 60.

Lithium monotherapy is rare today for several reasons. First, in the acute hospitalized manic patient, it is often difficult to get cooperation for blood level testing, and nutrition and hydration may be unstable in uncooperative patients. Lithium is appropriate only when hydration is stable and blood testing can be routinely achieved. Second, most patients receive antipsychotic treatment as their first-line treatment to achieve rapid behavioral control, and lithium is sometimes added as a polypharmacy treatment in order to allow discharge to the community as soon as possible. However, a patient should not be started on lithium treatment in the acute hospital phase if he has not had exposure to lithium in the past and commits realistically to using it prophylactically in the future. The danger of a patient being discharged on a dopamine antagonist plus lithium who then stops his lithium after discharge is great because the sudden discontinuation of lithium can cause a rebound relapse. Third, lithium monotherapy is also rare nowadays in prophylaxis because many more patients with a clinical diagnosis of psychotic bipolar disorder require the continuation of dopamine-serotonin antagonists with their lithium. If side effects of lithium develop, it is easy nowadays to replace it with a dopamine-serotonin antagonist, not requiring blood testing and without danger of fatal toxicity with the medicolegal responsibility that goes along with prescribing lithium without blood monitoring.

Lithium does not seem to have significant pharmacokinetic or drug–drug interactions with other psychoactive compounds and can be used in combination. Because many patients respond only partially to lithium (or other mood stabilizers as well), it is often clinical practice to add another antimanic compound or mood stabilizer rather than stopping lithium when some, even partial, response has been observed. This leads to polypharmacy. In the early post–World War II days of modern clinical psychopharmacology, Lasagna was greatly influential in American medicine in promoting monotherapy as the only way to achieve true knowledge in medical pharmacology but also the only way to avoid impossibly complex interactions in individual patient care. This has proved increasingly difficult to maintain in clinical practice. It is estimated today that 80% of patients taking lithium are taking other major psychoactive drugs as well, usually dopamine blockers but antiepileptic mood stabilizers as well. Initially and especially in academic centers and in textbooks, this practice was considered embarrassing, rarely talked about, and even more rarely studied. The FDA demands monotherapy in psychopharmacologic trials so that lithium must be compared to a placebo (with perhaps a third group such as valproate or quetiapine). This standard has been stricter, perhaps unfairly so, with psychiatry than with other disciplines. In the neurology of epilepsy, for instance, it is common practice for the FDA to allow add-on trials of one antiepileptic agent to another current ongoing treatment in partially responsive epilepsy patients. Robert Post and his group have given considerable intellectual backing to the reality of rational polypharmacy in psychopharmacology in general and in bipolar disorder in particular. Since lithium, the anticonvulsant mood stabilizers, and the dopamine-blocking mood stabilizers seem to have no obvious common denominator biochemically, it makes intuitive sense that their therapeutic modes of action might be at least additive and perhaps synergistic with each other. The goal will be for each patient to have an accurate record of what drug combinations he responded to best over his own history of illness as the best predictor so far of what he might respond to in the future. Charts such as Figures 33.10f–3 and 33.10f–4 may give important information regarding the individual patient to complement the information available from controlled large group studies.

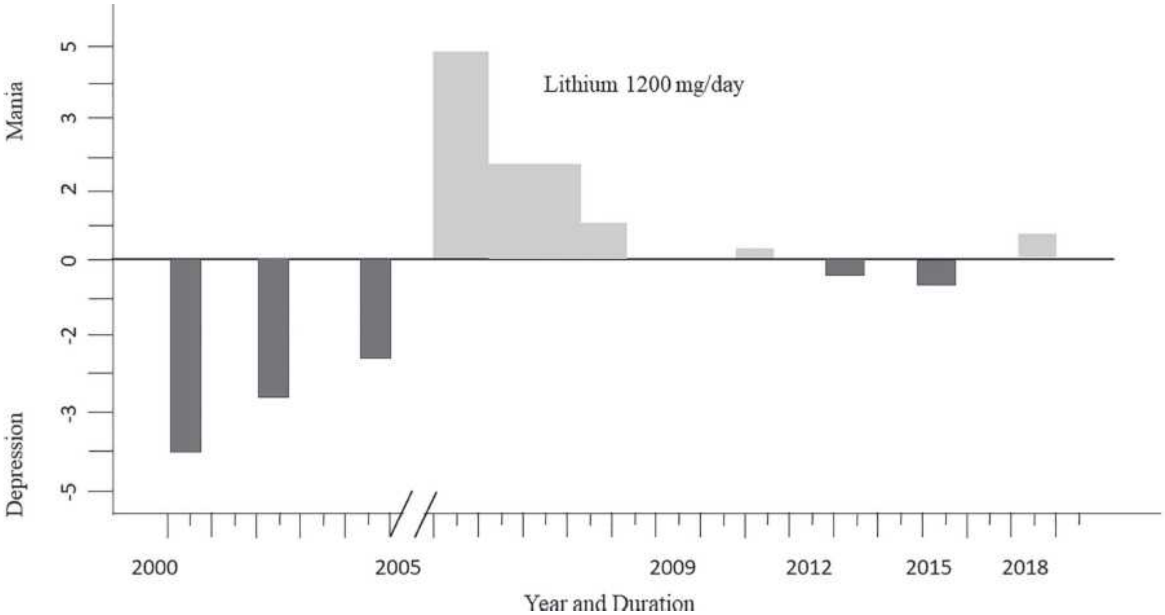


FIGURE 33.10f–3. Lithium responder. The patient is a 43-year-old married woman who had three episodes of depression in her 20s that lasted about 6 months each and resolved without treatment. At age 31, she had a clear manic attack with a few days of hospitalization in a general hospital and was started on lithium 1,200 mg per day. Since then, 12 years have elapsed, and she has had only subclinical cycling of mild depression or hypomania. Positive scores indicate mania and negative scores depression, with higher scores indicating greater severity of illness and zero indicating no illness.

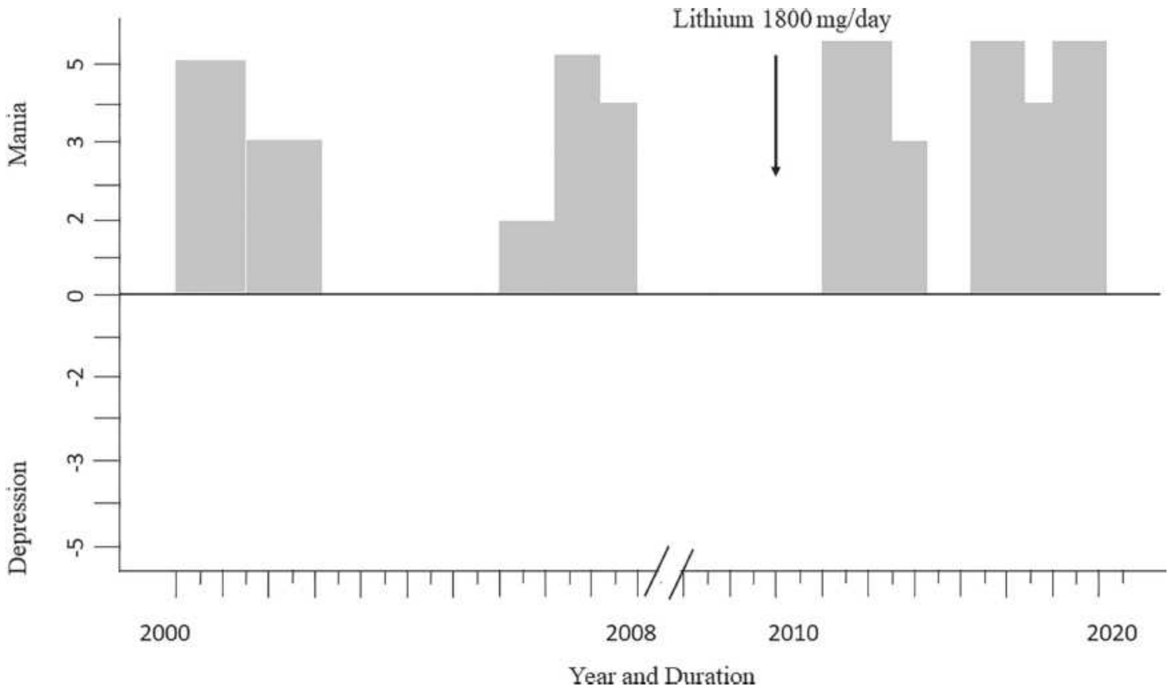

FIGURE 33.10f–4. Lithium nonresponder. The patient is a 56-year-old divorced man who had two long and difficult involuntary hospitalizations with mania separated by about 5 years in his 30s. He was begun on lithium after recovery from the second long hospitalization, and despite genuine motivation and apparent adherence to the treatment regimen, he has had two severe manias in the subsequent decade. Positive scores indicate mania, and negative scores depression, with higher scores indicating greater severity of illness and zero indicating no illness.

Patients treated in the hospital for mania with a dopamine antagonist often begin a mood stabilizer such as lithium toward the end of their hospitalization if they meet the criteria described above. If they have a past history of breakthroughs during lithium prophylaxis, or if they find the neuroleptic treatment to be oppressive to their cognition, motivation, or hedonic state, they will often demand reductions in their neuroleptic dosage as they reach euthymia. This is a good reason to add lithium. However, if, in the past, lithium was not enough for such a patient, it is often best to continue the dopamine-serotonin antagonists in a low dose while continuing on lithium prophylaxis. Patients who have only a partial response in prophylaxis on lithium but breakthroughs not severe enough to require hospitalization on dopamine blockers may often have their lithium prophylaxis augmented with an anticonvulsant mood stabilizer such as carbamazepine or valproate. There are no physiologic contradictions to such polypharmacy. Clinical experience, along with some small controlled studies, suggest that it is often effective in some patients who do not respond to lithium alone. Clozapine addition to lithium is powerfully effective in some very severe rapid cyclers or patients with highly violent manias. ECT can be safely given to a lithium prophylaxis patient who has had a severe breakthrough depression.

THE IMPORTANCE OF PATIENT HISTORY

Most cases appearing for treatment in an acute manic state have had prior treatment, and the results of this prior treatment should be assiduously sought out by the clinician before making his choice. For example, if a computerized record is available, it should be read carefully. If a family member accompanies the patient or is available by phone, he should be queried carefully. The patient should be asked more than once if he has any previous medical records in his wallet, purse, or at home where a family member might be able to find them and read them out on the phone. A patient with a previous history of response to valproic acid should not be started on lithium out of the assumption of its therapeutic equivalency. Similarly, a patient who has done well on lithium for years and is now undergoing a manic attack because he stopped his lithium should not be changed to carbamazepine in the emergency room merely because of its appearance as an equivalent drug in the latest guidelines of the resident’s clinical seminar. Patient history is the best predictor of patient response.

EFFECTS OF LITHIUM IN NORMALS

Lithium has rarely been studied in normal people without psychiatric disease. Evidence suggests that there might be some slowing of thinking and cognitive impairment, and some patients do complain of reductions in creativity. However, patients who experience both lithium monotherapy treatment and neuroleptic monotherapy treatment almost always prefer lithium treatment and feel that drugs that block dopamine receptors impair their hedonic experiences, motivation, and emotional life far more than lithium. In recent years, there has also been increasing awareness that monoamine enhancers, including serotonin specific reuptake inhibitors (SSRIs), may cause over time an “emotional blunting,” although this has been difficult to define in controlled objective tests. Nonetheless, it is important that the treating physician not dismiss all patient complaints of subjective mental side effects of lithium as if they were irrelevant. There may be some psychological price that some or many patients pay for the benefits of reduction of risk of mania and depression.

In animal studies, chronic lithium blocks the increase in activity, aggressiveness, and motivational behavior induced by amphetamine but much less effectively than neuroleptic dopamine-blocking drugs. It has been difficult to define chronic lithium effects on normal rats or mice, especially since the drug cannot be given by injection without causing pain and abscess in the intestines, and chronic administration in food is often associated with a bad taste in the food for the rodents and reduction in weight. Studies of acute single-dose lithium injections of animal behavior are of little relevance to understanding human effects. Returning to humans, several famous studies of lithium in highly creative individuals have not found negative effects of lithium on their creativity.

MECHANISMS OF ACTION INCLUDING ANIMAL MODELS

The mechanism of action of lithium is not known. This is true despite 70 years of intensive research and thousands of reports of biochemical effects in animal brain, human blood, and in vitro cell culture experimental studies. While “antidepressants” could be reasonably claimed to work by inhibiting the reuptake of noradrenalin or serotonin at the synapse, “antipsychotic” drugs could reasonably be claimed to work by inhibiting the dopamine D2 receptor at the synapse, there is no explanation for lithium’s mechanism of action. In over seven decades of psychopharmacologic study, every area that has been developed as a frontier of study has found effects of lithium; this is summarized in Table 33.10f–1. When monoamine metabolites were the frontier of study and the reuptake inhibition effects of “antidepressants” were discovered, lithium was also found to have effects. When the receptor concept was developed and neuroleptics were found to inhibit dopamine receptors, lithium was found to have effects. When the importance in the brain of the transcription of many active genes into mRNA was discovered, lithium was found to have effects. When neurogenesis was found to occur in discrete areas of the human brain and to be important in memory and perhaps mood, lithium was found to have effects. Many of these effects did not replicate in further laboratories, and this is a well-known problem in modern psychopharmacology. However, some of the findings are replicable but may be epiphonema or unimportant. An example might be the effect of lithium on increasing levels of choline in human red blood cells dramatically. This effect does not occur in brain cells in humans or in animals but seems to be a peculiar effect that, while replicable and dramatic, is not important. More recent is the story of lithium’s effect on second messenger systems that carry the synaptic signal that has been transmitted across the synapse into the cells that receive the message. These second messengers are clearly extraordinarily important. One of them is called the phosphatidylinositol cycle. A key enzyme in that cycle, inositol monophosphatase, is inhibited by lithium. If lithium works by reducing brain levels of inositol and choking off the phosphatidyl inositol second messenger system, then inositol should be a kind of “antidote” for lithium effects. However, it was not found to be an antidote for lithium toxicity. Inositol could stereospecifically reverse one behavioral effect of lithium in rodents. This behavioral effect in rodents may be an artifact of the fact that rodents have much lower brain inositol than humans, and a new inositol monophosphatase inhibitor, ebselen, that was hoped to be a new lithium congener was found in 2020 to have no effect in this behavioral system.

Table 33.10f–1.
History of Psychopharmacology and the Mechanism of Action of Lithium[a]

Period	Focus	Finding about Lithium
1967–1975	Monoamine metabolites	Increased deaminated norepinephrine metabolites
1976–1985	Neurotransmitter receptors	Prevents dopamine-receptor supersensitivity
1986–1995	Second messengers cAMP Phosphatidylinositol cycle GSK-3 beta	Inhibits adenylate cyclase Inhibits inositol monophosphatase Inhibits glycogen synthase kinase
1996–2000	Third messengers Immediate early-response genes Response elements	Affects c-fos, c-jun Increases CREB DNA binding
2000–2010	Neuroprotection and neurogenesis	Increases levels of neuroprotective protein bcl-2
2010–present	Gene transcription patterns	Multiple circuit-based and system-wide effects

[a] cAMP denotes cyclic AMP, and CREB cyclic AMP-responsive element-binding protein.

From Belmaker RH. Bipolar disorder. *N Engl J Med.* 2004;351(5):476–486. doi: 10.1056/NEJMra035354

Glycogen synthase kinase is a key enzyme in another second messenger system, and it is clearly lithium inhibitable in the test tube. The details of lithium inhibition are difficult to define, and of course, the devil is in the details: If the inhibition occurs only at 2 millimolar in the cell, then this could be a mechanism of lithium’s toxicity. If the inhibition occurs at 1 millimolar, it could be a mechanism of lithium’s therapeutic benefit. The lithium inhibitability depends on the magnesium concentration, and if the experimenter uses a magnesium concentration equivalent to that in the blood plasma and that is used routinely as the medium in biochemical experiments, results are different than if he chooses the magnesium concentration that is prevalent inside most cells including the brain. While glycogen synthase kinase 3 beta (GSK-3 beta) heterozygous knockout mice show behavioral traits reminiscent of lithium treatment, according to some reports, synthetic GSK-3 beta inhibitors have major effects on the body outside the brain, including on the pancreas, and none have been developed at this writing that would be brain penetrable, brain selective and available for testing as possible lithium substitutes.

A modern line of lithium research uses the hypothesis-free huge data sets that have become available using gene chips. An example would be Akkouh and colleagues, who studied the effect of lithium on the increases and decreases of mRNA levels simultaneously on thousands of different genes in brain tissues. Some levels went up, and some levels went down, and perhaps some sense could be made by looking at which system lithium seemed to affect. This would be a bit like saying that lithium is affecting the performance of a great orchestra, and you can see the lithium effect because some of the wind instruments get faster, some of the percussion instruments get slower, and some of the violins get higher in tone. However, this kind of data really begs the question of what the lithium is doing to the conductor himself. In order to develop a new lithium-like drug, we would need to find the proximal mechanism of the simultaneous effects on hundreds of gene expression changes. Stern and colleagues also present a paradigm shift in research on the mechanism of lithium action. They used cultures of human stem cells differentiated in vitro into neurons after originating in skin biopsies of bipolar patients or controls and also immortalized lymphocytes from bipolar patients and controls. Thus, they could use human tissue without invasive practices and address the question of whether lithium has different effects in bipolar lithium-responsive patients than in those free of this illness or lithium nonresponsive. Complex effects were found in cell membrane excitability, but it is difficult to know yet which are relevant or specific.

Some researchers have accepted the idea that lithium, valproate, and carbamazepine are all mood stabilizers, and it might be possible to look for which biochemical effects, among the numerous biochemical effects of these three compounds, are shared between them. While Manji and colleagues have done considerable work, there is clearly no common dominator that yet explains the biochemical basis of calling these three compounds mood stabilizers. The situation has become even more complicated as data has accumulated suggesting that many dopamine-serotonin antagonists are effective and convenient both in preventing mania and preventing depression and can be reasonably called mood stabilizers. Their common element is dopamine blockade, which is certainly not a primary effect of lithium. The honest answer to the textbook question of how lithium works is that we don’t know.

SUICIDALITY

One of the fascinating aspects of lithium’s clinical usage is its proven correlation with reduction both in serious suicide attempts and in completed suicide. Bipolar disorder is associated with high suicide rates, and thus this antisuicidal effect is potentially very important. Some scientists have considered suicidality to be a psychiatric syndrome in its own right and that it may have biochemical pathophysiology and treatment unrelated to the disorder in which it occurs. However, this evidence of lithium’s antisuicidal effects outside of bipolar disorder is not strong enough for lithium to be a recommended treatment in suicidal patients without bipolar disorder, such as recurrently suicidal borderline patients. In planning treatment options in bipolar patients with lithium versus other mood stabilizers, certainly, the evidence for its antisuicidal action can and should be taken into account. A mechanism for lithium’s antisuicide action is not known, although it is practical and commonsensical to note that clozapine is also proven to have antisuicidal effects different from the other neuroleptic drugs. Both lithium and clozapine require frequent blood level monitoring. It is certainly possible that the increased physician attention and discipline required to agree to monthly blood levels and choose patients who are willing to have monthly blood levels is the real reason why these two compounds seem to be associated with antisuicidal effects.

LITHIUM IN PREGNANCY, CHILDBIRTH, AND LACTATION

Lithium has been considered a classic teratogen and is clearly teratogenic in frog embryos and bird embryo models. However, human registers of patients born to mothers treated with lithium through their pregnancy have revealed rather modest and somewhat specific teratogenicity; Ebstein abnormality of the heart occurs in lithium-treated pregnancies at elevated rates compared to control pregnancies but still occurs in only a very small percentage of total pregnancies of “lithium babies.” If a woman must continue on lithium because her psychiatric history clearly requires it, and if she very strongly wants to become pregnant, a reasonable option would be to follow her throughout conception and delivery with regular ultrasound of the fetus with special attention to the fetal heart. Ebstein anomaly, while a serious cardiac birth abnormality, can be surgically corrected.

While this data on lithium babies is encouraging for those cases of women who must continue lithium and very much want to become pregnant, it is important for the physician to realize that studies of teratogenicity usually examine the newborn at birth and for limited time periods thereafter. The possibility of “behavioral teratogenicity,” meaning possible alterations in important substrates of control of mood in the brain or other systems, could be revealed in lithium babies only as they become older and has not yet been studied conclusively.

The pregnant patient being treated with lithium should have her lithium levels checked frequently and her dose adjusted as glomerular filtration rates change during the three trimesters of pregnancy. A day or two before the expected date of delivery or upon signs of impending delivery, such as breaking of the membranes, lithium should be stopped. This is because the massive intercompartmental shifts of electrolytes before, during, and after delivery can make sudden lithium toxicity possible. Lithium can be renewed a day or two after delivery as oral feeding and drinking resume. Lithium passes into breast milk, so breastfeeding should be avoided.

Alternatives to lithium in patients needing treatment who want to become pregnant should be introduced gradually at least 6 months to a year before the planned pregnancy. Valproate and carbamazepine are both teratogens and are not alternatives for lithium-stabilized bipolars. Olanzapine, quetiapine, or lamotrigine (in the case of patients whose main problem is depression) may be reasonable alternatives.

CHILDHOOD USE

The diagnosis of bipolar disorder in children has expanded exponentially in recent decades. Some have claimed that a large portion of these children, in fact, have no clear relationship to adult bipolar disorder and should be categorized as disruptive mood dysregulation disorder for which lithium has no demonstrable efficacy. Lithium is rarely used in prepubertal children, and controlled studies have been generally unimpressive in pediatric bipolar disorder (or disruptive mood dysregulation disorder). Bipolar children of a lithium-responsive bipolar parent may be an exception to this overall pessimistic evaluation. Lithium is of no use in the hyperactivity of ADHD. Side effects of lithium in children are not dramatically different than in adults, but dosage should be re-evaluated yearly as body mass increases. Target blood levels are the same as in adults.

GERIATRIC USE

Lithium is effective in late-onset mania after the age of 60, even in patients with no family history of bipolar disorder, and even if the mania seems secondary to a small stroke. Generalized cardiovascular disease, hypertension, or renal disease should advise caution. Bipolar patients who reach old age can be continued safely on lithium, preferably with lower target blood levels, more frequent monitoring, and careful warnings about nonsteroidal anti-inflammatory drug (NSAIDs) and diuretics. Such patients should not be routinely switched to another mood stabilizer as this can be a complicated retirement present with unintended negative consequences.

LITHIUM IN CLUSTER HEADACHE AND ALZHEIMER’S

The use of lithium in cluster headache, a rare disorder related to migraine but with definably different features, is proven to be effective prophylactically. The mechanism is speculative and unrelated to those biochemical mechanisms currently studied as the possible basis of lithium use in bipolar disorder. Then there is the inverse case of use of lithium in a disease where there may be good theoretical reasons but no good clinical data: Lithium might be expected to be useful in the prevention or treatment of Alzheimer disease because lithium inhibits GSK-3 beta in test tube biochemical studies. This effect might be expected to reduce the phosphorylation of tau and thereby reduce the deposition of amyloid, which is one popular pathophysiologic theory of Alzheimer disease. Good studies of this possible treatment of Alzheimer disease are scarce, and the majority of those that have been done are negative. The claims that lithium levels in drinking water predict the incidence of Alzheimer's in various regions or countries are highly speculative and suspect since the amount of lithium that could possibly accumulate in the body from such natural lithium in drinking water is far from the levels necessary to inhibit glycogen synthase kinase or to have any of the other biochemical effects of lithium that we know of today. Psychiatry has an obligation to point out to our biochemical colleagues and research colleagues in other fields that lithium can do almost anything biochemically if the concentration is high enough, but most of these effects are unlikely to have clinical implications.

LITHIUM IN AMPHETAMINE, METHYLPHENIDATE, OR COCAINE ABUSE

Chronic lithium in rodent models and in some human volunteer studies partially blocks the response to amphetamine, methylphenidate, or cocaine. However, lithium treatment has not been found useful in human abuse of these stimulant drugs, although adherence issues may be part of the reason. In bipolar patients with comorbid drug or alcohol abuse, improvement of the affective disorder with lithium or other treatments may improve the comorbid substance or alcohol abuse.

INDIVIDUAL DIFFERENCES AND PREDICTION OF LITHIUM RESPONSE IN BIPOLAR DISORDER

Despite numerous efforts of clinicians over the years, no replicable clinical syndrome has been shown to be strongly predictive of lithium response in bipolar disorder. The presence of psychosis in the manic phase or in the depressive phase is not an absolute negative predictor. Positive family history of bipolar disease is not a strong positive predictor, although a positive family history of lithium-responsive bipolar disorder has not been ruled out and should be considered by the clinician as a provisional predictor of lithium response. Positive family history of valproate response or carbamazepine response in other family members does not rule out a lithium response in the individual patient. Considerable numbers of studies have attempted to identify genomic variants by GWAS that might predict lithium response. None of these are currently proven or useful at a clinical level, despite efforts by several companies to market genetic tests for lithium response directly to patient consumers.

Studies comparing lithium with placebo find statistically significant advantages for lithium treatment in mania and bipolar prophylaxis, as said above. However, looking at the standard deviations shows that, as in almost all medicine, including psychiatry, the rule of thumb is that about one-third of the patients respond to a placebo, two-thirds respond to the drug or treatment, and one-third do not respond even with the appropriate drug or treatment. Often this gross rule of thumb conceals an even more complex reality where some individuals improve completely while others improve only partly, and yet others have an improvement in only one symptom rather than their whole disease syndrome. Thus, the prediction of the individual patient response is a major concern of modern medicine.

TOXICITY

Lithium is a drug with a very narrow therapeutic index and a high potential for severe toxicity. As discussed above, therapeutic plasma levels of lithium range from 0.5 mM to 0.8 mM; levels above 1.5 mM in the plasma show toxic effects, often beginning with polyuria, abdominal pain, vomiting, and diarrhea. These effects create a vicious cycle of dehydration and increasing plasma lithium levels because lithium is not excreted in vomitus, diarrheal stool, or in the dilute urine of lithium nephrotoxicity. Therefore, once it begins, lithium toxicity is liable to advance rapidly. As the blood level increases above 2.0 mM, cardiac abnormalities are frequent, and grand mal seizures often occur. Mortality is high. While lithium inhibits numerous magnesium-dependent enzymes, intravenous magnesium sulfate is ineffective in lithium toxicity. Dialysis is often done, but its value has been questioned because the gradient of lithium at 2 mM to 3 mM in the blood is not strong enough to make for efficient dialysis. Most important in cases of toxicity are oral rehydration when possible with liquids containing salt, an intravenous rehydration with isotonic saline if oral rehydration is not possible or effective, along with careful monitoring of renal function.

The prevention of lithium toxicity involves, first and foremost, patient education. Every patient should receive a written information sheet with a list of common lithium side effects that occur at therapeutic doses in contrast with symptoms of early toxicity. The lithium patient information sheet should also contain warnings to maintain normal hydration, avoid diets that limit sodium intake, and inform the treating psychiatrist when any new medication such as a thiazide diuretic for hypertension is introduced. The most common cause of lithium toxicity today is the onset of use of a thiazide antihypertensive medication prescribed by a family physician, unaware that the patient is under psychiatric care with lithium. Many NSAIDs also change lithium excretion and could induce toxicity unless patients are warned, and blood levels are monitored. The public and the medical profession should be aware that lithium is analogous to digitalis: Extremely useful compounds both in the history of medicine and in modern practice but which have by the nature of their effects on basic physiologic systems the capacity to induce severe and even fatal toxicity.

SIDE EFFECTS

Lithium treatment has a variety of side effects, many of which are unfamiliar to the clinical psychiatrist whose practice has included mostly the use of “antidepressants,” neuroleptics, and benzodiazepines. Lithium side effects should be studied carefully by the clinician prescribing lithium and discussed with the patient who is beginning treatment. Prominent among lithium side effects are several side effects outside of the central nervous system on physiologic systems where hormone receptors and second messengers are involved. It was therefore hypothesized for a time that lithium’s effects on second messengers in the brain might be paralleled by similar effects on second messengers in the thyroid, parathyroid, and kidney that could be responsible for the side effects in a manner parallel to the brain effects. However, this has not turned out to be the case, and lithium’s effects in each of the organs that mediate side effects are complex and not fully understood.

Thyroid

Almost all patients that start lithium treatment have a decrease in serum T3 and T4 and an increase in consequent physiologically compensatory TSH. This is transient in most patients, where these blood levels return to equilibrium. In about 10% to 15% of patients, TSH levels remain elevated, but serum T3 and T4 return to normal. Since TSH is the primary screening measurement in primary practice today for a thyroid disorder, many of these patients are flagged by the family physician as having thyroid disorder and perhaps, after various tests, advised to stop their lithium. The psychiatrist should be careful to advise the family physician and the patient in advance that elevation of TSH in the presence of normal serum T3 and T4 is not an indication for discontinuation of lithium. This is an indication that lithium is interfering with the secretion of T3 and T4 from the thyroid gland, but since T3 and T4 are the hormones necessary for physiologic function in all of their target organs, the elevation of TSH alone should be seen as a healthy compensated state. There is a minority view among endocrinologists to the effect that TSH itself may have effects on the body and that its elevation could be problematic. The present state of knowledge suggests that a patient who needs lithium should not be discontinued on the basis of TSH elevation alone.

In perhaps 1% or 2% of patients, the lithium-induced blockade of proper thyroid secretion of T3 and T4 will not be compensated by moderate increases in TSH. In these cases, TSH continues to elevate, and the thyroid gland cells multiply, resulting in a goiter. Psychiatrists should get a clear view of the patient’s neck in every follow-up of a lithium-treated patient and should also ask the patient about changes in neck size. Early detection of lithium-induced goiter should be treated by T3 or T4 oral replacement. Goiter enlargement will stop, but if the size of the thyroid has increased greatly, it will not recede to its previous normal size. The dose of thyroxine is usually about 100 mcg. Blood levels of TSH, T3, and T4 should then be followed until they return to normal. TSH levels alone are not adequate follow-up.

In a smaller but not completely defined percentage of patients, a lithium blockade of normal T3 and T4 secretion by the thyroid is not compensatable by elevated TSH nor by an increase in the number of thyroid cells, and lithium-induced hypothyroidism develops. This can have the classical symptoms of hypothyroidism or appear as a depression. This is not an indication for the discontinuation of lithium treatment. Such patients should have oral thyroid supplementation while continuing lithium therapy. Thyroid supplementation to achieve normal serum T3 and T4 levels along with normal TSH levels should not be confused with high-dose thyroid hormone augmentation treatment for resistant unipolar depression. Thyroid hormone supplementation to achieve normal thyroid function in lithium-treated patients should also not be confused with thyroid disease, including Hashimoto thyroiditis, thyroid cancer, and idiopathic hypothyroidism, all of which exist in elevated incidence in bipolar patients and their families, unrelated to lithium treatment (see relevant sections on bipolar disorder in this textbook). Thyroid hormone abnormalities discovered in bipolar patients unrelated in time to the onset of lithium treatment should be evaluated by an endocrinologist, including an appropriate radiologic scan of the thyroid gland.

Polyuria and Polydipsia

The most common kidney side of lithium is reversible nephrogenic diabetes insipidus, a syndrome caused by blockade of the effect of antidiuretic hormone (ADH) in the kidney. As with TSH in the thyroid, there is no effect of lithium at therapeutic concentrations on the ADH receptor itself. The blockade seems to occur distal to the receptor but is much more complex than early formulations of effects on the second messenger system. The blockade of the ADH, as might be expected, leads to a diuresis of dilute urine. Almost all patients starting lithium treatment will have polydipsia (thirst leading to increased drinking) and polyuria (an increased necessity for urination). Patients should be warned not to satisfy their thirst with sweet drinks, or they will increase weight in a manner not directly caused by the lithium treatment itself, although lithium is commonly blamed. Patients should also be warned in advance of the increased urination, especially if they have benign prostatic hyperplasia (BPH) or other reasons why they have a frequent need for urination and perhaps suffer from nocturia. The polyuria–polydipsia from lithium is not responsive clinically or experimentally to ADH, either by injection or in the sublingual or intranasal spray forms (DDAVP) used to treat primary enuresis in children or adults before bed or used to treat pituitary derived forms of diabetes insipidus. This is because, as said above, the block induced by lithium occurs distal to the receptor. The polyuria or polydipsia induced by lithium often disappears or becomes imperceptible or a nuisance side effect over a period of months but can return, sometimes severely, at any time in the course of years of prophylactic lithium treatment. The reasons for these reoccurrences and fluctuations are usually not clear. Sometimes reducing the dose of lithium while monitoring blood levels is helpful. The patient should not receive the impression that polyuria–polydipsia is a sign of a serious kidney disorder. If he is concerned about kidney damage resulting from lithium that he has read about on the internet, the diabetes insipidus should be clearly distinguished from the rare but far more serious nephrotoxicity of lithium.

Paradoxically, thiazide diuretics or the potassium-sparing diuretic amiloride are quite helpful in the relief of lithium-induced polyuria–polydipsia. The nephrologic mechanisms of this effect are partially understood but far too complex for this chapter. Every psychiatrist, though, should know that the thiazide treatment of lithium-induced polyuria-polydipsia can raise lithium levels which must be followed closely. The psychiatrist should do the thiazide treatment himself as with the thyroxine treatment of lithium-induced hypothyroidism as discussed above.

Chronic Renal Failure

In very rare cases, lithium can cause progressive anatomical damage to the kidney leading to chronic renal failure (CRF) and a high risk for the necessity of renal dialysis and even renal transplant. This is often traumatic for the patient and for the family but also difficult for the psychiatrist emotionally and even practically in terms of his medical malpractice insurance payments. It is difficult to determine the frequency of this catastrophic progression of events, although there is no question today that it does happen. CRF occurs with increasing age, above age 60 in 1% to 2% of the general population. An average of the epidemiologic evidence suggests that chronic use of lithium may double this percentage. The risk is associated with the years of lithium treatment, and so clearly, physicians who carefully follow up on their patients over years of successful prophylaxis of manic–depressive illness as is clinically indicated, will, unfortunately, as the decades pass, see more of these cases of CRF leading to dialysis and renal transplant. There is some association between this rare syndrome with increases in creatinine over years of treatment, and this has been called “creeping creatinine syndrome.” Increases in creatinine over a level of 1.4 mg/dL within a space of 5 years should be a reason to consider gradual crossover to alternative mood stabilizers. Kidney biopsy should be done in patients who have rapid increases in creatinine but whose psychiatric clinical necessity for lithium is strong. Some evidence today suggests that a lithium-specific pathologic diagnosis can sometimes be made, which would be an indication for the cessation of lithium. Surprisingly, patients with very severe CRF will not benefit nephrologically from lithium cessation (it is too late) and should be continued with lithium treatment if it is psychiatrically necessary, along with concomitant nephrologic follow-up for dietary treatment (protein restriction) and consideration of the necessity for dialysis. Some have claimed that careful lithium level monitoring, avoidance of even short periods of mild toxicity, preference for low doses of lithium, and avoidance of NSAIDs, will make lithium treatment possible without any risk of CRF.

Tremor

Lithium induces in most patients a mild resting tremor. It should be examined regularly by the psychiatrist in the office by observation. This is not a Parkinsonian tremor, and the patients do not show akinesia, mask faces, festinating gait, or cogwheel rigidity unless they are simultaneously taking neuroleptics or have been confusing their own lithium pills with their brother’s neuroleptics. The lithium tremor is more akin to what is described in neurology as a MacDonald Critchley essential tremor. Good clinical practice does not require neurologic evaluation of a tremor from lithium. If it is not severe, it is not a reason for the discontinuation of lithium. Interestingly, it is often treatable with a small dose of propranolol, e.g., 10 mg three times a day. It is not responsive to anticholinergic anti-Parkinson medication.

Parathyroid

Lithium has some effects on the parathyroid gland that are not entirely defined and are uncommon. Blood calcium levels should be checked yearly in patients on lithium. Unfortunately, surgical removal of benign parathyroid adenomas associated occasionally with lithium treatment is a dangerous operation and has resulted in death.

Dental Side Effects

Lithium reduces salivary gland secretion and can lead to an increase in dental cavities. Preventative dental care must be encouraged in lithium-treated patients.

Leukocytosis

Lithium causes a mild but consistent leukocytosis. There is no need for referral to an internist to identify the cause of inflammation. The ability of lithium to cause leukocytosis may be related to its ability to enhance stem cell regeneration. But lithium has not been found useful in clozapine-induced leukopenia or leukopenia induced by cancer chemotherapy. Thus, the hopes of its usefulness in neurodegenerative disorders based on the laboratory finding must soberly await clinical confirmation.

Dermatologic Side Effects

Lithium exacerbates psoriasis, and lithium treatment should be avoided in such patients. Lithium can cause de novo psoriasis, and if this occurs at the beginning of lithium treatment, lithium should be stopped because psoriasis will probably worsen with time. If psoriasis is discovered during ongoing lithium treatment (often the patient discovers it late or ignores it for months) and if the patient needs lithium for psychiatric indications, lithium in such cases can be continued. Often lithium patients live with their psoriasis for their whole lives. Clinical reports suggest that if such patients stop lithium later (i.e., not at the very beginning of treatment), psoriasis usually continues. A dermatologist should make the clinical diagnosis of psoriasis visually or by biopsy, and nonspecific skin rashes from lithium do not carry the above implications but are benign. Psoriasis treatments are not contraindicated with lithium treatment. The mechanism of lithium effects in psoriasis was often ascribed to the second messenger systems in the skin cell, but as with other side effects of lithium, the current data is not clear and multiple, complex mechanisms seem to be involved.

Lithium can exacerbate acne in adolescents or cause acne de novo. The usual treatments for acne are not contraindicated, but acne does not constitute a reason for lithium cessation.

LITHIUM IN SCHIZOAFFECTIVE DISORDER

The definition of schizoaffective disorder has changed frequently from DSM-III to DSM-IV to DSM-5 and between the American DSM and the international classification of diseases (ICD) definitions used over these periods. Research genetic studies have also often used different definitions than those used by clinicians in various countries and psychiatric traditions. One of the exciting developments after the introduction of lithium in the 1970s in the United States was the finding that patients who had been diagnosed as schizophrenic because of psychosis at the peak of their mania often responded to lithium. This led to an expansion of the diagnosis of bipolar disorder to include, first, mood-congruent delusions and hallucinations in both depression and mania and then later, in many diagnostic systems, to include even cases with mood-incongruent delusions and hallucinations in depression or mania. Most studies of bipolar disorder today find that more than one-third deteriorate cognitively, and more than 80% are receiving disability insurance. These facts represent the great expansion of bipolar disorder diagnosis to include patients with features formerly considered to be schizophrenic. In addition, many clinical case reports document responses to lithium in schizophrenic patients, even those with chronic forms of the illness, but who suffered from excited or depressed periods that constituted the most burdensome part of their illness. One study looked at "excited psychosis" in sequential admissions to a catchment area psychiatric hospital in western Jerusalem, Israel. Patients were all administered haloperidol. They randomly received lithium or a placebo as an addition. They were later divided into those that met the criteria for nonpsychotic mania, psychotic mania, schizoaffective disorder, or chronic schizophrenia with exacerbation. Surprisingly, the significant lithium benefit was not restricted to any one group, nor could it be demarcated at any point along this continuum from mania to chronic schizophrenia. Lithium seemed to always add benefit to neuroleptic treatment of these excited psychotic patients although the total treatment response was less the further along the continuum the patient fell between nonpsychotic mania and schizophrenia. In this tradition, lithium enhances response whenever affective symptoms are present in psychosis.

However, another completely contradictory tradition exists in psychiatry. This second tradition has defined the lithium responsive bipolar patient as one who has manias that are euphoric (rather than irritable as in the majority of manic patients today), nonpsychotic, patients without comorbidity and with a nondeteriorating life course, no cognitive impairment and full restitutio ad integrum after each episode. The latter tradition claims that lithium responsiveness can be predicted by these clinical characteristics. Clearly, lithium is valuable in the classic manic patient but should also be considered in those schizoaffective or even schizophrenic patients who have an affective component to their illness and who have not responded adequately to other therapies.

LITHIUM AND AGGRESSIVITY

A considerable number of small studies and case reports indicate that chronic lithium treatment reduces the severity of episodic impulsive aggression. Only a small percentage of persons who have committed aggressive or violent acts are found by history to have had repeated perhaps cyclical or perhaps unprovoked episodes of aggression. Not every patient with antisocial behavior disorder derives benefit from lithium treatment. However, there does seem to be such a small group, although it has not been confirmed in large well designed controlled trials. The effect of lithium in such cases seems to be similar to that described for antiepileptic drugs such as carbamazepine and valproate, which are also useful for bipolar disorder. It is hard to know whether coincidence is involved here or psychopathophysiology. Speculation is of little value and certainly does not constitute proof.

LITHIUM AUGMENTATION OF ACUTE ANTIDEPRESSANT TREATMENT

Lithium can augment the effects of tricyclic and SSRI monoamine enhancers in nonresponders to those medications, even when they are clearly unipolar depressive patients. The initial discovery by Blier and deMontigny found dramatic effects within a few days in the great majority of such patients. More recent and controlled studies suggest more modest effects that can take several weeks to develop. There does not seem to be clinical value in adding lithium to every antidepressant-treated patient from the outset of treatment.

LITHIUM IN UNIPOLAR DEPRESSION MAINTENANCE THERAPY

Lithium is not useful in the monotherapy maintenance treatment of unipolar depressive disorder, which occurs at least once in the lifetime of about 20% of the general population, according to the DSM-based epidemiologic studies of major depressive disorder. However, it is important to note that the definition of major depressive disorder and the concept of depression has expanded tremendously over the last 50 years. Some evidence suggests that a bipolar family history may predict responsiveness to lithium prophylaxis in such recurrent unipolar depressive patients. The inappropriate use of lithium in unipolar depressive disorder may be as much of a problem as its underuse in bipolar disorder.

IS LITHIUM IN ANY SENSE SPECIFIC?

Lithium has strong preventive actions against euphoric mood in mania and against depressive mood in bipolar depression but little if any effect on mood in normal volunteers. In this sense, it is “specific.” However, if specificity implies that lithium helps only in bipolar disorder and in every case of bipolar disorder, then we have seen in the above discussions that this is not the case. Lithium is helpful in many cases of schizoaffective disorder, in augmentation of the response to monoamine enhancers in unipolar disorder, in some cases of episodic aggression unrelated to mood disorders and in cluster headaches. The concept of lithium specificity generated a large number of scientific studies over the last 70 years and, in that sense, was heuristic and positive for scientific development. However, as a useful concept for the psychiatric clinician, the ideology of lithium specificity has passed its time. It should be clear today that there are multiple treatment options for mania, bipolar prophylaxis, and for bipolar depression and that lithium is sometimes useful also in conditions unrelated to bipolar disorder.

SUMMARY

Lithium is a useful treatment for bipolar disorders and several other psychiatric conditions. It has a simple molecular composition, but this in itself makes it no more unique clinically than gold treatment of rheumatoid arthritis or arsenic treatment of syphilis. Lithium responsiveness is not specific to bipolar disorder diagnosed by DSM-5 or any other explicit criterion. Elements of cycling or fluctuation in a psychiatric disorder such as described in bipolar II, borderline disorder, or recurring depression do not make them a priori lithium responsive. Attempts to define a specific “classical” picture of bipolar disorder that is always lithium responsive have failed. Attempts to understand a molecular or biochemical cause of bipolar disorder using the effects of lithium biochemically as a starting point has not yielded conclusive answers to this date. Genome-wide association studies (GWAS) or other genetic methods have not yet yielded a replicable genetic profile predictive of lithium response in a subgroup of manic-depressive patients. Lithium remains a viable treatment option among other treatment options available to the knowledgeable and flexible clinical psychiatrist for appropriate patients used with appropriate care in appropriate settings.

ACKNOWLEDGMENT

The author would like to gratefully acknowledge the help and inspiration of Thomas A. Ban, M.D., who read and commented on every draft and inspired a history-based version of the place of this treatment and its evolution over time.

33.11 Acetylcholine Blockers and Enhancers

33.11a Anticholinergics and Amantadine

Samoon Ahmad, M.D.

HISTORY

Anticholinergics inhibit the binding of acetylcholine to acetylcholine receptors located in the peripheral and central nervous system (CNS). They are used to treat numerous conditions, including motion sickness, nausea and vomiting, incontinence, parkinsonian symptoms like involuntary muscle movements, asthma, chronic obstructive pulmonary disease, and depressive disorders. In nature, anticholinergic substances exist as alkaloids and can be found in perennial herbaceous plants such as *Atropa belladonna* (deadly nightshade), *Mandragora officinarum* (mandrake), *Hyoscyamus niger* (henbane), and species of the genus *Datura*. Belladonna, for example, contains several compounds with anticholinergic properties, including atropine, hyoscine (scopolamine), and hyoscyamine.

There are two types of cholinergic receptors, nicotinic and muscarinic. Consequently, anticholinergics fall into two categories: antinicotinic and antimuscarinic. The focus of this chapter will be on antimuscarinic agents. Antimuscarinic agents affect both the central and peripheral nervous systems with varying selectivity among different agents. Antimuscarinic agents that block central cholinergic activity are used to treat symptoms associated with Parkinson disease, while those with nonselective antagonism have various clinical uses, including bronchospasm, antispasmodic, urinary incontinence, and anesthesia. The prototype of these agents is atropine which is the most common antimuscarinic agent and has been used for millennia in cosmetics, for medicinal purposes and homeopathy, and as a recreational drug. In addition to being hallucinogenic, *Atropa belladonna* is one of the most toxic plants found in the Eastern hemisphere.

ATROPINE

Atropine is a tropane alkaloid extracted from *Atropa belladonna* and other plants of the family *Solanaceae*. It is a secondary metabolite of the plants noted above and serves as a drug with a wide variety of effects. Being potentially deadly, it derives its name from *Atropos*, one of the three fates who, according to Greek mythology, chose how a person was to die. It was historically used to dilate the eyes either for ophthalmic examination or for aesthetic reasons, particularly among Italian women (*Bella Donna* is Italian for beautiful lady). Atropine also produces cardiac and gastrointestinal effects. Even small doses can cause a marked increase in heart rate, so it can help reverse reflex vagal cardiac slowing or asystole caused by various agents. Administered in small doses before general anesthesia, atropine diminishes oral and air-passage secretions. This same effect has made it popular as an ingredient in preparations commonly used for symptomatic relief of colds. Blockade of muscarinic receptors in the CNS by atropine has been found to be therapeutically useful in treating Parkinson disease but can lead to restlessness, excitement, and even hallucinations in large enough doses.

Atropine also serves as an antidote for poisoning by cholinesterase inhibitors (particularly certain kinds of mushrooms and organophosphate insecticides) and reverses the effects of nerve agents. Troops who are likely to be attacked with chemical weapons often carry autoinjectors with atropine, which can be quickly injected into the thigh (Fig. 33.11a–1).

Other commonly used anticholinergics include benztropine mesylate (Cogentin), diphenhydramine (Benadryl), trihexyphenidyl (Artane), and procyclidine (Kemadrin).

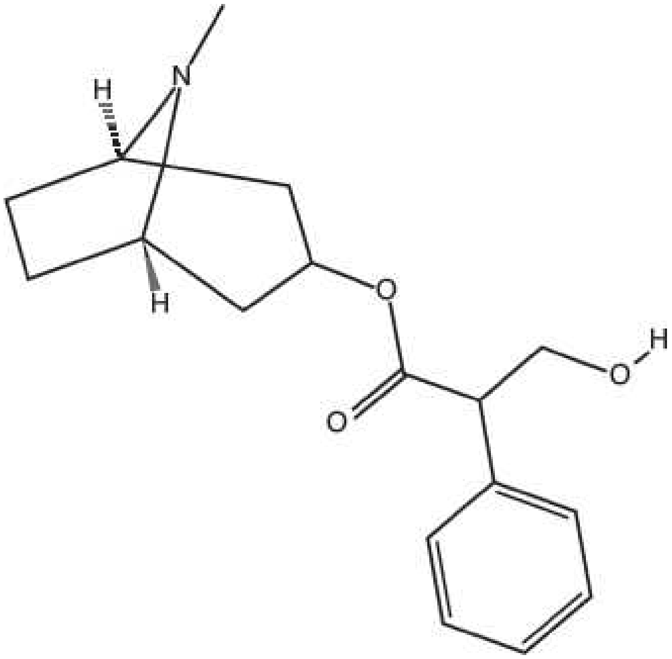

FIGURE 33.11a–1. Molecular structure of atropine.

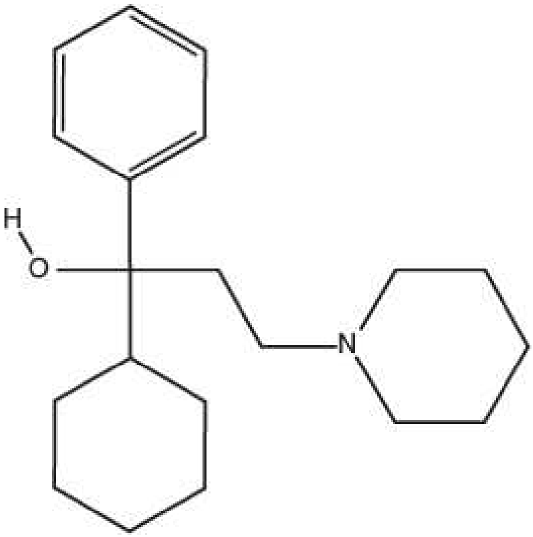

FIGURE 33.11a–2. Molecular structure of trihexyphenidyl hydrochloride.

ANTICHOLINERGIC AGENTS

Chemistry

Artane (trihexyphenidyl hydrochloride) is the substituted piperidine salt, 3-(1-piperidyl)-1-phenyl-cyclohexyl-1-propanol hydrochloride. It exerts a direct inhibitory effect on the parasympathetic nervous system. It is used in the treatment of parkinsonism and extrapyramidal disorders. Artane exhibits a direct spasmolytic action and weak mydriatic, antisialagogue, and cardiovagal blocking effects (Fig. 33.11a–2).

Benztropine mesylate is designated chemically as 8-azabicyclo[3.2.1]octane, 3-(diphenylmethoxy)-*endo*, methanesulfonate. Its empirical formula is $C_{21}H_{25}NO\bullet CH_4O_3S$. It is a crystalline white powder that is very soluble in water and has a molecular weight of 403.54. It possesses both anticholinergic and antihistaminic effects, although only the former has been established as therapeutically significant in the management of parkinsonism (Fig. 33.11a–3) or in the treatment of drug-induced dystonia. Cui and colleagues (2017) reported that benztropine mesylate may inhibit the growth of breast cancer stem cells, while Sogawa et al. (2020) found that it "can suppress tumor progression, circulating tumor cells, and metastasis" in murine models.

Diphenhydramine hydrochloride is an antihistamine that occurs as a white, crystalline powder and is freely soluble in water and alcohol. It has a molecular weight of 291.82 (Fig. 33.11a–4). It is regularly used to treat symptoms associated with the common cold and seasonal allergies, particularly runny nose, sneezing, and itching of the nose or throat.

Procyclidine hydrochloride (Fig. 33.11a–5), known chemically as α-cyclohexyl-α-phenyl-1-pyrrolidinepropanol hydrochloride, is a white, tasteless, crystalline powder that is soluble in water. It is a synthetic antispasmodic compound that has proven effective in the treatment of Parkinson disease and extrapyramidal symptoms. Compared to other antiparkinsonian treatments, some find fewer side effects with this agent. The dose is begun at 2.5 mg per day and increased gradually to a maximum of approximately 30 mg per day.

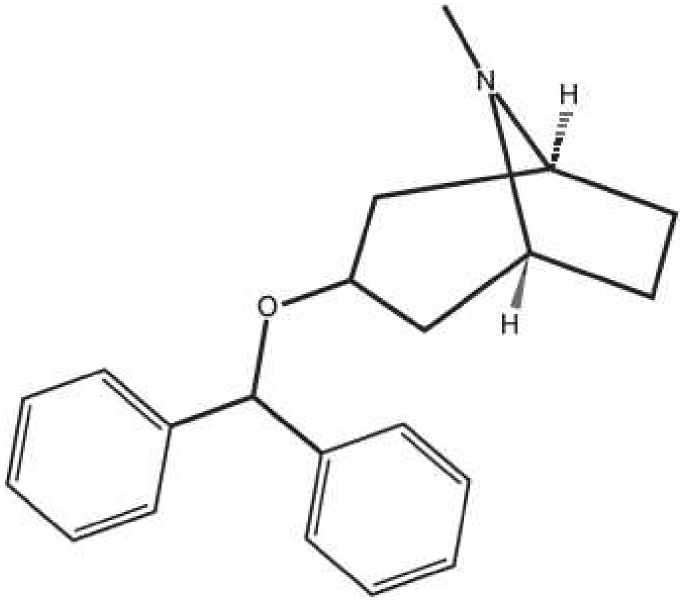

FIGURE 33.11a–3. Molecular structure of benztropine mesylate.

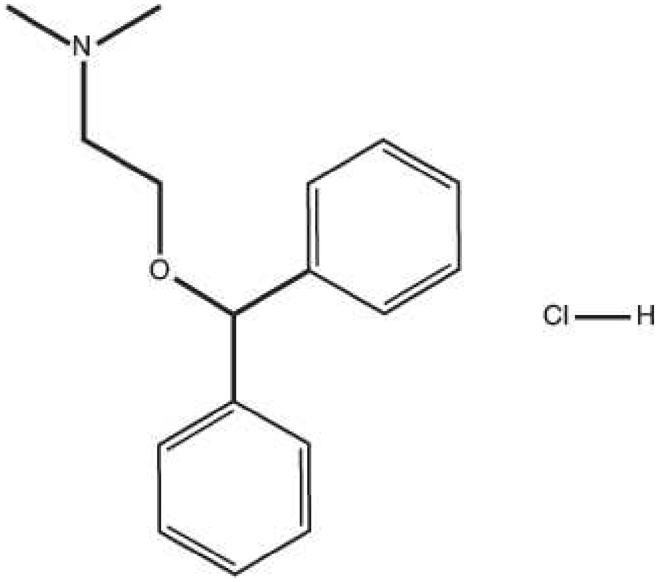

FIGURE 33.11a–4. Molecular structure of diphenhydramine hydrochloride.

Biperiden is an analog of trihexyphenidyl. It is approved for the treatment of parkinsonism and other movement disorders. Biperiden has greater pharmacologic anticholinergic activity than trihexyphenidyl. Recent research by Zhou and colleagues (2017) suggested that it may possess antidepressant effects in murine models.

Pharmacologic Actions

There is limited information available regarding the pharmacokinetics of these drugs, especially among older adults. This may limit the safe and effective use in this population. There are numerous factors contributing to this limited data, including newer and more effective treatments, loss of patent for older drugs, and very low dosages used for treatment.

Absorption and Distribution. All anticholinergic agents readily cross the blood–brain barrier (BBB) and are widely distributed after absorption. They achieve significant levels in the CNS within 30 minutes to 1 hour of administration, and this high concentration in brain tissue may be related to their high lipophilicity. In humans, the bioavailability of these drugs is not reported, and plasma protein binding is also poorly understood. These drugs are extensively metabolized and all unchanged drugs, as well as metabolites, are excreted in the bile and urine.

Trihexyphenidyl is rapidly absorbed from the GI tract after oral administration and is excreted in the urine. The onset of action typically occurs within 1 hour and reaches peak levels within 2 to 3 hours. The full duration of action can last anywhere between 6 and 12 hours.

Benztropine is well absorbed by the GI tract and has an onset of action of between 1 to 2 hours when given orally, but its pharmacologic effects may not be fully apparent for 48 to 72 hours following administration. Benztropine exhibits a more rapid onset of action when administered either by intravenous (IV) or intramuscular (IM) route. There is no difference in onset of action between these two parenteral routes. It is excreted through bile and urine.

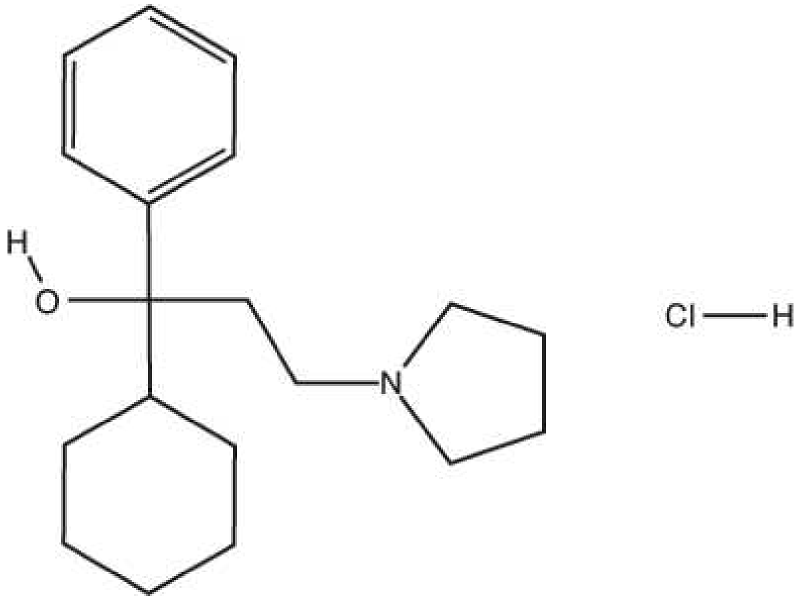

FIGURE 33.11a–5. Molecular structure of procyclidine hydrochloride.

Pharmacodynamics

Anticholinergic drugs act by blocking cholinergic receptors, which respond to the neurotransmitter acetylcholine. Within the nervous system, there are two major classes of cholinergic receptors: nicotinic and muscarinic. The distribution of the two receptors is varied.

Muscarinic receptors are G-protein–coupled receptors located in the CNS, smooth muscle, cardiac muscle, and parasympathetically innervated glands, such as the salivary glands. There are numerous muscarinic receptor subtypes (M1 to M5), and all are present in the brain. These receptor subtypes have selectivity for various brain regions, with the M1 receptor being the most abundant subtype in the CNS and are predominantly located in the neocortex, neostriatum, and hippocampus. The M2 and M3 receptors are also widely distributed throughout the brain, but the M3 receptor has a relatively lower density. The M4 receptors are mostly present in the neostriatum, while M5 receptors are localized in the hippocampus and within the projection neurons of substantia nigra, pars compacta, and ventral tegmental nuclei. Anticholinergic medications, such as benztropine, trihexyphenidyl, procyclidine, and biperiden, act as competitive antagonists at muscarinic receptors. The beneficial effect of agents in Parkinson disease is mediated by CNS muscarinic receptor blockade.

Nicotinic receptors are ligand-gated ion channels located on striated muscle at the neuromuscular junction (motor end plate), the autonomic ganglia, and in the CNS. There are multiple subtypes of nicotinic receptors.

The anticholinergic activity is independent of the serum drug levels of anticholinergic medications because drug levels vary up to 100-fold and hence, are not routinely measured. There is evidence that there is a threshold serum level for anticholinergics, and once this threshold is achieved, it is unlikely for extrapyramidal side effects to occur. This threshold level is a result of muscarinic receptor blockade. Consequently, the decrease in extrapyramidal side effects is not related to the dose of anticholinergic medication nor the dose or serum level of antipsychotic medication, but only to the serum level of anticholinergic activity.

Clinical Studies

Antimuscarinic drugs cause a wide variety of CNS side effects, which are largely dependent on their ability to successfully pass through the BBB, as well as their level of efficacy at receptor binding sites. Cognitive impairment is associated with antimuscarinic drugs, as is memory loss, which may result from antagonism of M1 and, to some extent, M2 or M4 receptors in the CNS. Clinical studies suggest that older patients are more vulnerable to these cognitive side effects, particularly if they are in the early stages of dementia, have a pre-existing cognitive impairment, or are struggling with age-associated memory decline.

Many studies have looked at the impact of these agents on cognitive functioning. A double-blind, crossover trial showed that agents that inhibit cholinergic transmission can impair the storage of new information in new long-term memory but that these agents do not disrupt memory retrieval or hinder tasks involving only immediate memory. Meanwhile, discontinuation of anticholinergic medications was associated with significant improvement in a group of older adult schizophrenia patients whose total cognitive score improved, as did the ideational praxia and orientation subscales.

Anticholinergics have been implicated in worsening psychoses, but there is conflicting evidence on the subject. A few recent small double-blind, placebo-controlled crossover studies have looked at anticholinergic medications and their effects on both positive and negative symptoms of schizophrenia. When patients are stabilized, the agents appear to have no effect, possibly because the presumed dopamine (DA) hyperactivity has been corrected. In schizophrenic patients who are acutely ill, studies consistently find that anticholinergic medications worsen positive symptoms (hallucinations, delusions, disorganized speech, etc.).

Limited data exist regarding the utility of measuring serum anticholinergic levels while assessing schizophrenic patients. One study compared the verbal memory and reaction time of ten schizophrenic patients at two different serum anticholinergic levels. The verbal recall was worse at higher drug levels, while reaction time tended to be improved by anticholinergic treatment.

The effect of anticholinergics on tardive dyskinesia (TD) is also a controversial subject, though studies have revealed that there is cause for concern even if the exact mechanism of effect is unknown. It has been postulated that the condition may be related to an abnormal influence of DA on striatal dopaminergic receptors. In one double-blind, placebo-controlled study, 10 schizophrenic patients with pronounced TD were withdrawn from treatment with anticholinergic medication because of increased symptom severity. Within 2 weeks of cessation, TD decreased significantly in nine patients. This improvement, most pronounced in the oral region, persisted during a 6-week placebo period.

TD is believed to arise because acetylcholine and DA exert opposite effects on the striatum and a delicate balance is necessary to maintain normal functioning. The neuroleptic-induced dopaminergic blockage is considered to be chemical denervation and analogous to pathologic anatomical denervation of idiopathic Parkinson disease. Studies have shown the incidence of TD to be higher in patients receiving both neuroleptic and anticholinergic medications. This hypothesis suggests that anticholinergic medications may predispose patients to the development of TD. Consequently, it is recommended anticholinergic medications should be avoided if possible or kept to a minimum in patients receiving long-term neuroleptic therapy. Discontinuation of anticholinergic medication is a possible therapeutic approach in patients with TD.

Effects on Specific Organs and Systems

Central Nervous System. The centrally acting antimuscarinic agents reduce the tremors associated with Parkinson disease and, when used in combination with a dopaminergic drug (levodopa [Dopar]), can have a more effective response.

In the usual recommended dosages, anticholinergic drugs have a mild stimulant effect and a slower, longer-lasting sedative effect. Initial central vagal stimulation causes bradycardia in the short term, but the antimuscarinic effects eventually stimulate the vagal nucleus in the medullary center and the sinoatrial node, which leads to tachycardia.

Eye. Anticholinergic agents can cause cycloplegia (paralysis of the ciliary muscle), leading to loss of accommodation and the inability of the eye to focus for near vision. These medications also cause dilation of the pupil by blocking the response of the sphincter muscle of the iris.

Anticholinergic medications have little effect on intraocular pressure, except in patients with narrow-angle glaucoma, in whom the pressure may rise to dangerous levels.

Cardiovascular System. In the heart, the atria are innervated by the parasympathetic (vagal) nerve fibers. As noted above, anticholinergic agents cause tachycardia when moderate to high therapeutic doses are used, while bradycardia may result in extremely high doses. In toxic doses, these agents can cause intraventricular conduction block.

Respiratory System. The secretory glands and the smooth muscle of the airways are innervated by muscarinic receptors. These agents inhibit secretions of the nose, mouth, pharynx, and bronchi and may manifest clinically as dry mouth.

Gastrointestinal Tract. The GI tract is innervated by both cholinergic and noncholinergic fibers and is also modulated by local hormones. The net effect of anticholinergic agents is decreased motility via inhibition of parasympathetic control, thereby resulting in constipation or paralytic ileus. These agents also cause dry mouth (as noted above) and delay gastric emptying time.

Genitourinary Tract. Anticholinergics cause relaxation of the smooth muscle in the ureter and the bladder wall and are used in the treatment of spasms caused by inflammatory conditions. Anticholinergics have also been prescribed to treat overactive bladder. Clinicians should also note that anticholinergics can cause urinary hesitancy, particularly in older adult men with prostatic hypertrophy.

Therapeutic Indications

Extrapyramidal Side Effects From Medications. Extrapyramidal side effects (acute dystonias, parkinsonism, and akathisia) are caused by neuroleptic blockade of dopaminergic nigrostriatal tracts, which leads to augmented cholinergic activity. Additionally, decreased serum calcium levels may affect the cholinergic and dopaminergic systems, thereby resulting in extrapyramidal side effects. Anticholinergics reduce cholinergic activity and restore the cholinergic and dopaminergic equilibrium, leading to improvement in these side effects. Acute dystonic reactions usually appear at the onset of most treatments and may occur within 1 to 4 days of neuroleptic therapy, while parkinsonism and akathisia may not manifest until the first 1 to 3 months of treatment.

ACUTE DYSTONIA. Acute dystonia is characterized by a spastic contraction of muscle groups and often affects the neck, eyes, and trunk. These involuntary muscle contractions can be painful and emerge suddenly, thereby frightening the patient. In rare cases, the contractions can be life-threatening (e.g., laryngospasm). The various forms of dystonia include torticollis, retrocollis, trismus or lockjaw, grimacing, dysarthria, blepharospasm, oculogyric crisis, and opisthotonos. Acute dystonia frequently develops after rapid dose escalation of antipsychotic medication or at the beginning of regular treatment, oftentimes within just a few days.

Dystonic reactions are typically treated with benztropine (1 to 2 mg) or diphenhydramine (25 to 50 mg), either IM or IV. The onset of action of these medications, IM or IV, is rapid, with a resolution of the symptoms often within 10 to 15 minutes. As dystonic reactions may recur, prophylaxis with oral medications such as benztropine (1 to 2 mg twice daily) or trihexyphenidyl (2 mg three times a day) is recommended. Tardive dystonia may develop after months or years of treatment with antipsychotic medications and usually does not respond rapidly to anticholinergic medication.

AKATHISIA. Akathisia is characterized by an internal sense of motor restlessness, often described as an inability to resist the urge to move. The most common forms of akathisia involve compulsive fidgeting, rocking back and forth, and pacing, and it most often occurs during the first few months of conventional antipsychotic use. At times, patients may have difficulty clearly describing the sensation of akathisia, which can lead to the misdiagnosis of agitation and an increase in antipsychotic medication—hence worsening the akathisia. Anticholinergics have limited utility in the treatment of akathisia; they should be considered second-line therapy and used when first-line agents, such as adrenergic receptor antagonists (propranolol), either fail or are contraindicated.

PARKINSONISM. Parkinson disease and secondary parkinsonism arising from the use of antipsychotics can be indistinguishable. Secondary parkinsonism is more common with high-potency antipsychotics and is seen much less frequently with atypical antipsychotics. These symptoms may manifest at any time during antipsychotic treatment but usually begin within the first 3 months of treatment and can be managed by lowering the antipsychotic dose to the lowest effective dose. Symptoms include generalized slowing of movement (akinesia), rigidity, resting tremor, hypersalivation, cogwheeling, and hypomimia (masked facies), and are caused by a blockade of DA receptors of nigrostriatal neurons, which terminate in the caudate nucleus. In some cases, these symptoms may also be mistaken for the negative symptoms of schizophrenia.

Anticholinergics have been found to be useful in treating the symptoms of neuroleptic-induced parkinsonism. The additions of benztropine (0.5 to 6.0 mg per day), trihexyphenidyl (2 mg, two to four times daily), procyclidine (5 to 20 mg per day), and biperiden (2 to 24 mg per day) have been found to be effective therapies.

Long-Term Use of Anticholinergics

Patients with schizophrenia often require long-term treatment with conventional antipsychotics. As noted above, these medications have serious adverse effects such as extrapyramidal side effects, including acute dystonic reactions, akathisia, parkinsonism, and TD, and anticholinergics may mitigate their severity. Despite this, the prophylactic use of anticholinergic medication is controversial because the long-term use of anticholinergics may predispose patients to TD. Additionally, anticholinergics can be abused and may have serious side effects. Long-term use may affect memory, and cognitive impairment can be seen as early as 60 days if these medicines are taken continuously. In the case of overdose, anticholinergic agents can create a dangerous condition with tachycardia, hyperthermia, mydriasis, hallucinations, seizure, and coma. Consequently, the World Health Organization (WHO) released a consensus statement that “the prophylactic use of anticholinergics in patients on neuroleptic treatment is not recommended, and may be justified only early in treatment (after which it should be discontinued and its need should be reevaluated).”

Despite the consensus statement from WHO, subsequent studies have found that there is evidence to support the prophylactic use of anticholinergic agents, especially in young men receiving high-potency antipsychotics and who remain at high risk for developing acute dystonia. They also reviewed the literature for continuing prophylactic treatment and concluded that continuing prophylaxis is helpful for many patients because of the relatively high risk of developing parkinsonism upon cessation of anticholinergic medication. The prophylactic use of these agents is not routinely indicated and should be used on a case-to-case basis for patients with a high risk of developing acute dystonic reactions.

Table 33.11a–1.
Adverse Effects of Anticholinergics

- Cardiovascular system
    - Tachycardia
    - Digestive system
    - Constipation
    - Dry mouth
    - Nausea
- Nervous system
    - Confusion
    - Disorientation
    - Memory impairment
- Visual system
    - Blurred vision
    - Dilated pupils
    - Worsening of narrow-angle glaucoma
- Urogenital system
    - Urinary retention

Precautions and Adverse Reactions

Anticholinergic medications can produce adverse reactions in the CNS, as well as in the peripheral nervous system, due to their widespread antagonism of muscarinic receptors in the periphery. These agents produce clinically meaningful effects on the cardiovascular, GI, autonomic, and urogenital systems. The major adverse reactions of these medications are summarized in Table 33.11a–1.

Anticholinergic agents block muscarinic acetylcholine receptors throughout the body and produce system-wide side effects. Dry mouth is a common side effect at low doses, while higher dosages can cause nausea, drowsiness, mild tachycardia, abdominal cramps, urinary retention (especially in men), and severe constipation, which can progress to intestinal pseudo-obstruction and bowel dilation. Dry skin and impaired sweating have also been reported, and patients may risk heat stroke if precautions are not taken. Anticholinergics are contraindicated in patients with closed-angle glaucoma. In the CNS, anticholinergics can cause confusion and memory loss, and in the more advanced and demented patients, hallucinations and disorientation can occur. Lowering or discontinuing the drug can treat the side effects.

Toxic doses or an overdose of anticholinergic medication may lead to an atropine-like poisoning, which may manifest as confusion, nervousness, psychosis, ataxia, blurred vision, tachycardia, elevated blood pressure, dry mouth, GI discomfort, anhidrosis, hyperthermia, and respiratory collapse. In general, supportive measures are used after an overdose. However, 1 to 2 mg of physostigmine salicylate (Antilirium), an acetylcholinesterase inhibitor, may be used to reverse the anticholinergic symptoms of overdose. If required, a second dose of physostigmine may be administered 2 hours after the first dose.

Anticholinergic Abuse

Anticholinergic agents have an abuse potential on account of their euphoriant and hallucinogenic effects, especially when combined with other street drugs. The prevalence of anticholinergic abuse varies from 0% to 34%. The most common reason for abuse is the drug-induced euphoria. Trihexyphenidyl is the most commonly abused anticholinergic for the reason that it tends to be the most stimulating of all anticholinergics.

Table 33.11a–2.
Anticholinergic Preparations and Dosages

Generic Name	Brand Name	Preparations	Daily Oral Dose
Benztropine	Cogentin	0.5, 1.0, 2.0 mg tablets	0.5–2.0 mg b.i.d. or t.i.d.
		1 mg/mL injection	
Trihexyphenidyl	Artane	2, 5 mg tablets	2 mg b.i.d. to q.i.d.
		2 mg/5 mL elixir	
Biperiden	Akineton	2 mg tablets	2 mg t.i.d. to q.i.d.
		5 mg/mL injection	

Drug Interactions

Any medication with anticholinergic or antihistaminic properties may be pharmacodynamically additive to the effects of anticholinergic medications, thereby leading to side effects and potential issues of toxicity. Pharmacokinetic interactions with these agents occur as well. For example, the coprescription of benztropine and digoxin (Digitek) has been reported to increase digoxin levels (Table 33.11a–2).

Any medication with anticholinergic properties may also potentiate the anticholinergic effects of amantadine (see below). Medications that decrease renal clearance may result in higher plasma concentrations of amantadine and, consequently, a greater risk for side effects. These include triamterene hydrochlorothiazide (Maxzide), trimethoprim sulfamethoxazole (Bactrim), and quinidine.

Laboratory Interference

Anticholinergic medications and amantadine are not known to alter the results of any standard laboratory tests and values.

Dosage and Administration

Anticholinergic doses can vary widely among individuals and must be empirically determined. In general, prophylactic doses are the same as the doses usually needed to treat parkinsonism. For acute dystonias, an IM or IV medication such as benztropine (1 to 2 mg IM) or the antihistamine diphenhydramine (25 to 50 mg IM or IV) is usually given. The starting dose for trihexyphenidyl is 0.5 to 1 mg per day, and the dose should be increased no faster than every 7 to 14 days. A dose increase of 1 mg per day is reasonable and a dose of 2 mg three to four times per day is the usual goal.

The dose of benztropine is begun at 0.5 mg per day and can be raised to 4 to 8 mg per day and requires dosing two to three times per day.

The dose of procyclidine is begun at 2.5 mg per day and increased gradually to a maximum of approximately 30 mg per day.

The starting dose of diphenhydramine is 25 mg per day, and it can be titrated to 150 to 200 mg per day in divided doses.

SCOPOLAMINE

Introduction and Chemistry

Scopolamine is a tropane alkaloid drug and a competitive acetylcholine antagonist with a significant affinity for the M3 receptor and has a minimal effect on nicotinic receptors. Scopolamine has a high affinity for the M3 receptor and is 30 times more potent than amitriptyline. Plants containing scopolamine have been in use since prehistoric times, but the compound has only been used in its purified forms (including hydrobromide, hydrochloride, hydroiodide, and sulfate) since 1880. It has a more potent antimuscarinic effect on the eye and the salivary glands than atropine but exhibits less potent effects on the heart, respiratory system, and intestinal smooth muscle (Fig. 33.11a–6). Scopolamine is used for motion sickness and produces drowsiness, and can cause amnesia in sensitive individuals. Toxic doses can cause agitation, hallucinations, excitement, and coma.

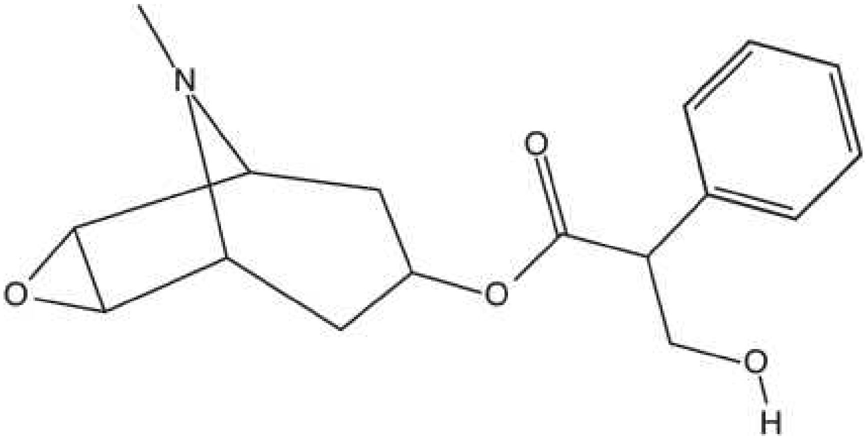

FIGURE 33.11a–6. Molecular structure of scopolamine.

Pharmacologic Actions

Scopolamine is well absorbed from the GI tract, with absorption primarily occurring in the upper small intestine. Its onset of action varies depending on the formulation but ranges from 15 to 30 minutes for an injectable form and up to 4 hours for the transdermal form. The therapeutic effects last up to a maximum of 72 hours with the transdermal patch. Scopolamine crosses the BBB, as well as the placenta, and is secreted in breastmilk. Consequently, it is classified as a pregnancy category C drug. It is reversibly bound to plasma proteins and principally eliminated in the urine. The transdermal formulation has fewer side effects and a longer duration of action compared to the oral form. It is also used preoperatively to inhibit gastric and respiratory tract secretions.

Dosage and Administration

Scopolamine can be administered orally, as a transdermal patch or injected IM, direct IV or sub-Q. The oral adult dosage ranges from 0.4 to 0.8 mg initially and up to three times daily as needed. The injectable dose ranges from 0.32 to 0.65 mg and can be repeated up to three times daily.

Therapeutic Indications

Scopolamine is mostly used for motion sickness and postoperative nausea and vomiting. Recent studies suggest additional uses for scopolamine. Jeraisy and colleagues (2020) report that transdermal patches of scopolamine may help control pediatric drooling (sialorrhea), while ongoing research seems to support scopolamine's efficacy in treating unipolar and bipolar depression, as well as anxiety, particularly in women.

Precautions and Adverse Reactions

Adverse reactions to scopolamine can range from mild drowsiness, somnolence, dizziness, and confusion to more severe effects like disorientation, amnesia, delirium, and acute toxic psychoses. Scopolamine may also cause dryness of the mouth, dilated pupils, increased intraocular pressure requiring adjustment of therapy, increased pulse rate, decreased GI motility, urinary retention, and decreased bronchial secretions with the formation of bronchial plugs.

Design and Interpretation of Clinical Drug Studies

During the last few years, the role of anticholinergic medications has expanded to include the treatment of depressive disorders. The hypothesis that an adrenergic–cholinergic imbalance could lead to depression was proposed as early as 1972, and though initially ignored, most of the recent body of research is based on this theoretical model. Increasing cholinergic activity using physostigmine (an anticholinesterase inhibitor) is known to exacerbate acute depressive symptoms in patients with major depressive disorder (MDD). In addition, increased cholinergic signaling may also induce depressive symptoms in currently manic patients with bipolar disorder (BD). Numerous studies have also demonstrated that the inverse is true: inhibiting cholinergic activity is associated with symptom improvement in major depression. It is also well established that REM sleep changes are associated with MDD, and REM sleep deprivation as induced by anticholinergic medications leads to a reduction in these symptoms.

Scopolamine has generated the most interest as a potential anticholinergic agent that could treat symptoms associated with moderate to severe depression. The first evidence of this finding was suggested in 1991 research conducted on a small group of patients with moderate depression using IM scopolamine and showed a statistical difference. Furey and colleagues (2006) then established the efficacy of scopolamine in depressive disorders while studying the cognitive effects of IV scopolamine and incidentally found antidepressant effects of this drug. To validate these findings, the investigators designed two crossover randomized controlled trials and showed a significantly robust and rapid antidepressant response of IV scopolamine compared to placebo. A later study by the same researchers in 2010 validated these findings specifically in patients with unipolar depression.

Another study conducted at the National Institute of Mental Health enrolled patients with MDD who received multiple sessions of placebo or scopolamine hydrobromide (4 μg/kg) and were randomized to a placebo/scopolamine or scopolamine/placebo sequence of infusions 3 to 5 days apart. Patients were evaluated using the Montgomery–Åsberg Depression Rating Scale and the Hamilton Anxiety Rating Scale to assess their responses to scopolamine. Patients showed reductions in depression and anxiety from baseline during scopolamine infusions compared to placebo infusions. The antidepressant and anxiolytic effects occurred in less than 3 days compared to conventional antidepressants, which may take up to 4 weeks. The group receiving scopolamine infusions first followed by placebo infusions continued to show response, which suggests alternative mechanisms beyond scopolamine’s known effect on neuroreceptors. This persistence of improvement in mood beyond the initial infusion period also negates the hypothesis of anticholinergic euphoria and suggests a sustained antidepressant response. This study showed a rapid antidepressant response to scopolamine in depressed patients that is well tolerated and safe relative to other rapid antidepressant treatments, including ketamine and high-dose TCA therapy. Another study at the National Institute of

Mental Health showed that IV scopolamine had a significant effect on unipolar and bipolar depression.

Recognizing the fact that a significant number of patients with MDDs do not respond to antidepressant medications, the need for augmentation strategies from the beginning is being increasingly entertained. Considering the role of scopolamine as discussed above, it is no surprise that it may have a substantial role in such treatments. One major limitation is that treating MDD with scopolamine requires either an IM or IV route of administration, which presents logistical issues for its use in an everyday practice setting.

To overcome this barrier and assess the tolerability and efficacy of oral scopolamine, investigators designed a randomized, placebo-controlled, double-blind, parallel-group study to evaluate the role of oral scopolamine as an adjuvant therapy to citalopram in moderate to severe MDD. Forty patients were randomized into two groups, the active group receiving citalopram and scopolamine hydrobromide (containing 0.5-mg scopolamine) with the second group receiving citalopram and placebo. The total dose of scopolamine used was 1 mg/day (0.5 mg b.i.d.), while citalopram was adjusted from an initial dose of 20 mg in the first week to 40 mg/day for the next 5 weeks. The patients were assessed using 17-item Hamilton Depression Rating Scale (HDRS) for 6 weeks, with assessments on days 4, 7, 14, 28, and 42. By week 6, all patients in the scopolamine group and most patients in the placebo group had achieved a 50% reduction in the HDRS, while the remission rate by week 6 was significantly higher (65%) in the scopolamine group compared to the placebo group (20%).

The results of this study validated the role of scopolamine as an adjunct to antidepressant therapy when initiated from the beginning of the treatment with a high response and remission rate. It resulted in few adverse effects. These studies suggest that scopolamine as monotherapy, as well as when used as an adjunct, is a safe and effective strategy in MDDs.

More recently, researchers at the Medical University of Lublin in Poland (Kruk-Slomka et al., 2015) studied the antidepressant efficacy of cannabinoids, including oleamide, AM 251, JWH 133, and AM 630, alone and in conjunction with nicotine hydrogen tartrate and scopolamine hydrochloride in murine models. Among other things, the studies found that scopolamine, in conjunction with noneffective concentrations of cannabinoids, did have antidepressant effects.

Various theories abound regarding the antidepressant efficacy and precise mechanism of action of scopolamine in MDDs, and to date, none have been established. Some of these theories suggest alterations in type 2 and 3 muscarinic receptors, as well as polymorphisms in the type 2 muscarinic receptor gene, and that scopolamine has a high affinity for the type 3 muscarinic receptor. Other possible mechanisms include cholingeric hyperactivity, REM sleep deprivation, as well as hyperactivity of the glutamatergic system, which has been implicated in the development of MDD. Scopolamine decreases glutamatergic transmission, thereby alleviating depressive symptoms. Given that activation of the endocannabinoid system is known to inhibit glutamatergic transmission, this could potentially explain observed antidepressant effects following the coadministration of cannabinoid receptor ligands and scopolamine.

Scopolamine seems to be an appropriate treatment option for difficult-to-treat patients with major and bipolar depression. Its relatively simple dosing and minor side effect profile with no significant impact on cognition based on the low doses used in the studies suggest its place as an adjunct to antidepressant treatment. Moreover, it should be noted that combination therapy from the beginning of treatment results in greater improvement than monotherapy. Some early studies reported less robust antidepressant effects, but those results may have been due to the uncontrolled nature of the studies as well as the lower-dose range utilized. Despite the positive implications of the studies, numerous limitations remain regarding its impact on cognition (confusion and delirium), dosing, and safety, and more research is needed to study its efficacy in the long term and rapid antidepressant response as an adjunct when added later in the treatment.

Finally, scopolamine’s rapid antidepressant effect in some patients has made it a candidate for the study of biomarkers. A study in 2012 showed that neural responses in the visual cortex, especially to emotional stimuli, maybe a potential biomarker for patients with a favorable response to scopolamine. The study conducted at the National Institute of Mental Health suggests differences in treatment response based on brain-based variables and requires a more personalized approach to treatment for depressive disorders.

AMANTADINE

Amantadine (Symmetrel; 1-aminoadamantane hydrochloride) is an antiviral drug that was developed in the 1960s for the prophylaxis and treatment of influenza A, but was found to have antiparkinsonian properties. In 1973, it received FDA approval for the treatment of Parkinson disease and is also used to treat drug-induced extrapyramidal symptoms such as parkinsonism, akinesia, and the rabbit syndrome (focal perioral tremor of the choreoathetoid type).

Chemistry

Amantadine is a tricyclic symmetric amine and is a stable, white, or nearly white, crystalline powder that is freely soluble in water and soluble in alcohol and in chloroform. Its molecular weight is 187.71 with a molecular formula $C_{10}H_{18}NCl$ (Fig. 33.11a–7).

Pharmacologic Actions

ABSORPTION AND DISTRIBUTION. Amantadine is well absorbed orally, reaching peak plasma concentrations of 0.2 to 0.4 μg/mL within 1 to 4 hours and attains a steady-state in 4 to 7 days. Doses above 200 mg per day may result in a greater than proportional increase in maximum plasma concentrations. It is approximately 67% bound to plasma protein.

METABOLISM AND ELIMINATION. Amantadine is primarily excreted unchanged in the urine by glomerular filtration and tubular secretion. Increasing plasma concentrations can lead to toxicity, but no absolute values of amantadine concentrations associated with adverse effects have been fully established. The mean half-life ranges from 10 to 14 hours. One study involving 19 healthy volunteers showed the plasma half-life averaged 16 ± 6 hours (range 9 to 31 hours).

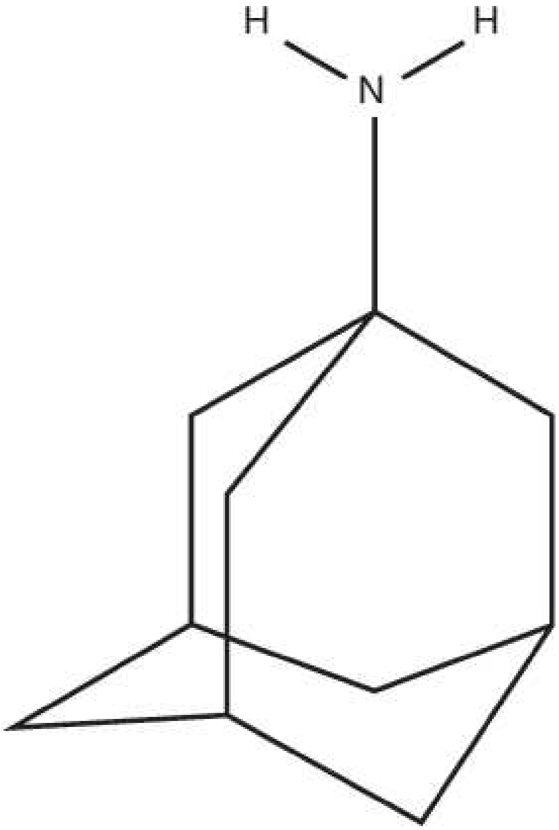

FIGURE 33.11a–7. Molecular structure of amantadine.

SPECIAL CONSIDERATION IN OLDER ADULTS AND RENALLY IMPAIRED. In healthy older adult individuals aged 60 and older, the oral plasma clearance of amantadine is reduced, while the plasma half-life and plasma concentrations are increased. It is unclear whether these changes are due to a decline in renal function or other age-related factors, though evidence suggests that impaired renal function can significantly reduce the clearance of amantadine. The elimination half-life increases two- to threefold or greater when creatinine clearance is less than 40 mL/1.73 m^2 per minute. Acidic urine increases the excretion rate of amantadine, and urine-acidifying drugs may increase the elimination of the drug from the body. Amantadine is removed in negligible amounts by hemodialysis.

Pharmacodynamics

MECHANISM OF ACTION. The exact mechanism of action of amantadine in the treatment of Parkinson disease and drug-induced extrapyramidal reactions is not known. It has preferential selectivity for central catecholamine neurons and acts by potentiating the release of endogenous catecholamines and DA from presynaptic vesicles, blocking the reuptake of DA and having an agonist effect on postsynaptic DA receptors. Amantadine is a weak, noncompetitive NMDA receptor antagonist, and some studies suggest that it may have direct and indirect effects on dopaminergic cell groups. It has no anticholinergic activity, and though it is only 1/209,000 as potent as atropine, it does cause side effects like other anticholinergics, including constipation, dry mouth, and urinary retention. When used alone or in combination with other treatments for mild parkinsonism, many patients derive only transient benefits, if any at all.

In addition to showing NMDA receptor antagonism, amantadine is also a sigma-1 agonist, which may potentially play a role in its effects on parkinsonian symptoms and its antiviral properties. Amantadine has also shown neuroprotective properties via induced expression of glial-cell–derived neurotrophic factor (GDNF) or other antioxidative or anti-inflammatory avenues.

Design and Interpretation of Clinical Trials

Amantadine has been used as an antiviral drug for more than 50 years and was initially developed to fight influenza caused by type A influenza viruses. However, widespread drug resistance has reduced its popularity to such an extent that its use is no longer recommended. Reports of antiparkinsonian effects were observed a few years later, and the first clinical study (n = 163) using amantadine to treat patients with Parkinson disease was published by Schwab and colleagues in 1969 when they reported a positive outcome. Four years later, in 1973, the FDA approved the use of amantadine to treat Parkinson disease.

Since that time, many studies have compared the effectiveness of amantadine and anticholinergic agents, but to date, there are no conclusive data to establish its efficacy as a first-line agent. A double-blind study compared the effects of amantadine and biperiden in treating extrapyramidal side effects in 42 schizophrenic subjects treated with haloperidol (Haldol). Of note, the treatment effect of amantadine and biperiden was similar. This study supports the notion that amantadine is a useful alternative to anticholinergics.

In another double-blind, placebo-controlled study, amantadine was compared to trihexyphenidyl in treating drug-induced parkinsonism. The study showed that amantadine not only produced far fewer adverse effects but also was equally effective as trihexyphenidyl and is a useful alternative to atropine-like drugs. Some case reports show that amantadine may alleviate symptoms of TD. This is a controversial issue, and there are no controlled studies to replicate these results.

A relatively new form of an extended-release formulation of amantadine is available for the treatment of Parkinson disease. The initial starting dose is 137 mg and can be increased to 274 mg per day. The extended-release formulation of amantadine is effective in decreasing motor fluctuations and has a side-effect profile similar to the regularly available form of amantadine. The new extended-release formulation is taken at bedtime and is slowly released into the bloodstream overnight. As a result, the peak levels of the drug are present when it is time to wake up.

Recent studies have also looked at weight-loss potential, reversal of sexual dysfunction, and improvement in cognitive functioning by amantadine, as well as its potential neuroprotective properties and management of sequelae following cerebrovascular events like stroke or traumatic brain injuries. There is also research currently testing to see if amantadine is effective at treating COVID-19, possibly by disrupting viral replication through the viroporin E channel of the virus or agonistic behavior at sigma-1 receptors. One study assessed the weight loss potential of amantadine in patients who were treated with olanzapine (Zyprexa). Significantly fewer subjects taking amantadine gained weight compared to the placebo group. Amantadine stabilized weight in patients treated with olanzapine but did not improve fasting insulin or lipid levels. Recent studies have also found that amantadine may enhance the therapeutic effects of antidepressants. A preliminary study involving four patients with acute bipolar depression found depressive symptoms improved after 1 week of treatment. More studies are needed to confirm these results. Amantadine has a predilection for the nigrostriatal dopaminergic system compared to the mesolimbic system and enhances the CNS dopaminergic activity. This can lead to delusion, paranoia, alterations and elevation of mood, confusion, and disorientation. A few case reports suggest psychotic decompensation in patients treated with amantadine. The vast majority who are treated for extrapyramidal symptoms show a lack of psychotic relapse. Clinicians should be alerted to the fact that patients treated with amantadine are vulnerable to psychotic decompensation.

A double-blind study showed that amantadine did not cause memory impairment in patients treated with the medication, and, therefore, it is a good alternative for older adults who are more prone to these side effects.

Effects on Specific Organs and Systems

Amantadine relieves parkinsonian symptoms by increasing dopaminergic function and increasing the release of catecholamines. These effects can be manifold and manifest as adverse reactions. These include restlessness, depression, irritability, insomnia, agitation, excitement, and occasionally psychotic decompensation. Amantadine is excreted unchanged by the kidneys and patients with renal dysfunction should be monitored closely.

Therapeutic Indications

DRUG-INDUCED EXTRAPYRAMIDAL REACTIONS. Amantadine is indicated in the treatment of drug-induced extrapyramidal reactions, but there are no data that support the use of this drug as a first-line agent, particularly for acute dystonic reactions. Some studies suggest that it is as effective as anticholinergics for extrapyramidal signs and symptoms but is not effective in treating TD and akathisia. Although side effects have been noted with amantadine, the incidence of anticholinergic-type side effects is lower than that observed with the anticholinergic antiparkinsonian drugs. This is particularly useful in older adults who are more sensitive to the anticholinergic effects, both in the CNS, such as anticholinergic delirium, and in the peripheral nervous system, such as urinary retention.

PARKINSON DISEASE AND PARKINSONISM. The usefulness of amantadine in the treatment of parkinsonism is controversial because its efficacy in comparison with the anticholinergic antiparkinsonian drugs has not yet been established. In a controlled trial of 17 patients with parkinsonism, amantadine hydrochloride in a dose of 100 mg b.i.d. showed a minor beneficial effect on physical signs but failed to demonstrate any significant effect on functional disabilities. This improvement in physical signs was only sustained for 8 weeks, but numerous patients noticed deterioration in functional performance after 2 to 5 weeks of treatment.

Amantadine has been shown to be less effective than levodopa in treating idiopathic Parkinson disease (paralysis agitans), postencephalitic parkinsonism, and symptomatic parkinsonism, which may follow injury to the nervous system by carbon monoxide intoxication. It appears to be more effective in treating older adult patients believed to have developed parkinsonism in association with cerebral arteriosclerosis.

Amantadine has been reported to be beneficial in the treatment of selective serotonin reuptake inhibitor-associated side effects, such as lethargy, fatigue, anorgasmia, and ejaculatory inhibition.

BRAIN INJURY. Traumatic brain injury (TBI) is one of the leading causes of death and disability in persons between 15 and 30 years of age. Currently, there are no interventions or treatments to change the prognosis of this condition, and it leads to chronic disability in more than 90,000 survivors of brain injury. The trauma to the brain usually impacts the frontal region, disrupting neurotransmitters, including DA, and causing frontal lobe dysfunction. This syndrome includes problems with aggression, disinhibition, attention, impulsivity, planning, perseveration, amotivation, apathy, memory deficits, mood dysregulation, and problem solving. Other causes of brain injury with similar sequelae include stroke, encephalitis, and aneurysm. The role of DA and lower levels of its metabolites is well established in brain injury, specifically in the frontal lobe regions. Multiple studies have shown that DA is involved in the regulation of cognition, mood, and behavior. In patients with brain injury, there is deficiency and dysregulation of DA in the frontal lobes.

Amantadine was first used in 1988 in two patients for the treatment of TBI. Subsequently, a study assessed 30 patients aged 5 to 59 with TBI with behavior problems including agitation, mood lability, and inattention. Treatment with amantadine led to improvement in 63% of the patients. These positive results led to the hypothesis that since amantadine impacted the dopaminergic system (presynaptic and postsynaptic), it would be an appropriate treatment for patients with TBI with compromised dopaminergic systems. Numerous studies since then have validated these results, and amantadine is now considered safe and beneficial for arousal, agitation, and problems with executive functioning in patients with a head injury. Amantadine has been used frequently for the treatment of head injuries for decades.

Amantadine is one of the most frequently used medications for patients undergoing neurorehabilitation. Various authors have reported the use of amantadine alone or in combination therapy with a positive response in patients with brain injury, specifically in the frontal lobe syndrome. Recent studies suggest that amantadine and other dopaminergic agents may substantially improve the level of executive functioning in these patients. The clinical effects can be seen within a few days to a week. In one study of 184 patients with TBI who were minimally conscious 1 to 4 months after the brain injury, amantadine use after 4 weeks showed a significantly faster recovery compared to the placebo group. Of note, despite the high risk of seizures in this population, amantadine did not increase the risk of adverse effects, including any medical or neurologic events.

Another study showed improvements in attention span, speed of information processing, learning, and alertness. Other studies have shown improvements in apathy, amotivation, and perseveration. The greatest improvements have been seen in a reduction of agitation, physical aggression, distractibility, and mood swings. More recently, amantadine has shown promising results in improving clinical status of dementia patients. According to one report, it is also useful in treating fatigue and depression from multiple sclerosis. Despite the fact that these case reports show promising results, there are limitations to these small and uncontrolled studies, which underscores the need for double-blind, large, and controlled studies.

The exact mechanism of action remains unclear, but amantadine appears to act as an NMDA antagonist and indirect DA agonist. Amantadine may increase dopaminergic activity by increasing presynaptic release and blocking reuptake postsynaptically, targeting the nigrostriatal, mesolimbic, and frontostriatal circuits. The final result is increased arousal, drive, and attention.

These results suggest that patients with severe TBI can be treated with amantadine safely at doses between 200 and 400 mg.

Treatment in Children

Head injury is a common problem in children: nearly 300 out of 100,000 children suffer TBI by the age of 18. Most children are able to survive these injuries yet are left with deficits, including inattention, difficulties with executive functioning, and academic performance. The use of agents to treat these behavior disturbances secondary to head injuries in the pediatric population is less well known, but a small number of studies suggest the use of amantadine. Despite the limited body of literature on the use of amantadine in the pediatric population, it is a useful and beneficial treatment in children with a head injury and symptoms of arousal and alertness.

Pathologic Gambling and Drug Addiction

Pathologic gambling (PG) is a persistent gambling behavior with devastating consequences and is identified as one of the substance abuse and addictive disorders. Despite significant research, there have been no FDA-approved treatments for this condition. Considering the fact that PG and addictive disorders may have similar clinical and biologic underpinnings, it may be appropriate to use drugs for the treatment of PG that are used for drug addiction. Numerous studies suggest the role of DA in addictive, reinforcing, and rewarding behaviors. The pleasure and reward-seeking behavior present in drug addiction is linked to the hypodopaminergic state and may also be responsible for gambling behavior triggering the release of DA and, consequently, a sense of pleasure. In addition, an imbalance in glutamate (Glu) homeostasis may also be responsible for reward-seeking behaviors.

One study suggested that amantadine may be effective in reducing PG and showed symptoms resolving after 4 days of treatment. Another case study of a male patient with PG, comorbid depression, and alcohol dependence showed that amantadine 100 to 150 mg daily had a 43% to 64% reduction in the Gambling Symptom Assessment Scale (G-SAS).

The data suggest that the glutamatergic system may play an important role in PG, and amantadine could be a potential treatment option for this condition.

Amantadine exerts its effects on DA neurotransmission by increasing DA release and DA reuptake inhibition and acts as an antagonist at NMDA glutamatergic receptors. These effects may explain its role as an antidepressant. Numerous studies have suggested that its dopaminergic properties may be beneficial in cocaine-dependent patients with withdrawal symptoms, but more studies are required to validate these results.

Precautions and Adverse Reactions

The most frequently reported CNS adverse reactions (5% to 10%) are insomnia, dizziness, and impaired concentration. CNS adverse reactions that are reported less frequently (1% to 5%) include restlessness, irritability, agitation, excitement, depression, anxiety, and confusion. More severe CNS side effects are seizures and psychotic symptoms. Overdose may produce acute toxic psychosis.

For patients already receiving medications for Parkinson disease, the addition of amantadine to their treatment may lead to intense urges to engage in sex acts, gamble, or spend money in wanton and reckless ways because medications that increase central dopaminergic tone, as amantadine does, may impair a patient's ability to exhibit self-control. Prescribers should routinely inquire about the development of these urges (gambling, sexual, uncontrolled spending, or other urges) and lower the dose of amantadine or completely stop the medication if a patient reports the development of such urges.

Other less frequently (1% to 5%) reported adverse reactions are anorexia, dry mouth, peripheral edema, orthostatic hypotension, congestive heart failure, headache, somnolence, nervousness, dream abnormality, dry nose, diarrhea, and fatigue. Livedo reticularis of the legs (purple discoloration of the skin caused by dilatation of the vessels) may occur in some patients. The phenomenon usually clears within a month after cessation of amantadine.

Rare (less than 0.1%) occurring adverse reactions are instances of convulsion, leukopenia, neutropenia, eczematoid dermatitis, oculogyric episodes, suicidal attempt, suicide, and suicidal ideation.

Amantadine is relatively contraindicated in patients who have a known history of seizures or renal disease. It should also be used only with caution in persons with congestive heart failure or edema. There is evidence to suggest that it is teratogenic. Consequently, it should not be used by pregnant women or women who are breastfeeding.

Amantadine should not be discontinued abruptly in patients with Parkinson disease since a few patients have experienced a parkinsonian crisis (i.e., a sudden marked clinical deterioration upon abrupt cessation of this agent) (Table 33.11a–3).

Deaths

Amantadine has been associated with deaths secondary to overdose in amounts as low as 2 g. Anticholinergic effects may be responsible for these deaths secondary to cardiac, respiratory, renal, or CNS toxicity.

Table 33.11a–3.
Adverse Effects of Amantadine

Cardiovascular system
- Arrhythmia
- Tachycardia

Nervous system
- Delirium
- Paranoia
- Paresthesias

Drug Interaction

Coadministration of amantadine with phenelzine (Nardil) or other MAOIs may result in a significant increase in blood pressure. There is an increased likelihood of side effects such as confusion, hallucinations, nightmares, dry mouth, and blurred vision if administered with anticholinergics. The coadministration with CNS stimulants can result in insomnia, irritability, nervousness, and possibly seizures.

Laboratory Interferences

Amantadine is not known to alter the results of any standard laboratory tests and values.

Dosage and Administration

ADULT. The usual starting dose of amantadine hydrochloride is 100 mg twice a day when used alone and can be cautiously increased to 200 mg twice a day in patients whose responses are not optimal. Amantadine has an onset of action, usually within 48 hours.

The initial dose of amantadine hydrochloride is 100 mg daily for patients with serious associated medical illnesses or who are receiving high doses of other drugs to treat Parkinson disease. After one to several weeks at 100 mg once daily, the dose may be increased to 100 mg twice daily, if necessary.

Some patients have reported a notable decrease in efficacy after a few months and may benefit by increasing the dose to 300 mg daily or temporarily discontinuing amantadine for several weeks, followed by reintroduction of the drug.

Dosage for Concomitant Therapy

When patients do not respond to monotherapy with anticholinergic anti-Parkinson drugs, monotherapy or concomitant therapy with amantadine may be beneficial. In some cases, when amantadine and levodopa are initiated concurrently, the patient can exhibit rapid therapeutic benefits. Amantadine should be held constant at 100 mg daily or twice daily while the daily dose of levodopa is gradually increased to optimal benefit.

Table 33.11a–4.
Dosage for Impaired Renal Function

Creatinine Clearance (mL/min/1.73 m^2)	Amantadine Hydrochloride Dosage
30–50	200 mg 1st day and 100 mg each day thereafter
15–29	200 mg 1st day followed by 100 mg on alternate days
<15	200 mg every 7 days

The recommended dosage for patients on hemodialysis is 200 mg every 7 days.

Dosage for Drug-Induced Extrapyramidal Reactions

The usual starting dose of amantadine hydrochloride is 100 mg twice a day. Occasionally, patients whose responses are not optimal with amantadine hydrochloride at 200 mg daily may benefit from an increase of up to 300 mg daily in divided doses (Table 33.11a–4).

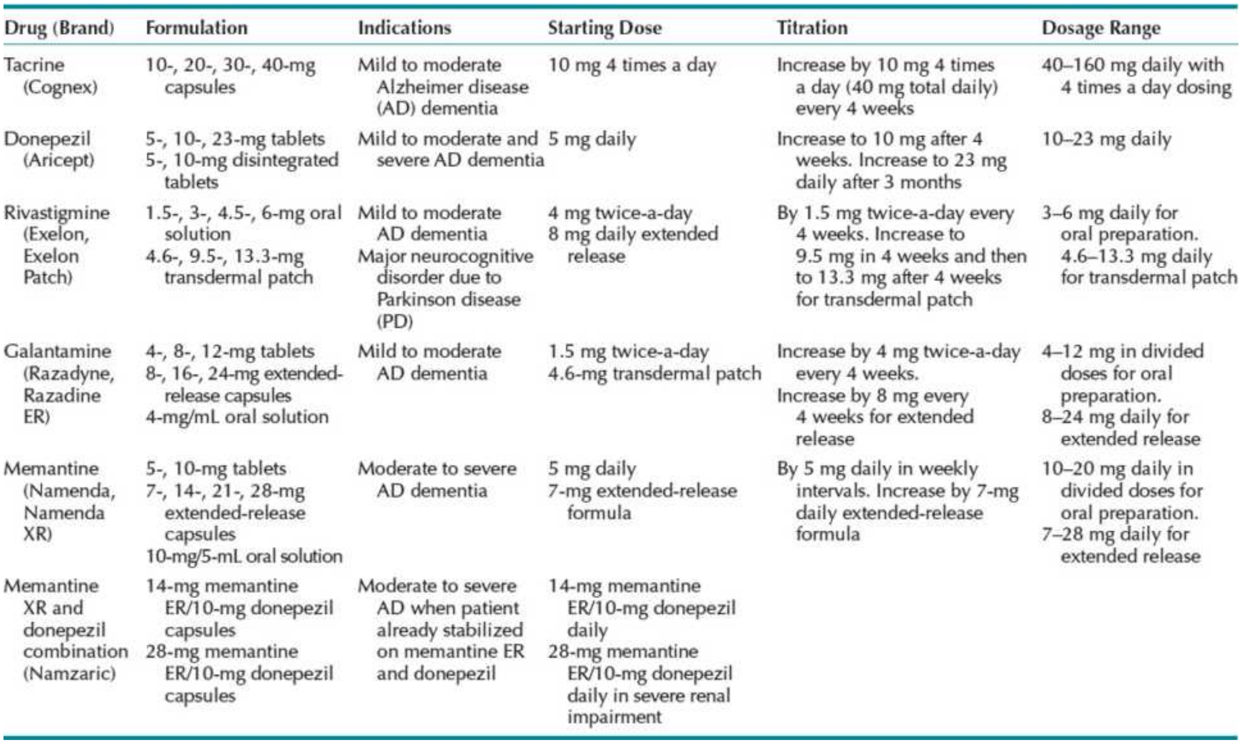
33.11b Cholinesterase Inhibitors and Memantine

Samir A. Sabbag, M.D., Zelde Espinel, M.D., M.P.H., Luminita Luca, M.D., Ph.D., and Elizabeth A. Crocco, M.D.

In 2015, the total number of individuals affected by dementia worldwide was 47 million. It is predicted that this number will increase to 75 million in 2030 and 132 million by 2050. With the aging of the population, particularly in the United States, the annual number of new cases due to Alzheimer and related dementias is expected to double by 2050. The incidence of Alzheimer disease (AD) increases with age. Epidemiologic studies in the United States report its prevalence to be about 3% at age 65, which increases to greater than 30% by age 85. In 2021, it was estimated that 6.2 million Americans aged 65 and older were living with Alzheimer dementia. As the population ages, the prevalence of the disease will increase and significantly impact society and its health care systems.

Currently, cholinesterase inhibitors and memantine (Namenda) are the medications approved by the U.S. Food and Drug Administration (FDA) for the treatment of AD and other dementias (Table 33.11b–1). Since their introduction in the early 1990s, cholinesterase inhibitors were indicated only for mild to moderately ill patients with AD. Their indication has expanded over time to include patients with moderate to severe AD and patients with dementia associated with Parkinson disease (PD). These agents are also being studied as a potential treatment for other types of non-AD dementias, but they presently lack an FDA indication. Memantine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, has been approved for moderate to severe AD. It is routinely used with a cholinesterase inhibitor in clinical practice, as studies have demonstrated how this combination provides a potentially better response compared to monotherapy with a cholinesterase inhibitor.

Table 33.11b–1.
Medications Used in Neurocognitive Disorders



Drug (Brand)	Formulation	Indications	Starting Dose	Titration	Dosage Range
Tacrine (Cognex)	10-, 20-, 30-, 40-mg capsules	Mild to moderate Alzheimer disease (AD) dementia	10 mg 4 times a day	Increase by 10 mg 4 times a day (40 mg total daily) every 4 weeks	40–160 mg daily with 4 times a day dosing
Donepezil (Aricept)	5-, 10-, 23-mg tablets 5-, 10-mg disintegrated tablets	Mild to moderate and severe AD dementia	5 mg daily	Increase to 10 mg after 4 weeks. Increase to 23 mg daily after 3 months	10–23 mg daily
Rivastigmine (Exelon, Exelon Patch)	1.5-, 3-, 4.5-, 6-mg oral solution 4.6-, 9.5-, 13.3-mg transdermal patch	Mild to moderate AD dementia Major neurocognitive disorder due to Parkinson disease (PD)	4 mg twice-a-day 8 mg daily extended release	By 1.5 mg twice-a-day every 4 weeks. Increase to 9.5 mg in 4 weeks and then to 13.3 mg after 4 weeks for transdermal patch	3–6 mg daily for oral preparation. 4.6–13.3 mg daily for transdermal patch
Galantamine (Razadyne, Razadine ER)	4-, 8-, 12-mg tablets 8-, 16-, 24-mg extended-release capsules 4-mg/mL oral solution	Mild to moderate AD dementia	1.5 mg twice-a-day 4.6-mg transdermal patch	Increase by 4 mg twice-a-day every 4 weeks. Increase by 8 mg every 4 weeks for extended release	4–12 mg in divided doses for oral preparation. 8–24 mg daily for extended release
Memantine (Namenda, Namenda XR)	5-, 10-mg tablets 7-, 14-, 21-, 28-mg extended-release capsules 10-mg/5-mL oral solution	Moderate to severe AD dementia	5 mg daily 7-mg extended-release formula	By 5 mg daily in weekly intervals. Increase by 7-mg daily extended-release formula	10–20 mg daily in divided doses for oral preparation. 7–28 mg daily for extended release
Memantine XR and donepezil combination (Namzaric)	14-mg memantine ER/10-mg donepezil capsules 28-mg memantine ER/10-mg donepezil capsules	Moderate to severe AD when patient already stabilized on memantine ER and donepezil	14-mg memantine ER/10-mg donepezil daily 28-mg memantine ER/10-mg donepezil daily in severe renal impairment		

Both the histopathology and clinical features of AD were first described over 100 years ago by Alois Alzheimer. Even today, its underlying pathophysiology and genetic basis continue to be investigated. Amyloid-β peptide and phosphorylated tau proteins make up the neuritic plaques and neurofibrillary tangles seen in AD. These proteins play a central role in the two leading theories behind the pathogenesis of the disease. Amyloid positron emission tomography (PET) is now FDA-approved as a diagnostic biomarker in the diagnosis of AD. Additionally, Tau PET imaging is also being investigated for its role in AD as well as other related dementias such as frontotemporal dementia (FTD).

Loss of cholinergic neurons and impairment in cholinergic function have for many years been demonstrated in AD. Early subcortical changes occur in the nucleus basalis of Meynert, which provides cholinergic innervation to the hippocampus and cortex. The decline of acetylcholine in this area has been linked to the cognitive impairment seen in AD and has been the basis for cholinergic therapies.

Currently, the most effective approach to increasing acetylcholine activity is achieved with the use of cholinesterase inhibitors. Cholinesterase inhibitors deter the activity of the enzymes that break down acetylcholine at the synapse. Two enzymes are known to hydrolyze acetylcholine: acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE). AChE has two binding sites—anionic and esteratic—and is present in several areas of the brain, as well as in erythrocytes, platelets, lymphocytes, and skeletal muscle. BuChE has a similar structure to that of AChE but lacks the peripheral anionic binding site. It is synthesized in the liver, secreted into the plasma, and found in the gastrointestinal tract and heart, comprising approximately 10% of the total amount of cholinesterase in the central nervous system (CNS) present in glial cells. In vitro studies indicate that cholinesterase inhibitors can selectively inhibit AChE and BuChE to varying extents. Currently, three cholinesterase inhibitors are available in the United States: donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). The first cholinesterase to be approved for the treatment of dementia, tacrine (Cognex), was removed from the U.S. market due to its high side-effect profile.

Tacrine inhibits BuChE 18 times more potently than AChE, while donepezil inhibits AChE with higher selectivity. Rivastigmine inhibits both AChE and BuChE, and galantamine selectively inhibits AChE while also producing allosteric modulation of nicotinic receptors. Although the actions of AChE have been thoroughly studied, the relevance of BuChE and nicotinic receptor modulation has become increasingly apparent to the overall function of cholinergic neurons. BuChE has been shown to be important in the development of amyloid plaques. When a polymorphic mutation of BuChE, known as the K variant, is combined with the apolipoprotein E4 (APOE4), this may result in an increased risk factor for developing AD. Nicotinic modulation results in increased ion channel opening, enhancing cholinergic transmission independent of enzymatic inhibition. Nicotinic receptors are found in presynaptic and postsynaptic neurons. Presynaptic nicotinic receptors regulate the release of acetylcholine, glutamate, and γ-aminobutyric acid (GABA), while postsynaptic nicotinic receptors mediate cholinergic transmission in the hippocampus and cerebral cortex. Both receptor types play an important role in memory and learning.

Cholinesterase inhibitors can be classified into three categories: reversible, pseudo-irreversible, and irreversible. These categories are based on the duration of enzyme inhibition. Reversible inhibitors bind to the enzyme for a very short time (seconds to minutes). Pseudoirreversible inhibitors bind for hours, but new enzymes are not developed to assist in the body's biochemical functions. Irreversible inhibitors bind to the enzyme and prevent further activity, prompting the body to synthesize new enzymes.

Prior to the appearance of medications for cognitive impairment, the estimated total direct and indirect costs for the treatment and care of Alzheimer patients in the United States was nearly $100 billion in 1990. Their introduction was associated with a moderate reduction in costs of medical and social services, as well as a slight increase in functioning and a delay in nursing home placement.

In addition to AD, there are other neurodegenerative illnesses that can commonly lead to a major neurocognitive disorder. Major neurocognitive disorders due to PD, Lewy body disease (LBD), vascular dementia (VD), as well as FTD, have distinct pathophysiologic mechanisms, although some overlap may occur. Dementia can occur in up to 40% of idiopathic PD patients who demonstrate a decline in cholinergic function. The cholinesterase inhibitor, rivastigmine, is indicated by the FDA for the treatment of cognitive impairment in PD, and there is some evidence that other cholinesterase inhibitors like donepezil may also improve major neurocognitive disorder due to PD. Diffuse LBD, although a distinct illness clinically, has similar pathophysiologic mechanisms to PD and may possibly benefit from cholinesterase inhibitors. VD may produce cerebrovascular damage-causing cholinergic dysfunction. Additionally, the added presence of AD pathology rather than pure VD may explain why some studies demonstrate higher rates than others of improvement in VD with the use of cholinesterase inhibitors. Currently, there are no adequate randomized controlled trials (RCTs) showing the efficacy of cholinesterase inhibitors in the treatment of

FTD and similar dementias with tau neuropathology. Given the heterogeneity of neurodegenerative dementias in older adults as well as the lack of adequate disease-modifying treatments for these progressive conditions, cholinesterase inhibitors are commonly used off-label in clinical practice in several select non-AD dementia conditions. Ultimately, tolerability and adverse reactions must be carefully taken into account during off-label use as quality clinical research evidence is lacking, and the benefits must outweigh the risks.

Patients with mild neurocognitive disorders, including mild cognitive impairment (MCI), are a group of patients who display a modest decline in cognition. They do not meet the criteria for dementia, as this decline does not preclude them from the independent performance of everyday activities. These individuals pose a challenging dilemma, as cholinesterase inhibitors are not approved for the treatment of their illness, even though the annual progression into a major neurocognitive disorder is approximately 10% to 15%. Trials with these medications have not been found to decrease the rate of progression to dementia, and at this time, there is weak support for using them.

Very few studies have looked into the efficacy of cholinesterase inhibitors in treating behavioral and psychiatric symptoms, such as agitation, visual hallucinations, or apathy in patients with AD. The evidence is limited due to methodologic problems with these studies. Currently, despite not having FDA approval for the treatment of behavioral or psychiatric problems, their use could be an alternative in the absence of other safe and effective options.

Cholinesterase inhibitors and memantine are moderately effective in treating the symptoms of AD, including cognitive, functional, and behavioral impairment. Unfortunately, these agents are not disease modifying, and risks versus benefits must be carefully weighed by the clinician before starting treatment. Clinicians, caregivers, and patients should be made aware of and educated on realistic goals of therapy. The overall results of the pharmacologic intervention should be to maintain for a longer period of time the patient’s quality of life and functional ability. By detecting, diagnosing, and treating AD early during its development, there is an opportunity for clinicians and caregivers to optimize drug therapy and other psychosocial interventions that are important in the disease process. Cholinesterase inhibitors are indicated for all stages of the disease, and early therapeutic interventions can maximize pharmacologic efficacy with these agents.

TACRINE

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Acetylcholine
Mechanism of Action	Enzyme inhibitor (Butyrylcholinesterase [BuChE] and AchE)

The first cholinesterase inhibitor approved by the FDA for the treatment of AD, tacrine, was introduced to the market in 1993. Tacrine is a reversible cholinesterase inhibitor that works by making intrasynaptic acetylcholine readily available in the brain of patients with AD. Despite being the first agent developed for AD, the use of tacrine was inconvenient due to its multiple daily dosing of three to four times a day and the likelihood of hepatotoxicity, which required constant monitoring of liver function during its use. In 2013, tacrine was removed from the U.S. market due to concerns with safety and is no longer available.

DONEPEZIL

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Acetylcholine
Mechanism of Action	Enzyme inhibitor (acetylcholinesterase)

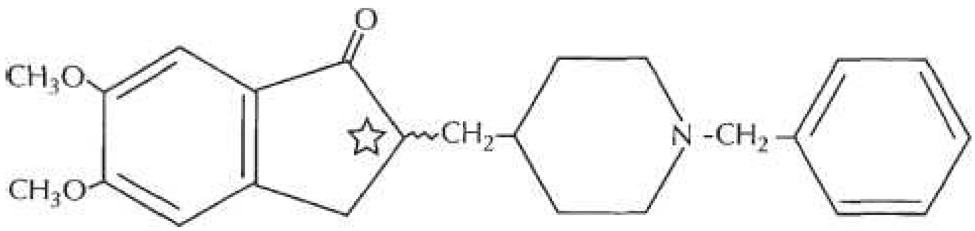


FIGURE 33.11b–1. Molecular structure of donepezil.

Originally developed in 1986, Donepezil was approved by the FDA in 1997 for its use in mild to moderate AD. It was later approved in 2006 for the treatment of severe AD as well. Unlike its predecessor, tacrine, this medication immediately appealed to clinicians thanks to its once-a-day administration, lack of hepatotoxicity, and not having to measure serum liver transaminase levels constantly.

Chemistry

Figure 33.11b–1 shows the molecular structure of donepezil hydrochloride. It is a piperidine compound that consists of (±) –2,3 dihydro-5,6-dimethoxy-2-[[1-(phenylmethyl)-4-piperidinyl]methyl]-1H-inden-1-one hydrochloride.

Pharmacologic Actions

Pharmacokinetics. Donepezil is not affected by food intake in its regular or oral disintegrating tablet presentations. The relationship between donepezil dose and its area under the plasma concentration–time curve (AUC) is linear at a dose range of 1 to 10 mg. It is bound to plasma proteins by approximately 96% (75% to albumin and 21% to α_1-acid glycoprotein). The donepezil 10-mg formulation reaches peak plasma concentration at approximately 3 hours, compared to 8 hours in the 23-mg tablet. Its volume of distribution at a steady state is between 12 and 16 L/kg, reaching steady state after 2 weeks of use.

Donepezil undergoes extensive hepatic metabolism by the CYP 2D6 and 3A4. 6-O-desmethyl-donepezil is its major active metabolite and possesses equal potency. It is also converted into an inactive *cis*-*N*-oxide metabolite and two glucuronide conjugates. The elimination half-life of donepezil is approximately 70 hours, allowing for once-daily administration. Age, gender, hepatic disease, and renal impairment have not been shown to affect donepezil disposition to any significant degree. Due to this, dose adjustments based on renal or liver function are not necessary. Donepezil is classified as a category C drug. There are currently no adequate trials of donepezil in pregnant women; however, animal trials revealed that it may cause fetal harm. It, therefore, should not be used on pregnant women. It is unknown if it is excreted in breast milk.

Pharmacodynamics. Donepezil enhances cholinergic neurotransmission by increasing the concentration of acetylcholine through reversible, noncompetitive inhibition of AChE, the main enzyme involved in the hydrolysis of acetylcholine. Unlike tacrine, it is not highly selective for inhibition of BuChE. It is a potent, selective inhibitor that acts on the CNS, and it does not act on the peripheral nervous system.

Design and Interpretation of Clinical Drug Studies

A substantial number of randomized, double-blind, placebo-controlled studies have provided evidence of the effectiveness of donepezil as a treatment for AD at all its stages. The results of these studies confirmed that donepezil was effective and well-tolerated in treating the symptoms of mild to moderate AD, leading to its initial FDA approval. Additionally, the effectiveness of donepezil for the treatment of severe AD has been demonstrated by studies using both 10-mg daily doses and, more recently, 23 mg.

To establish donepezil's effect on mild to moderate AD, two large multicenter clinical trials were conducted, both using similar study methods. One of them was a U.S. study that took place during a 15-week period (12 weeks of active treatment followed by a 3-week blind placebo washout period), and the other one was a multinational study done during a 30-week period (24 weeks of treatment followed by a 6-week washout period). Patients were randomized into three groups: placebo, donepezil 5 mg, and donepezil 10 mg. In both studies, at the end of each treatment period (weeks 12 and 24), participants treated with placebo had a decline in their ADAS-cog score, while donepezil-treated patients showed statistically significant dose-dependent improvement. A scale measuring clinician’s assessment of functionality with the help of information provided by a caregiver called the Clinician’s Interview-Based Impression of Change with caregiver input (CIBIC-plus) revealed scores at weeks 12 and 24 in each study that showed statistically significant improvement in the donepezil-treated groups. The 12-week study presented no difference between the 5-mg and 10-mg groups. On the other hand, the international study group demonstrated a statistically significant difference between the two doses, with the 10-mg donepezil group showing greater benefits in all outcome measures when compared to the 5-mg group. After the placebo washout periods, ADAS-cog scores declined in both donepezil-treated groups of the two studies, reaching scores that could not be differentiated from the placebo groups.

A 6-month randomized, double-blind, parallel-group, placebo-controlled study of 248 nursing home-dwelling patients with severe AD (Mini-Mental State Examination [MMSE] score of 1 to 10) evaluated the effect of donepezil on cognition and daily functioning. Patients were assigned to donepezil or placebo. Donepezil dose was 5 mg/day for 30 days and then increased to 10 mg/day for the remainder of the study. The primary study endpoints were changed from baseline to 6 months on the Severe Impairment Battery (SIB) and the Alzheimer’s Disease Cooperative Study–Activities of Daily Living–Severe Impairment Version (ADCS-ADL-SIV). The SIB uses a validated 40-item scale developed for the evaluation of the severity of cognitive dysfunction in more advanced AD patients. ADCS-ADL-SIV is a caregiver-based ADL scale composed of 19 items developed for use in clinical studies of dementia. When compared to baseline at 6 months, patients treated with donepezil displayed more improvement in SIB scores and less decline in the ADCS-ADL scores than placebo in severe AD subjects.

The use of donepezil 23 mg in moderate to severe AD was approved by the FDA in 2010, based on the conclusions of a multinational, randomized, double-blind study that included patients who were already being treated with a 10-mg dose for at least 3 months. 1,467 patients were randomly assigned to receive either a 23 mg once-a-day dose of donepezil or a standard dose of 10 mg for 24 weeks. At week 24, changes in cognition and global functioning were assessed with the SIB and the CIBIC-plus, respectively. This study revealed a statistically significant benefit in cognition with the 23-mg dosing but did not find a significant change in global functioning. Side effects were also monitored, revealing an increased incidence of gastrointestinal symptoms, which included nausea, vomiting, and diarrhea, in the higher 23-mg dose group.

One randomized placebo-controlled study was conducted over a 1-year period, evaluating the preservation of function in 431 patients with probable AD who received either placebo or donepezil. Participants randomized into the active treatment arm were started on 5 mg with a posterior dose increase to 10 mg on day 28. The function was assessed by evaluating basic activities of daily living (ADLs) and instrumental ADLs through the AD Functional Assessment and Change Scale. The results indicated that after 1 year, donepezil had a 38% reduction in the risk of functional decline when compared to placebo. Moreover, this study showed how donepezil delayed functional decline by 5 months in patients with AD. At 48 weeks, the probability of survival with no evidence of functional loss was 51% for those taking donepezil, compared to only 35% for those on placebo. These results demonstrated that continued use of donepezil benefits patients over a period of 1 year and that untreated patients tend to decline in their functional ability.

Effects on Specific Organs and Systems

In older adults, hepatic function is frequently decreased, leading to reduced tolerability of certain medications. Donepezil does not induce elevation of liver transaminases or cause hepatotoxicity and is, in general, well tolerated. Even though kidney function may also decrease with aging, donepezil may be safely administered in patients with moderate to severe renal impairment. This medication may produce vagotonic effects in the sinoatrial and atrioventricular nodes by acting on the muscarinic receptors, causing a slowing of the heart rate. Like all cholinesterase inhibitors, it should be used with caution in patients with cardiac arrhythmias and significant cardiac dysfunction. Due to its increased cholinergic activity, donepezil may also augment gastric acid secretion in a dose-dependent fashion, causing gastrointestinal complications that potentially may increase the risk of gastric disease and gastrointestinal bleeding.

Therapeutic Indications

Donepezil is indicated for the treatment of mild, moderate, and severe AD. Additionally, select randomized, double-blind, placebo-controlled studies have demonstrated some benefit in cognition and functioning when treating VD. Donepezil has not been approved by the FDA for this use, as there is a concern for its safety in this population due to cardiovascular and cerebrovascular risks. Similarly, small studies have shown improvement in cognition in patients with LBD, traumatic brain injury, and dementia associated with PD, but the use of donepezil in these populations remains off-label.

Precautions and Adverse Reactions

The most common adverse reactions leading to discontinuation and poor tolerability of dose optimization in clinical settings include diarrhea, nausea, vomiting, insomnia, muscle cramps, fatigue, and anorexia. These side effects are usually mild and transient and have not resulted in a significant dropout rate during clinical trials with donepezil. Less commonly, donepezil can potentially cause more severe reactions such as seizures, cerebrovascular disease, or exacerbation of chronic obstructive pulmonary disease (COPD).

The incidence of gastrointestinal adverse side effects did not differ between patients with mild to moderate dementia when compared to severely ill patients. Patients who suffer from peptic ulcer disease, or are taking NSAIDs, need to be carefully monitored for gastrointestinal bleeding. Caution should also be exerted when using the 23-mg dose in patients who weigh less than 55 kg, as there have been increased reports of nausea, vomiting, and weight loss in this group. Due to donepezil’s effect on cardiac conduction, donepezil should be used with caution in patients with cardiac arrhythmias, especially sick sinus syndrome. Patients may be at risk of developing bradycardia. It is recommended to titrate donepezil slowly to minimize the incidence of side effects. Additionally, donepezil is contraindicated in patients with known hypersensitivity to the drug or to piperidine derivatives.

Drug Interactions

Although metabolized mainly through the CYP 2D6 and 3A4 and highly protein-bound at 96%, donepezil has minimal influence on drugs metabolized through these pathways. Pharmacokinetic studies have been conducted assessing the induction effects of donepezil on cimetidine, ketoconazole, risperidone (which is also metabolized through 2D6 and 3A4), warfarin, and digoxin, and no effects have been observed on the pharmacokinetics of these drugs.

In vitro studies of inhibitors of CYP 3A4, such as ketoconazole, and 2D6, such as quinidine, have shown inhibition of donepezil metabolism. These studies have not translated into clinically significant drug–drug interaction. Phenytoin, carbamazepine, dexamethasone, rifampin, and phenobarbital, which are inducers of 2D6 and 3A4 pathways, can potentially increase donepezil’s elimination rate. Donepezil is not affected by the concomitant use of cimetidine or digoxin. As with all cholinesterase inhibitors, caution is advised when patients are taking anticholinergic medications, as donepezil may interfere with their activity due to its mechanism of action. Donepezil may also lengthen the action of succinylcholine-type muscle relaxants during anesthesia.

Laboratory Interferences

Donepezil has not been shown to interfere with any laboratory test, including biochemical, urinalysis, or spectrometry.

Dosage and Administration

Donepezil is available in 5-, 10-, and 23-mg tablets and in an orally disintegrating tablet form of 5 and 10 mg. The recommended starting dose is 5 mg once a day at bedtime. After 4 to 6 weeks, the dose can be increased to 10 mg depending on tolerability. For mild to moderate AD, 5 and 10 mg are the recommended effective doses. In patients presenting with moderate to severe dementia, clinical trials have found doses of 10 and 23 mg effective. In the moderate to severe group, for those who are tolerating it well, the dose may be increased to 23 mg after a minimum of 3 months on a 10-mg dose. The medication should be administered at bedtime so that peak plasma concentrations occur during the night and potential adverse effects are minimized. As food intake does not affect its absorption, donepezil may be taken with or without food.

RIVASTIGMINE

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Acetylcholine
Mechanism of Action	Enzyme inhibitor (AchE, Butyrylcholinesterase [BuChE])

Rivastigmine has been approved for the treatment of mild to moderate AD since 2000 by the FDA. It is also the only cholinesterase inhibitor approved, since 2006, for the treatment of mild to moderate dementia due to major neurocognitive disorder related to PD. Additionally, in 2013, rivastigmine was approved for severe AD. Rivastigmine is a second-generation cholinesterase inhibitor and has a different pharmacologic profile in comparison to the earlier cholinesterase inhibitors, tacrine and donepezil.

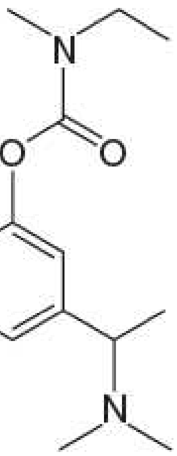

FIGURE 33.11b–2. Molecular structure of rivastigmine.

Chemistry

Rivastigmine is composed of the chemical compound (S)-3-[1-(dimethylamino)ethyl]phenylethyl(methyl)carbamate. Its molecular structure is shown in Figure 33.11b–2.

Pharmacologic Actions

Pharmacokinetics. Rivastigmine is rapidly absorbed in its oral formulation, with a mean time to maximum plasma concentration (T_{max}) of 1 hour (range 0.8 to 1.7 hours). Additionally, it has a mean absolute bioavailability of 60% in comparison to intravenous drug administration. When ingested with food, its C_{max} is decreased by 30% and increases the total amount of drug in the body (AUC) by 30%. Because its bioavailability is unaffected, it is recommended that oral rivastigmine always be given with food to potentially prevent the drug's most common side effects, which are nausea, vomiting, and other forms of gastrointestinal distress. Rivastigmine is only 40% bound to plasma proteins with a volume of distribution between 1.8 and 2.7 L/kg. The relationship between drug dose and AUC is linear, with a mean elimination half-life of 1.6 hours. The drug easily crosses the blood–brain barrier. Cerebrospinal fluid (CSF) rivastigmine concentrations are rapidly reached with a T_{max} of 1.4 to 3.8 hours, and it is quickly eliminated from the CSF with a half-life of 0.31 to 2.95 hours. Rivastigmine is converted after activity to an inactive metabolite which undergoes *N*-demethylation and sulfate conjugation prior to elimination. Rivastigmine is mainly eliminated through renal excretion, and it is not metabolized by hepatic oxidative CYP isozymes. Age, hepatic impairment, and renal insufficiency do not significantly affect rivastigmine disposition, and dosage adjustments are not necessary for those individual patients. Additionally, the drug is not affected by inducers or inhibitors of CYP450 metabolism. There are currently no adequate trials of rivastigmine in pregnant women; however, animal trials have revealed no evidence of teratogenicity. It is unknown if it is excreted in breast milk.

A rivastigmine transdermal patch (5 to 20 cm^2) was developed and approved by the FDA in 2007. The 10-cm^2 patch pharmacokinetic profile is comparable to the oral 6-mg twice-daily dose, while the 20-cm^2 patch is similar to a 9- to 10-mg twice-daily oral dose. The patch showed a 30% lower C_{max}, a longer T_{max} (8 hours vs. 1 hour), and a 1.8-fold greater increase in AUC compared to the oral dose. Markedly less fluctuation in plasma drug concentrations between peak and trough levels was found with the patch. The 10-cm^2 patch showed adequate efficacy with fewer side effects than the 20-cm^2 patch and therefore was initially recommended as the primary target dose in mild to moderate AD and major neurocognitive disorder due to PD. A higher, 15-cm^2 transdermal patch formulation is currently available and is the FDA-recommended dose for patients with severe AD. Drug exposure is optimal when the rivastigmine patch is applied to the upper arm, chest, or back. These locations are the recommended application sites.

Pharmacodynamics. Rivastigmine is a noncompetitive, pseudo-irreversible cholinesterase inhibitor due to its prolonged enzyme inhibition activity, where a single dose was shown to produce inhibition for as long as 10 to 12 hours. Rivastigmine displays equal potency in inhibiting both AChE, and BuChE reported from both in vitro and in vivo data. This period of activity inhibition indicates that twice-a-day dosing is optimal. A linear relationship was reported between rivastigmine dose and AChE and BuChE inhibition measured in CSF. Plasma BChE inhibition rose slowly with the patch compared to two distinct peaks with the oral twice-daily dosing.

Design and Interpretation of Clinical Drug Studies

There have been a number of randomized, placebo-controlled, double-blind studies that have demonstrated the efficacy of rivastigmine in the treatment of AD. The majority of trials have been conducted on community-dwelling subjects with mild to moderate AD and were of 26-week duration or shorter. Doses ranged from 6 to 12 mg daily for oral doses and 5 to 20 cm^2 for the transdermal patch. The more efficacious oral dose was found to be 6 to 12 mg daily, with higher doses demonstrating increased side effects and worse tolerability. For the transdermal patch, doses ranged from 5 to 20 cm^2, with 10 cm^2 having better tolerability than higher doses with significant clinical outcomes. Moderate improvement in cognitive and functional scales occurred, as well as an impression of improvement as assessed by the subjects' clinician. These improvements demonstrated equivalent efficacy with donepezil and other cholinesterase inhibitors.

Specifically for the oral drug form, two placebo-controlled multicenter clinical studies with rivastigmine (N = 1,424) were conducted prior to FDA approval. Subjects were randomized into the placebo group, rivastigmine 1 to 4 mg/day, and rivastigmine 6 to 12 mg/day. Drug doses were adjusted weekly for the first 7 weeks as subjects reached the minimum assigned dose range. From weeks 8 to 26, subjects could be maintained on a flexible dose but in their assigned range to maximize therapeutic benefit and minimize side effects. Both studies showed a dose-dependent improvement effect on ADAS-cog scores from baseline to the study endpoint. The placebo group showed a decline of two to four points in the ADAS-cog, while the rivastigmine 6- to 12-mg/day group had about a one-point increase in ADAS-cog score. The rivastigmine 1- to 4-mg/day group had approximately a one- to two-point decline in ADAS-cog scores. Both rivastigmine groups showed significant benefit in the CIBIC-plus scores compared to placebo.

Additionally, the subjects in one of these large trials continued into an open-label extension study where both, the placebo and rivastigmine groups, were treated with rivastigmine 6 to 12 mg/day for an additional 26 weeks. In this study, both the placebo and rivastigmine groups showed improvement at the study endpoint compared to the projected rate of decline in untreated subjects. However, their scores were lower than the rivastigmine 6- to 12-mg/day group, with about a three- to four-point decrease in ADAS-cog scores at week 52. Subjects treated with rivastigmine 6 to 12 mg/day had almost maintained their ADAS-cog scores from baseline with an approximate two-point decrease after 52 weeks. These results imply that with a 6-month delay in treatment or inadequate treatment with low doses, subjects may not be able to demonstrate the same level of improvement as patients with therapeutic treatment from the start. For maximum benefit, when a diagnosis of AD is established, treatment with cholinesterase inhibitors such as rivastigmine, when indicated, should be started as soon as possible. Dosing at suboptimal levels for extended periods can also hinder drug efficacy.

In a 24-week, randomized, double-blind trial, patients with severe AD were randomized, receiving a 4.6-mg/24-hour patch versus a 13.3-mg/24-hour rivastigmine patch. There was an 8-week titration phase and a 16-week maintenance phase. As in the donepezil severe AD clinical trial, the SIB, as well as the ADCS-ADL-SIV, were used as clinical endpoints. The decline in both the SIB and the ASCS-ADL-SIV were both significantly less at 16 and 24 weeks for the 13.3-mg/24-hour dose.

In a 24-week, double-blind, placebo-controlled trial, rivastigmine with doses ranging from 3 to 12 mg was evaluated in 541 patients with PD dementia. The diagnosis was based on a 2-year or greater history of idiopathic PD before the onset of dementia, and patients did not meet the criteria for other etiologic causes of dementia. Based on ADAS-cog scores comparing baseline to week 24, rivastigmine-treated PD dementia patients had a mean improvement of 2.1 points, whereas the placebo group declined by a mean of 0.7 points. The Alzheimer’s Disease Cooperative Study Clinical Global Impressions of Change (ADCS-CGIC) scores also showed benefit for rivastigmine, as 19% had improved compared to 13% for placebo. Clinically meaningful worsening was reported to be only 13% for rivastigmine compared to a higher occurrence of 23% with placebo. Of note, the most frequent adverse side effects for rivastigmine were gastrointestinal, with nausea in 29% and vomiting in 16%, as well as tremors in 10% of patients. Worsening tremor may signify increased clinical relevance in PD dementia patients and warrants closer monitoring with rivastigmine treatment. Rivastigmine has also proved to be somewhat effective in LBD. In a randomized controlled study on 120 patients with LBD, patients receiving oral rivastigmine up to 12 mg daily were less apathetic and less anxious than the placebo-treated subjects, as 63% of patients in the treatment group showed a significant improvement in their symptoms measured by the Neuropsychiatric Inventory compared to 30% of control. The rivastigmine–treated group demonstrated a trend toward improvement in the Mini-Mental Status Examination (MMSE) scores, yet this trend was not found to be statistically significant.

Rivastigmine had little or no effect on cognition in VD, according to a recent Cochrane review. Rivastigmine transdermal did, however, improve or maintain cognitive status on ADAS-cog scores on 52 out of 100 patients with AD and small vessel cerebrovascular disease in a 24-week, open-label study.

Effects on Specific Organs and Systems

Rivastigmine does not produce hepatotoxicity or liver transaminase elevations, and therefore no monitoring of liver function tests are required with its use. Like other cholinesterase inhibitors, rivastigmine can produce vagotonic cardiovascular effects and should be used cautiously in patients with cardiac arrhythmias and cardiac conduction delays. Gastrointestinal problems can occur with all cholinesterase inhibitors but are particularly seen with rivastigmine use in a more dose-dependent manner. Rivastigmine can also increase gastrointestinal acid production. Patients on NSAIDs with peptic ulcer disease or other gastrointestinal illnesses should be carefully monitored, as they may be at greater risk of gastrointestinal bleeding.

Therapeutic Indications

Rivastigmine is indicated for the treatment of mild to moderate AD. It is also the only cholinesterase inhibitor with an FDA indication for mild to moderate dementia associated with PD. Similarly, rivastigmine has demonstrated benefits in LBD.

Precautions and Adverse Reactions

The most common adverse side effects of rivastigmine are typical of all cholinesterase inhibitors. These include diarrhea, nausea, vomiting, insomnia, muscle cramps, fatigue, and anorexia. These side effects are usually mild and transient, but in clinical trials, rivastigmine-treated groups had a higher dropout rate than placebo, usually due to GI side effects. Additionally, in a study comparing rivastigmine with donepezil in AD patients, oral rivastigmine-treated participants had a significantly higher dropout rate due to side effects. Gastrointestinal side effects with rivastigmine are not different when comparing mild to moderate individuals with those with moderate to severe AD. The transdermal patch formulation demonstrates much fewer gastrointestinal problems, most likely because of reduced plasma drug concentration, due to longer T_{max} and lower C_{max} when compared to oral preparation. Less commonly, rivastigmine can potentially cause adverse reactions such as seizures, cerebrovascular disease, or worsening COPD. It can also worsen urinary obstruction. Reanalysis of the electrocardiograph data from the clinical trial data revealed no significant differences between rivastigmine and placebo in heart rate, PR, QRS, and QTc interval. However, patients with cardiac conduction delays and significant heart disease should use rivastigmine with caution, given the potential for bradycardia with cholinesterase inhibitors. The transdermal patch formulation reported skin erythema barely visible or mild that self-resolved within 24 hours. The upper back site, arms, and chest had a lower incidence of erythema compared to the abdomen and thigh sites.

Drug Interactions

Because rivastigmine is not metabolized by hepatic oxidative CYP isozymes, it does not interact with the substrates of CYP450. Subsequently, there have been no drug interactions reported with digoxin, warfarin, diazepam, or fluoxetine. A retrospective analysis of the clinical trials did not find an increase in adverse side effects in patients who received various medications, including β-blockers, antihypertensives, and other drugs that may potentially produce pharmacodynamic interactions such as bradycardia. As with all cholinesterase inhibitors, caution is advised when patients are taking anticholinergic medications. Rivastigmine may also increase the action of succinylcholine-type muscle relaxants during anesthesia.

Laboratory Interferences

Rivastigmine has not been shown to interfere with any laboratory test, urinalysis, or spectrometry.

Dosage and Administration

Oral rivastigmine is available in 1.5-, 3.0-, 4.5-, and 6.0-mg capsules. Based on clinical trials, the suggested dosage range is 3 to 12 mg/day. Patients should be initiated at 1.5-mg twice-a-day and gradually increased every 2 to 4 weeks by 1.5 mg daily until the maximum daily dose of 12 mg/day is reached or titrated to the patient's tolerability. It is highly recommended to take food with rivastigmine to minimize side effects. The transdermal patch preparation (5 to 15 cm^2) is able to be applied once a day due to its pharmacokinetic and pharmacodynamic profile for cholinesterase inhibition, reported producing a slow and consistent release of the medication. The average exposure of transdermal patch dose of 10 cm^2 was comparable to an oral dose of 9.5 mg/24 hr. Patients should be initiated at a dose of 5 cm^2/4.6 mg daily and increased to 10 cm^2/9.5 mg in 4 weeks. Once this dose is maintained for 4 weeks and the patient tolerates it well, the maximum effective dose of 15 cm^2/13.3 mg/24 hour may be given. The slow release of rivastigmine from the patch should improve its gastrointestinal tolerability.

GALANTAMINE

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Acetylcholine
Mechanism of Action	Enzyme inhibitor (acetylcholinesterase), alpha-7 nicotinic receptor positive allosteric modulator

Galantamine was approved by the FDA for the treatment of AD in 2001 and is the fourth cholinesterase inhibitor made available in the United States. Galantamine is extracted from daffodils of the snowdrop plant *Galanthus nivalis* and is a phenanthrene alkaloid similar to codeine.

Chemistry

Galantamine is a (4aS,6R,8aS)–4a,5,9,10,11,12-hexahydro-3-methoxy-11-methyl-6H-benzofuro [3a,3,2–ef][2]benzazepin-6-ol hydrobromide compound. Its molecular structure is shown in Figure 33.11b–3.

Pharmacologic Actions

Pharmacokinetics. Galantamine immediate release (IR) has an 85% to 100% bioavailability in comparing tablets to the oral solution and is readily absorbed with a T_{max} from 0.5 to 2.0 hours. C_{max} is decreased by 25% with a slight delay of T_{max} by 1.5 hours with food intake. Coadministration with food does not affect galantamine IR AUC. The volume of distribution at a steady state was 2.6 L/kg with a very low protein binding of 18%. The elimination half-life of galantamine IR is about 7 hours. The bioequivalence of galantamine extended-release (ER) 24 mg was reported to be within the 90%

confidence intervals for AUC_{24} and C_{min} of galantamine IR 12-mg tablets twice daily. The mean time to peak plasma concentration was 4.4 hours, with an elimination half-life of 8.3 hours after fasting and 8.0 hours after food intake. Galantamine ER formulation does not differ in its pharmacokinetic profile, whether given it with food or while fasting.

Galantamine is mainly metabolized by hepatic CYP 2D6 and CYP 3A4 isozymes. Sanguinine (*O*-desmethylgalantamine) is formed by CYP 2D6 and accounts for 20% of the parent drug. Sanguinine is its major active metabolite and was shown to be three times more potent than galantamine in producing AChE inhibition. Other metabolites include galanthaminone and *N*-desmethylgalantamine, but they are much less potent than sanguinine. Although a 25% decrease in drug clearance of galantamine IR was found between poor metabolizers and extensive metabolizers of CYP 2D6, and a 50% higher drug exposure in galantamine ER, these findings are probably not significant due to the large interpatient variability in galantamine disposition. The doses can be titrated to individual tolerability.

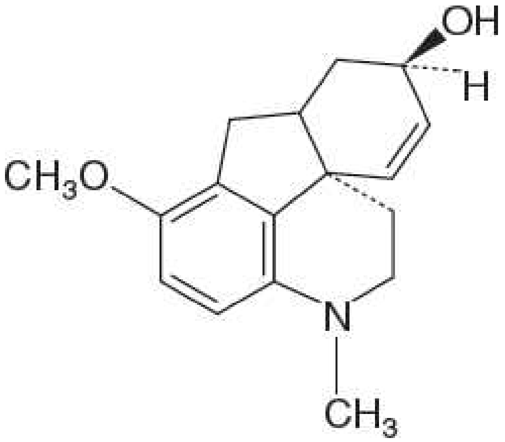

FIGURE 33.11b–3. Molecular structure of galantamine.

Age and mild hepatic impairment (defined as a Child–Pugh score of 5 to 6) were shown not to affect galantamine pharmacokinetics. Patients with moderate hepatic impairment (Child–Pugh score of 7 to 9) had galantamine AUC, and elimination half-life increased by 30%. Patients with mild renal impairment had galantamine concentrations similar to Alzheimer patients without renal impairment. No dosage adjustments are needed for galantamine in older adult patients or in patients with mild hepatic impairment. A maximum dose of 16 mg/day is recommended for patients with moderate hepatic impairment. Galantamine is contraindicated in patients with severe renal (creatinine clearance less than 9 mL/min) and severe hepatic impairment (Child–Pugh score greater than 9). Galantamine is classified as a category C drug with no trials in pregnant women and animal trials revealing potential teratogenicity. Additionally, it is unknown if it is excreted in breast milk.

Pharmacodynamics. Galantamine is a competitive, reversible inhibitor that is significantly more selective for AChE over BuChE based on in vitro data. Galantamine also produces allosteric modulation of nicotinic receptors that are distinct from acetylcholine and nicotinic agonists or antagonists. Allosteric modulators upregulate or potentiate ion channel activity of nicotinic receptors in response to acetylcholine. This mechanism of action may play a unique clinical role as AD is associated with a deficit in nicotinic transmission. By enhancing the release of acetylcholine, this action can additionally modulate the release of other neurotransmitters such as GABA, serotonin, and glutamate.

Design and Interpretation of Clinical Drug Studies

A number of large, multicenter clinical trials with galantamine have been conducted. 978 subjects were evaluated in the main clinical trial that established the minimum effective galantamine dose. After a 4-week single-blind placebo treatment, patients were randomized into four treatment groups: placebo, galantamine 8, 16, and 24 mg/day. Patients were initiated on 8 mg/day, and the dose was increased by 8 mg/day after 4 weeks until the target dose was achieved. The total study duration for the randomized groups was 5 months. All three groups showed improvement in ADAS-cog scores from baseline to the study endpoint when compared to placebo. During the intent-to-treat analysis, the 16- and 24-mg/day groups were found to be superior to placebo, but not the 8-mg group. The CIBIC-plus evaluations showed that 64% to 68% of the patients in the 16- and

24-mg/day groups remained stable or improved after 5 months versus 47% of the placebo group. The 8-mg/day group had only a 53% reported incidence of stability or improvement.

Several multicenter double-blind, placebo-controlled clinical trials have evaluated galantamine at higher doses of 18, 24, and 32 mg/day. Each study employed a different dosing strategy to reach these three dose groups, with a starting dose of 8 mg/day. Doses were either increased weekly or every 2 to 3 days until the assigned target dose was reached. The duration of the studies ranged from 12 weeks to 6 months. Each trial revealed that the 18- and 24-mg/day dose groups were superior to placebo. The 32-mg/day group also showed improvement compared to placebo but did not reveal increased benefit when compared to the 24-mg group. The incidence of gastrointestinal adverse effects was highest in the 32-mg/day group, thereby limiting its usefulness. The results of these studies suggested that the optimal dose of galantamine is 24 mg daily.

One of these clinical trials reported a 6-month extension where patients assigned to the placebo group were placed on galantamine 24 mg/day. After the subsequent 6 months, the placebo/galantamine group had ADAS-cog scores that resembled the galantamine 32-mg group, which had its dose decreased to the 24-mg/day dose group and above the projected rate of decline in untreated patients. The original 24-mg/day dose group at 6 months had ADAS-cog scores above baseline and at the 12-month time slightly decreased to baseline scores. The two other groups (placebo/galantamine and galantamine 32 mg or 24 mg) had ADAS-cog scores below the original 24-mg dose group at the 12-month time period. These results suggest that a 24-mg dose is the optimal galantamine dose and that a delay of 6 months by the placebo group could worsen the outcome in AD.

A 24-week double-blind, placebo-controlled study compared galantamine IR to galantamine ER in 971 patients with mild to moderate AD. Galantamine IR and ER were started at 8 mg/day and to 16, and then to 24-mg by 8-mg increments every 4 weeks as tolerated. The IR and ER were significantly better than a placebo in regard to cognition, measured by the ADAS-cog, but not in global change (CIBIC-Plus), where they did not differ from placebo. Although these findings with CIBIC-Plus differ from the original IR studies, the secondary ADCS-ADL measure favored ER over placebo.

A recent long-term study evaluated the effects of cholinesterase inhibitors on cognition and the progression to severe dementia. This longitudinal cohort study followed over 17,000 patients with AD, cholinesterase inhibitor-users and cholinesterase inhibitor-nonusers who were enrolled in the Swedish national dementia registry from 2007 to 2018. Cognitive trajectories were measured with MMSE. While each cholinesterase inhibitor showed an association with higher MMSE scores on follow-up, galantamine alone was found to reduce the risk of developing severe dementia (MMSE < 10). Cholinesterase inhibitors also reduced the overall mortality risk within the cohort in a dose-dependent manner, although galantamine at any dose was protective.

Effects on Specific Organs and Systems

Galantamine does not elevate hepatic transaminases and is not known to cause hepatotoxicity. Like the other cholinesterase inhibitors, this medication may cause vagotonic cardiovascular effects and should be used cautiously in patients with cardiac arrhythmias. Gastrointestinal problems may occur in a dose-dependent manner, and patients with peptic ulcer disease and other gastrointestinal problems should be carefully monitored.

Therapeutic Indication

Galantamine is indicated for the treatment of mild to moderate AD.

Precautions and Adverse Reactions

The most commonly reported side effects of galantamine are dizziness, headache, nausea, vomiting, diarrhea, anorexia, and weight loss. These side effects are mild and transient and did not produce a significant dropout rate during clinical studies. As previously stated, patients with renal and hepatic impairment may have substantially increased levels of galantamine. A maximum daily dose of 16 mg/day is the recommended dose for patients with moderate hepatic impairment. Galantamine is contraindicated in patients with severe renal and severe hepatic impairment. Less commonly, galantamine can potentially cause more severe reactions such as seizures, cerebrovascular disease, or exacerbation of COPD. The adverse side-effect profile of galantamine ER is similar to that of the IR formulation.

Drug Interactions

Galantamine is metabolized by hepatic CYP 2D6 and CYP 3A4 isozymes and could have significant drug–drug interactions. Galantamine AUC was reported to be increased by 40% when coadministered with paroxetine, 30% when given with ketoconazole, and 12% when erythromycin was coadministered. Patients should be monitored closely when known CYP 2D6 and CYP 3A4 inhibitors are given along with galantamine. As with all cholinesterase inhibitors, caution is advised when patients are taking anticholinergic medications, as galantamine may interfere with their activity due to its mechanism of action. It may also lengthen the action of succinylcholine-type muscle relaxants during anesthesia.

Laboratory Interferences

Galantamine has not been shown to interfere with any laboratory test, including urinalysis, spectrometry, and biochemical.

Dosage and Administration

Galantamine IR is available in 4-, 8-, and 16-mg tablets. The suggested dose range is 16 to 32 mg/day given twice-a-day in a divided dose. It should be given with food. The 32-mg dose is less well tolerated than lower doses, and clinical trial data do not indicate significant benefit. If patients tolerate the 24-mg dose, an increase to the 32-mg dose can be warranted. The initial dose is 8 mg/day, and after a minimum of 4 weeks, the dose can be increased. Further dose increases should be based on tolerability, with a minimum time period of 4 weeks on the previous dose. An oral solution is also available in a 4 mg/mL presentation. It should be taken as the IR form. Galantamine ER is available in 8-, 16-, and 24-mg tablets. The ER formulation should be taken with food with an initial dose of 8 mg daily in the morning and increasing the dose to 16 mg daily after a minimum of 4 weeks.

MEMANTINE

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Glutamate
Mechanism of Action	Receptor antagonist (NMDA)

Memantine is the only noncholinesterase inhibitor indicated for the treatment of AD. It was first synthesized in the early 1960s as a possible hypoglycemic agent but was found to be devoid of such activity. It was not until 2003 after multiple studies revealed its utility in dementia, that the FDA approved memantine for the treatment of moderate to severe AD. This agent is not indicated for mild to moderate AD, as are the cholinesterase inhibitors.

Chemistry

Memantine is a 1-amino-3,5-dimethyladamantane hydrochloride, a derivative of amantadine (Symmetrel) (1-amino-adamantane). Its molecular structure is shown in Figure 33.11b–4.

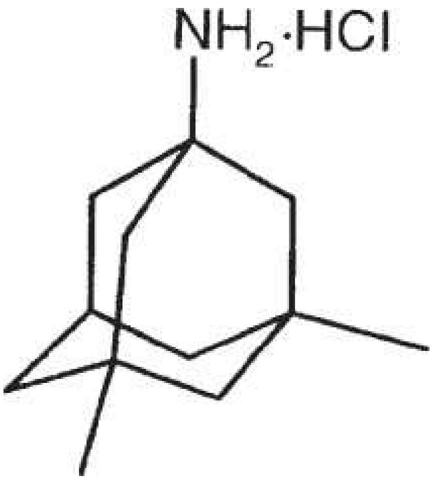

FIGURE 33.11b–4. Molecular structure of memantine.

Pharmacologic Actions

Pharmacokinetics. Memantine is absorbed completely from the gastrointestinal tract and achieves peak T_{max} within 3 to 7 hours. Protein binding is low, from 42% to 45%, and readily crosses the blood–brain barrier with a CSF serum concentration of 0.52. The elimination half-life of memantine is between 60 and 80 hours and is excreted unchanged in the urine. Steady-state conditions are reached in about 21 days. In a study comparing 28 mg once daily of memantine XR to 10 mg twice daily of memantine, C_{max}, and AUC0–24 values were 48% and 33% higher for the XR dosage regimen, respectively. Memantine is largely excreted unchanged in the urine, and the remaining is converted to three minimally active polar metabolites. Memantine is a weak base with a pKa of 10.27, and urinary pH can affect renal clearance. A reduced renal clearance occurs at alkaline urinary pH (pH 8) and results in increased plasma concentrations of the drug. Memantine has linear pharmacokinetics and, with doses of 10 to 20 mg/day, has produced minimal inhibitions of CYP enzymes, having no significant interactions with CYP inhibitors. Pharmacokinetic studies in healthy young adults and AD patients indicate that memantine can be safely coadministered with cholinesterase inhibitors. With repeated administration, total serum concentrations reach 0.5 μM, which corresponds to the Ki value of memantine at the MK-801 binding site in the human frontal cortex, indicating that NMDA receptor antagonism occurs at therapeutic concentrations. There are currently no adequate trials of memantine in pregnant women, and animal trials have revealed minimal evidence of teratogenicity. It is unknown if it is excreted in breast milk.

Pharmacodynamics. The pharmacologic effects of memantine are believed to result from the selective uncompetitive inhibitor blockade of the NMDA receptor class of glutamate receptors. Memantine does block the binding of glutamate to the receptor, but it blocks the ion current (Ca^{+2}, Na^{+}) through the receptor channel activated by glutamate. Memantine blocks the NMDA receptor with a strong voltage dependence and rapid blocking and unblocking kinetics, dissociating from the receptor in response to membrane depolarization. Blockade of the NMDA receptor channel during chronic, low-level excitation is thought to be a therapeutic benefit in neurodegenerative diseases such as AD.

Design and Interpretation of Clinical Drug Studies

Memantine indication for moderate to severe AD was based on two multicenter clinical trials. The first was a double-blind, placebo-controlled study comparing memantine 20 mg/day versus placebo in moderately to severely ill Alzheimer patients ($N = 252$). They had MMSE scores between 3 and 14 or a stage 5 or 6 on the Global Deterioration Scale (GDS). The study duration was 28 weeks, with an optional 24-week open-label extension phase. Patients receiving memantine had a significantly better outcome than placebo patients measured by the CIBIC-plus, ADCS-ADLsev, and SIB at 28 weeks. The second study was a double-blind, placebo-controlled trial, but it had a single-blind, placebo lead-in period of 1 to 2 weeks to assess compliance. Afterward, patients were randomized to drug or placebo for the next 24 weeks. The memantine dose was initiated at 5 mg/day, with weekly increases to 20 mg/day at the beginning of week 4. The primary outcome measures were the SIB, CIBIC-plus, and the ADCS-ADLsev at week 24. Patients were allowed to remain on stable donepezil doses of 5 to 10 mg/day throughout the trial if the medication was prescribed for at least 6 months prior to study entry.

The change in SIB, CIBIC-Plus, and ADCS-ADLsev outcome scores were all statistically significant in favor of memantine versus placebo. The SIB scores had a slight increase above baseline at week 12 and then remained above baseline by a mean of 1 point at 24 weeks. ADCS-ADLsev scores showed a gradual decline from baseline to 24 weeks for the placebo group, while the drug group displayed a slower rate of decline.

A 24-week open-label extension trial with moderate to severely ill patients reported continued benefit and a much slower decline in ADCS-ADL scores in those patients who were initially treated with memantine. Patients assigned to the placebo group were then placed on memantine. The newly treated patients showed less worsening of SIB, CIBIC-plus, and ADCS-ADL scores compared to the projected decline in untreated patients. At the end of 52 weeks, both groups had similar SIB, CIBIC-Plus, and ADCS-ADL scores and significantly higher scores than the projected scores for untreated patients. These findings indicate that memantine-treated patients continued to benefit from medication and had significantly delayed impairment compared to projections in untreated patients.

Although memantine is indicated only for moderate to severely ill patients, trials have been conducted on mild to moderate AD patients. These trials did not result in FDA indication for the mild stage of AD. A 24-week double-blind, placebo-controlled trial (N = 403) compared 20-mg memantine per day to placebo in mild to moderately ill AD patients, defined by MMSE scores of 10 to 22 points. The outcome measures included the ADAS-cog, CIBIC-plus, and ADCAS-ADL rating scales, comparing baseline to week 24. The study results indicated that only a modest treatment effect in favor of memantine had occurred. The mean ADAS-cog score for the placebo group increased by 1.1 points, while the memantine group score decreased by 0.8 points (P = .003). The mean end point CIBIC-plus scores for placebo and memantine groups were 4.52 and 4.20, respectively (P = .004). A significant difference was not found in ADCS-ADL scores between the two groups.

A more recent meta-analysis examined the efficacy and safety tolerability of memantine versus placebo and memantine +

cholinesterase inhibitors versus cholinesterase inhibitors alone in subjects with all levels of AD severity. As previously shown, memantine was superior to placebo in moderate to severe disease status for improving cognitive function but also demonstrated a reduction in behavioral disturbances as well. Memantine + cholinesterase inhibitors also had improved efficacy in behavioral disturbances over cholinesterase inhibitors alone. Memantine was well tolerated in both combination and monotherapy.

Effects on Specific Organs and Systems

Memantine does not cause an increase in hepatic transaminases or hepatotoxicity. Memantine XR terminal elimination half-life increased by 16% in patients with moderately impaired liver function compared to controls. It is recommended that patients with severe hepatic impairment take memantine ER with extreme caution. Memantine is mainly excreted through the kidneys. Even though there is scarce data about renally impaired patients taking memantine, drug doses should be reduced in patients with mild to moderate renal impairment. For patients with severe renal impairment, memantine is not recommended.

Therapeutic Indications

Memantine is indicated for the treatment of moderate to severe AD.

Precautions and Adverse Reactions

The most common side effects observed with memantine are constipation, dizziness, headache, and confusion. These effects are usually mild and transient and did not result in a significant dropout rate during clinical trials. With the use of memantine ER, the most common side effects are headache, diarrhea, and dizziness.

Drug Interactions

The use of memantine along with other NMDA antagonists such as amantadine and dextromethorphan has not been evaluated, and this combination should be used with caution. In vitro studies with CYP substrates 1A2, 3A4, 2A6, 2C9, 2D6, 2E1, and 3A4 showed minimal inhibition by memantine. Therefore, no pharmacokinetic interaction by these enzymes should occur. Using memantine with donepezil did not affect the pharmacokinetics of either compound. The adverse side-effect profile of the combination of memantine and donepezil was similar to that of patients treated with donepezil alone. Memantine is eliminated by renal tubular secretion, and if administered with other drugs that are excreted through the same mechanism, the plasma concentration of both agents could be altered. Examples of these drugs include hydrochlorothiazide, triamterene, cimetidine, ranitidine, quinidine, and nicotine. Concomitant use of memantine, hydrochlorothiazide, and triamterene did not affect the disposition of memantine or triamterene, but the bioavailability of hydrochlorothiazide was decreased by 20%. Memantine clearance was reduced by 80% with alkaline urine conditions at pH 8. If the urine pH is altered, drug accumulation may occur. This condition could be caused by diet, drugs like carbonic anhydrase inhibitors and sodium bicarbonate, and medical conditions such as renal tubular acidosis. Memantine should be cautiously used in this situation.

Laboratory Interferences

Memantine has not been shown to interfere with any laboratory test, including biochemical, urinalysis, and hematology. No clinically significant electrocardiographic changes were noted during clinical trials.

Dosage and Administration

Memantine is available in 5- and 10-mg tablets, with a recommended starting dose of 5 mg daily. The recommended target dose is 20 mg/day. The drug is administered twice daily in separate doses with 5-mg increment increases weekly depending on tolerability. Memantine ER is available in 7-, 14-, 21-, and 28-mg capsules. The starting dose is 7 mg daily, with a target dose of 28 mg daily. The ER formulation should be increased to no greater than 7 mg weekly. Patients with renal impairment should have a target dose of 14 mg daily. A drug is now available as a combination of memantine XR and donepezil (Namzaric). It is available in 14-mg/10-mg and 28-mg/10-mg formulations. It is only indicated for patients with severe AD already stabilized on memantine ER 14 or 28 mg and donepezil 10 mg.

FUTURE DIRECTIONS

In more recent years, drugs have been actively developed with different pharmacodynamic mechanisms to modify and delay the onset of AD. Multiple treatment trials with the goal of slowing or even reversing the course of cognitive and functional decline among AD subjects continue. They include secretase inhibitors, amyloid-β inhibitors, tau and amyloid-β-aggregation inhibitors, as well as vaccines against amyloid-β and tau. These potentially disease-modifying therapies focus mainly on agents that will decrease amyloid-β content and tau hyperphosphorylation. To date, trials have not demonstrated any significant improvement in the decline of patients already suffering the full clinical picture of AD. Current research has shifted to better recognition of AD in its earliest clinical phases. The aim is to enlist those at-risk populations with the mildest symptoms, such as those with MCI or even those still clinically asymptomatic, such as preclinical AD, into active clinical trials to potentially reverse or even prevent AD as well as other neurodegenerative disorders.

Aducanumab injection is the first amyloid beta-directed antibody approved by the FDA in 2021 for the overall treatment of AD. The indication proceeded under accelerated approval based on a reduction in amyloid-beta plaques in the brains of study participants; however, the clinical trials were limited to patients with very early disease, and clinically significant improvement was not robust. The continued approval for this very broad indication may be altered upon verification of clinical benefit in future confirmatory Phase 4 trials.

33.12 Histamine Modulators

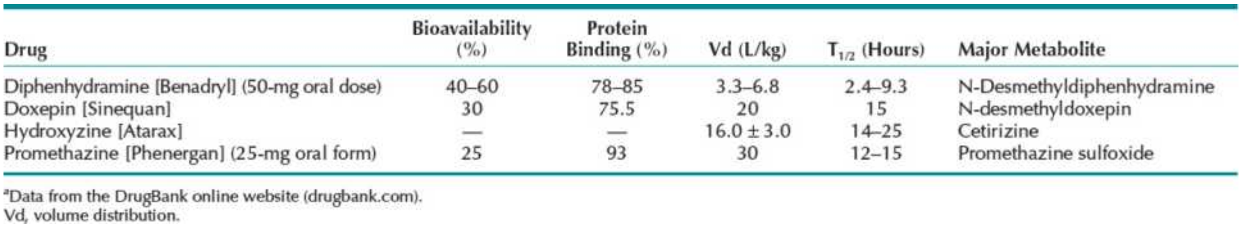
33.12a Histamine Blockers and Enhancers

Sasson Zemach, M.D., and Abraham Weizman, M.D.

HISTORY

Histamine is a phylogenetically old amine, widely distributed throughout the central nervous system (CNS) of many species. The role of histamine in immunomodulation and smooth muscle relaxation was originally described in the early 1900s. Charles Best and colleagues were the first to isolate histamine (H substance) in 1927. The antihistamines were first discovered by the Swiss-born Italian pharmacologist Daniel Bovet in 1937. The first nontoxic histamine-blocking drug, pyrilamine (Poly-Histine-D), was developed in 1944. In the 1950s, diphenhydramine (Benadryl) and tripelennamine (Pyribenzamine) were introduced as highly effective histamine antagonists. The sedative and anticholinergic activity of antihistamines constituted the basis for their frequent prescription for a panoply of psychiatric symptoms. The more recent nonsedating antihistamines are less frequently prescribed in psychiatric practice.

Table 33.12a–1.
Pharmacokinetics of Selected H_1 Receptor Antagonists Used in Psychiatry[a]



Drug	Bioavailability (%)	Protein Binding (%)	Vd (L/kg)	$T_{1/2}$ (Hours)	Major Metabolite
Diphenhydramine [Benadryl] (50-mg oral dose)	40–60	78–85	3.3–6.8	2.4–9.3	N-Desmethyldiphenhydramine
Doxepin [Sinequan]	30	75.5	20	15	N-desmethyldoxepin
Hydroxyzine [Atarax]	—	—	16.0 ± 3.0	14–25	Cetirizine
Promethazine [Phenergan] (25-mg oral form)	25	93	30	12–15	Promethazine sulfoxide

Vd, volume distribution.

CHEMISTRY

With approximately 50 H_1 receptor (H_1R) antagonists currently available worldwide, antihistamines are among the most widely utilized class of agents. Although the antihistamines are structurally unrelated, they share a common ethylamine moiety. The typology, first- and second-generation antihistamines refer to sedating and nonsedating agents, respectively. More recently, nonsedating antihistamines (i.e., substrates of P-glycoprotein) with less arrhythmogenic potential (e.g., fexofenadine [Allegra], loratadine [Claritin], desloratadine [Clarinex], and cetirizine [Zyrtec]) have been referred to as third-generation antihistamines.

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Some general properties of important histamine antagonists commonly used in psychiatry are shown in Table 33.12a–1.

Absorption

The first-generation H_1R antagonists are readily absorbed via the gastrointestinal (GI) tract. Most agents achieve maximum plasma levels within 1 to 3 hours (T_{max}).

Distribution

Antihistamine binding of plasma protein varies from approximately 50% to 98%. The H_1R antagonists' volume of distribution varies more than 100-fold from 0.33 L/kg (i.e., levocetirizine [Xyzal]) to greater than 100 L/kg (i.e., loratadine [Claritin]). Sedating antihistamines are widely distributed in the body and CNS. The antihistamine CNS adverse event profile is a consequence of its relative ability to traverse the blood–brain barrier (BBB). Factors that influence BBB permeability are lipophilicity, molecular weight, and recognition by the P-glycoprotein efflux pump expressed on luminal surfaces of nonfenestrated endothelial cells in the vascular wall of the CNS. Radioligand studies utilizing carbon-11 doxepin (Sinequan) indicate that first-generation H_1R antagonists occupy approximately 50% to 90% of the H_1Rs in the frontal and temporal cortices, hippocampus, and pons. Second-generation H_1R antagonists occupy approximately 0% to 30% of CNS H_1Rs, largely due to their minimal lipophilicity and affinity for P-glycoproteins.

METABOLISM

Most antihistamines are subject to phase I metabolism via hepatic cytochrome P450 systems. In vitro studies evaluating human liver microsomes transfected with cytochrome P450 2D6 (CYP2D6) complementary deoxyribonucleic acid (cDNA) indicate that several antihistamines (e.g., diphenhydramine, chlorpheniramine, clemastine [Dayhist-1], perphenazine [Trilafon], hydroxyzine, tripelennamine) inhibit the metabolism and are hepatically biotransformed by CYP2D6 and CYP3A4. Second- and third-generation antihistamines are neither potent inhibitors nor inducers of the cytochrome P450 system. The H_1R antagonist terminal elimination half-life ($t_{1/2}\beta$) ranges from approximately 2 to 27 hours. Pediatric populations rapidly metabolize antihistamines; individuals who are slow metabolizers may exhibit drug accumulation.

ELIMINATION

Most antihistamines are excreted largely unchanged in the urine and feces.

PHARMACODYNAMICS

Histamine is a pleiotropic, low–molecular-weight amine synthesized endogenously in diverse cell types by the enzyme histidine decarboxylase from the semiessential amino acid L-histidine. Histamine is produced in the CNS, in neurons of the tuberomammillary nucleus of the posterior hypothalamus with projections to both cortical and subcortical regions. Although no precise topographical organization of the histaminergic projection field has been elucidated, the cerebral cortex, amygdala, substantia nigra, and striatum receive moderate to dense histaminergic innervation. Innervations to the hippocampus, thalamus, retina, and spinal cord vary. Histaminergic networks interact and modulate classical monoamine networks. Afferent projection to tuberomammillary neurons includes the infralimbic cortex, lateral septum, preoptic nucleus, and brainstem (from the adrenergic cell group C1 to C3, the noradrenergic group A1 to A3, the ventral tegmental area [VTA] and the serotonergic group B5 to B9).

In addition to histamine, the tuberomammillary neurons also contain the gamma-aminobutyric acid (GABA)-synthesizing enzyme —glutamic acid decarboxylase (GAD), as well as galanin, thyrotropin-releasing hormone, proenkephalin-derived peptides, substance P, and adenosine deaminase. The CNS histamine pool is also comprised of mast cells, glial cells, and vascular endothelium, which are activated by proinflammatory agents.

To date, there are four known histamine receptors, all of which are G-protein–coupled receptors (GPCR): The H_1Rs and H_2Rs exert mostly excitatory actions on neurons, while the H_3Rs are high-affinity auto- and heteroreceptors, inhibiting tuberomammillary neurons and reducing neurotransmitter release. H_4Rs are localized in immunocompetent cells (mast cells, dendritic cells, T cells) and are involved in the release of chemokines and cytokines. H_1Rs participate in synaptic plasticity and long-term potentiation (LTP) via their effect on intracellular Ca^{2+} and protein kinase C (PKC). H_2R activation potently stimulates the cyclic adenosine monophosphate (cAMP) pathway, a critical substrate for late-phase N-methyl-D-aspartate (NMDA) receptor-dependent LTP. H_2R activation also participates in the induction of mossy-fiber LTP. High histamine concentration in the CA1 region of the hippocampus facilitates the induction of LTP in the presence of H_1R and H_2R antagonists, suggesting direct action at the NMDA receptors.

Histamine plays a critical role in CNS arousal. Lesioning of the posterior hypothalamus results in hypersomnia and decreased psychomotor activity. Histamine also regulates cortical activity by stimulating cholinergic neurons of the basal forebrain and serotonergic neurons of the dorsal raphe nucleus. The wakefulness-promoting effects of orexins may be mediated by increased histamine release as inactivation mutations of the H_1R decrease the orexin-mediated arousal effect. Histamine is also involved in vasopressor effects, temperature regulation, and analgesia.

In addition, histamine regulates energy homeostasis via effects on leptin networks. Central administration of leptin increases histamine turnover in the hypothalamus. Leptin-induced suppression of food intake and upregulation of uncoupling protein 1 expression in brown adipose tissue is attenuated in H_1R knockout (KO) mice. H_1R as well as proopiomelanocortin (POMC) melanocortin 4 receptor (MC4-R) regulate energy homeostasis in the brain. The effect of histamine on drinking behavior and osmotic homeostasis is mediated by its stimulatory effect on vasopressin-producing neurons in the supraoptic nucleus. Histamine also regulates neuroendocrine systems (e.g., prolactin, growth hormone, adrenocorticotropin, and thyrotropin-releasing hormone).

Unlike other aminergic systems, histamine and the levels of its metabolites increase with age in the cerebrospinal fluid (CSF). In Alzheimer disease, neurofibrillary tangles occur prominently in the tuberomammillary nucleus, with a corresponding decrease in the number of tuberomammillary neurons. Histamine levels and histidine decarboxylase activity are diminished in brain regions affected by Alzheimer disease and Down syndrome. In Parkinson patients, histamine levels are selectively increased in the putamen, substantia nigra, and external globus pallidus. Levels of tele-methylhistamine (t-MeHA), the primary metabolite of histamine, are unchanged in the substantia nigra. In contrast, t-MeHA is elevated in the CSF of individuals with schizophrenia, particularly those with prominent negative symptoms. These observations indicate that increased histamine release and turnover may be pathophysiologic features in schizophrenia, providing the basis for evaluating the efficacy of H_2R antagonists. Interestingly, results from relatively small placebo-controlled clinical trials in schizophrenia indicate that adjunctive famotidine to ongoing antipsychotic treatment was superior to placebo in reducing overall objectively measured negative symptom severity. In addition, global psychopathology in famotidine-treated subjects may exhibit significantly greater reduction when compared to placebo treatment. However, a meta-analysis of studies with three H_2R antagonists did not demonstrate a significant difference from placebo.

During the past several decades, the human H_1Rs, H_2Rs, H_3Rs, and H_4Rs have been cloned and characterized, each differing in structure, function, localization, and pharmacology. Immunocytochemical studies have isolated H_3R throughout the CNS, and it was found to be a heptahelical protein that exists in both active and inactive forms in dynamic equilibrium. Several isoforms of each of the histamine receptors have been identified with reverse transcription polymerase chain reaction. The four major histamine receptors transduce extracellular signals via G proteins to intracellular second-messenger systems. Histamine receptors are active, and, following stimulation with specific agonists, each one independently is capable of signaling, both in vitro and in vivo.

The human H_1Rs have approximately 45% homology with muscarinic receptors. Mutations of the H_1R gene associated with inactivation result in deficits in learning, memory, and locomotor activity, as well as in impaired immunologic activity. The H_1Rs also mediate the increased permeability of small vessels associated with allergic responses. Extravascular smooth muscle (e.g., bronchiole smooth muscle) contraction is also mediated by H_1R. H_3Rs are presynaptic autoreceptors on histamine-containing neurons; they mediate the synthesis, release, and inhibition of histamine. They are also involved in modulating the release of several other monoamines and neuropeptides.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

A substantial body of evidence has established the efficacy of H_1R antagonists for allergy-related conditions as well as motion sickness. There are no recent studies that establish the efficacy of H_1R antagonists for any of the mental disorders defined in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). These antagonists are frequently prescribed to achieve ataraxia and to reduce psychomotor agitation and sleep latency. The anticholinergic effects of H_1R antagonists have provided the basis for prescribing these agents in Parkinson disease and for dopamine blocker–induced movement disorders. Data on the use of H_2R antagonists in the treatment of Alzheimer disease, medication-associated weight loss, anxiety disorders, and autism are equivocal. H_3R antagonists/inverse agonists have been shown to have some beneficial effects in narcolepsy.

The involvement of histamine receptors both in immune activity regulation and monoamine release raises the possibility of it playing a role in the pathophysiology of depression. It was suggested that the interaction between the histaminergic system that affects cytokine release (neuroinflammation) and the monoamine release is relevant to the pathophysiology of depression. However, these suggestions have not been studied as yet.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

The anxiolytic and sedative effects of antihistamines are related to their direct antagonism at the H_1Rs. In some cases, paradoxical excitation characterized by restlessness, agitation, and nervousness has also been reported. The stimulating effects of H_1R agonists have been particularly apparent in tasks that require a high level of attention (e.g., divided attention tasks, vigilance, and driving tasks). In some cases, however, there are dose-dependent stimulating effects of some antihistamines. The precise biochemical mechanism subserving the excitatory effects of antihistamines has not been elucidated; it is hypothesized that neurotransmitters such as dopamine and GABA are salient or that the effect is mediated by the H_3R.

Antihistamines also have prominent autonomic nervous system effects. They exert a drying effect on mucous membranes in the respiratory system, and their effects on smooth muscles result in bronchodilation and the inhibition of vasoconstriction. H_1R antagonists do not significantly affect blood pressure, but parenteral administration of antihistamines may result in a transient lowering of blood pressure.

COMMONLY USED HISTAMINERGIC AGENTS IN PSYCHIATRY

Diphenhydramine

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Histamine
Mechanism of Action	Receptor antagonist (H1)

Oral diphenhydramine is efficacious in the treatment of dopamine blocker–induced movement disorders. Diphenhydramine is approved by the U.S. Food and Drug Administration (FDA) for the treatment of dopamine blocker–induced parkinsonism, allergic and anaphylactic reactions, as well as motion sickness. When prescribed for parkinsonism, diphenhydramine is often combined with anticholinergic agents. The parenteral availability of diphenhydramine presents a viable treatment option for Parkinson patients with difficulty swallowing and for acute dystonic reactions. It has historically been prescribed as a nonspecific sedative for children and older adults. Reports of paradoxical excitation, as well as cognitive impairment (e.g., anticholinergic effect), reduce its therapeutic index.

Hydroxyzine

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Histamine
Mechanism of Action	Receptor antagonist (H1)

Hydroxyzine is indicated for the short-term treatment of anxiety and tension due to psychological factors. A Cochrane review of 39 studies found the efficacy of hydroxyzine in the treatment of generalized anxiety disorder (GAD) to be similar to that of benzodiazepines and buspirone. However, it was associated with a larger rate of sleepiness/drowsiness. In addition, hydroxyzine trials were associated with significant study bias. Preliminary evidence suggests that hydroxyzine may be superior to placebo at reducing the overall severity of bruxism in children. It is often included in numerous over-the-counter preparations for the treatment of anxiety or insomnia. Hydroxyzine is also indicated for use as an antipruritic and as a sedative as part of a premedication regimen in conjunction with general anesthesia.

Promethazine

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Histamine, dopamine
Mechanism of Action	Receptor antagonist (H1, D2)

Promethazine is indicated before or after surgery as an antiemetic, as well as an adjuvant for analgesia. It is also indicated for sedation in both pediatric and adult populations, and similar to diphenhydramine, it is also used for allergic reactions and to treat motion sickness. In 2016, the British National Institute for Health and Care Excellence (NICE) approved the use of the haloperidol and promethazine combination as a treatment for acute aggression in patients with psychosis. It was suggested that the synergy between the sedative effect and the anticholinergic properties of promethazine that attenuate haloperidol-induced extrapyramidal side effects results in aggression reduction.

Cyproheptadine

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Histamine, serotonin
Mechanism of Action	Receptor antagonist (H1, H2, 5HT2A)

Cyproheptadine is indicated for allergic reactions. It is a potent H_1R and H_2R antagonist, and is also a serotonin (5-HT) 2AR antagonist. Cyproheptadine is used for various purposes in psychiatry (e.g., to counter antidepressant-associated sexual dysfunction, stimulant-induced weight loss, or insomnia) and for the symptomatic treatment of schizophrenia (e.g., agitation, akathisia), autism spectrum disorder (ASD), serotonin syndrome, or migraine.

OTHER THERAPEUTIC INDICATIONS IN PSYCHIATRY

H_1R antagonists are widely prescribed in the treatment of insomnia (including during pregnancy), analgesia, akathisia, serotonin syndrome, anxiety, motion sickness, vertigo, emesis, and bruxism.

Insomnia and Sedation

Although benzodiazepines and other classes of psychotropic agents have largely replaced antihistamines in clinical practice, H_1R antagonists are still considered effective for sedation and sleep promotion. The rationale for considering antihistamines is supported by evidence that histaminergic stimulation is critical for wakefulness.

It is of note that agents with H_1R antagonistic activity at low doses, like the monoamine transmission modulators/enhancers mirtazapine (Remeron), doxepin (Sinequan), and amitriptyline (Elavil), as well as the dopamine blocker quetiapine (Seroquel), are effective for insomnia. Similar to diphenhydramine, doxepin has also been reported to induce non-REM sleep, while mirtazapine at a low dosage is also effective for the treatment of dopamine blocker–induced akathisia.

Narcolepsy

Narcolepsy is a chronic disorder characterized by excessive daytime sleepiness (EDS), which leads to difficulties in concentration. It was proposed that narcolepsy is related to the denervation of hypothalamic hypocretin (orexin)-producing neurons. Dopaminergic stimulators (mainly modafinil and armodafinil) are still the first choice of treatment. Pitolisant (Wakix), a selective H_3 autoreceptor blocker, was approved for the treatment of narcolepsy by the european medicines agency (EMA) in 2016 and by the FDA in 2020. Clinical trials demonstrated significant improvements in EDS and cataplexy, with adverse events including headaches, insomnia, and nausea. Serious safety concerns were not detected. Another study comparing pitolisant to placebo and modafinil found no significant differences between the beneficial effects of the two active agents. However, post hoc analyses did not show pitolisant to be noninferior to modafinil, possibly due to the small sample sizes ($N =$ 30 in each group). Hence, pitolisant may be an optional therapeutic strategy when stimulants fail.

FUTURE DIRECTIONS

Attenuation of Iatrogenic Weight Gain

H_2R antagonist use in psychiatric practice has primarily been for weight loss in overweight individuals and persons experiencing dopamine blocker–associated weight gain. Initial studies indicated that the H_2-receptor antagonist nizatidine (Axid) was efficacious as a secondary prevention strategy for olanzapine (Zyprexa)-associated weight gain. Subsequent placebo-controlled studies with this agent as a primary or secondary prevention strategy for olanzapine- and quetiapine-associated weight gain have produced more equivocal results. The mechanism mediating nizatidine’s modest weight loss effect is hypothesized to be via central appetite–regulating centers.

Aside from H_2R antagonists, other histaminergic agents were also investigated for the prevention of dopamine blocker–induced weight gain. A double-blind, randomized placebo-controlled trial assessed the effects of a combination of betahistine (H_1R agonist/H_3R antagonist) and reboxetine (a norepinephrine reuptake inhibitor previously demonstrated as having a positive effect on weight gain) versus placebo among olanzapine-treated patients. At the end of the trial, patients in the betahistine/reboxetine group gained significantly less weight than those in the placebo group (2.02 ± 2.37 and 4.77 ± 3.16 kg, respectively). Nonetheless, it is of note that metformin may be superior to betahistine in the treatment of weight gain induced by antipsychotic dopamine-blocking agents.

Neurocognitive Disorders

Data regarding the role of histamine in Alzheimer disease is inconsistent. Yet, ecologic studies suggested that H_2R antagonists may decrease the emergence of Alzheimer disease. Subsequent randomized, double-blind, placebo-controlled trials with nizatidine, however, failed to demonstrate a therapeutic effect in the treatment of cognitive deterioration that is part of Alzheimer disease. Notwithstanding, several lines of preclinical studies suggest that antihistaminergic therapy may facilitate the reduction in amyloid-beta neuropathology and prevention of autophagic failure. Although, to date, there is no clear-cut evidence for procognitive effects of H_3R antagonists, the approval of pitolisant for narcolepsy and its increasing use may offer an opportunity to collect new data on its cognitive effect as well.

PRECAUTIONS AND ADVERSE EVENTS

The most common side effect of first-generation H_1R antagonists is CNS depression, manifesting as sedation, somnolence, cognitive impairment, and reduction in psychomotor activity. Simple and complex tests of psychomotor performance indicate that second-generation antihistamines are less impairing than first-generation antihistamines. Although second- and third-generation antihistamines are less sedating when coadministered with other agents that alter P-glycoprotein function, their propensity for CNS adverse events increases.

The coadministration of alcohol, benzodiazepines, or other CNS depressants may result in additive sedation, requiring dose adjustment. Other reported CNS side effects include blurred vision, nervousness, and tremors. Other non-CNS side effects associated with antihistamines are dry mouth, increased appetite, nausea, vomiting, diarrhea, or constipation. H_1R antagonists should be administered with caution in patients treated with anticholinergics since the combination may aggravate side effects such as dry mouth, blurred vision, and bladder neck obstruction, especially in patients with an enlarged prostate.

The use of antihistamines in older adults could result in confusion and disorientation. Pediatric populations and individuals overdosing with H_1R antagonists are at risk for excitatory effects, which include ataxia, agitation, incoordination, and seizures. Other adverse events resulting from overdose resemble atropine poisoning and include flushed face, dilated pupils, tachycardia, and fever. Treatment of overdose is generally through supportive medical therapy.

Table 33.12a–2.

Dosage and Administration of Common Histamine Antagonists

Medication	**Route**	**Preparation**	**Common Dosage**
Diphenhydramine (Benadryl)	Oral	Capsules and tablets: 25 mg, 50 mg	Adults: 25–50 mg three to four times per day
		Liquid: 12.5 mg/5.0 mL	Children: 5 mg/kg three to four times per day, not to exceed 300 mg/day
	Deep IM or IV	Solution: 10 or 50 mg/mL	Same as oral
Hydroxyzine Hydrochloride (Atarax)	Oral	Tablets: 10, 25, 50, and 100 mg	Adults: 50–100 mg three to four times daily
		Syrup: 10 mg/5 mL	Children younger than 6 years of age: 2 mg/kg per day in divided doses
			Children older than 6 years of age: 12.5–25.0 mg, three to four times daily
	IM	Solution: 25 or 50 mg/mL	Same as oral
Hydroxyzine Pamoate (Vistaril)	Oral	Suspension: 25 mg/mL	Same as dosages for hydrochloride
		Capsules: 25, 50, and 100 mg	

Promethazine (Phenergan)	Oral	Tablets: 15.2, 25.0, and 50.0 mg	Adults: 50–100 mg three to four times daily for sedation
		Syrup: 3.25 mg/5 mL	Children: 12.5–25.0 mg at night for sedation
	Rectal	Suppositories: 12.5, 25.0, and 50.0 mg	
	IM	25 and 50 mg/mL	
Cyproheptadine (Periactin)	Oral	Tablets: 4 mg	Adults: 4–20 mg/day
		Syrup: 2 mg/5 mL	Children 2–7 years of age: 2 mg two to three times daily (maximum of 12 mg/day)
			Children 7–14 years of age: 4 mg two to three times daily (maximum of 16 mg per day)

IM, intramuscular; IV, intravenous.

Of particular concern with H_1R antagonists is the possibility of cardiotoxicity, particularly in cases of overdose or when coprescribed with other agents. The arrhythmogenic potential of several second-generation H_1R antagonists is mediated by nonhistaminergic receptors. Reports in the late 1980s of cardiac arrhythmia associated with intentional overdose and therapeutic use of terfenadine (Seldane) drew attention to the hazards of drug–drug interactions via cytochrome P450 oxidative enzymes. The first-generation H_1R antagonists exhibit both muscarinic and alpha-adrenergic blocking effects as well as dose-dependent prolongation of QT intervals in the electrocardiogram (ECG).

Second-generation H_1R antagonists astemizole (Hismanal) and terfenadine (Seldane) are known to block the rapid component of the delayed rectifier potassium current (I_{Kr}) with a 50% inhibitory effect in the nanomolar range. This results in prolongation of the monophasic cardiac action potential and the QT interval, engendering early depolarization and dispersion and eventually increasing the risk for torsades de pointes. Terfenadine is similar in potency to quinidine at inhibiting the I_{Kr} in cardiac tissue.

Second-generation antihistamines that were introduced later exhibit less potency in blocking the I_{Kr}, bestowing these agents with less cardiac toxicity potential.

Intentional or unintentional overdose of antihistamines can be fatal. Fortunately, the abuse liability of H_1R antagonists is generally low, although some first-generation agents may be used for recreational purposes (e.g., dimenhydrinate [Dramamine]). Some first-generation H_1R antagonists have been associated with sudden infant death syndrome. Other adverse events include eruption, photosensitivity, fever, hepatotransaminase elevation, and agranulocytosis.

Antihistamines are frequently used by pregnant women for the treatment of nausea, vomiting, and insomnia. First- and second-generation H_1R antagonists are FDA category B or C. Despite there being no clear association between antihistamines and fetal malformations, cardiac abnormalities, or obstetric outcomes, and despite the data being generally reassuring, antihistamines during pregnancy should be used only under medical supervision.

DRUG INTERACTIONS

Pharmacodynamic drug interactions are not uncommon and usually have additive CNS depressant and anticholinergic effects. Many over-the-counter agents contain antihistamines. Coprescribing antihistamines with monoamine oxidase inhibitors (MAOIs) may aggravate the anticholinergic effects.

LABORATORY INTERFERENCES

Promethazine has been reported to cause false results on pregnancy tests and increase glucose levels. Hydroxyzine may falsely elevate urinary 17-hydroxycorticosteroid levels. All available H_1R antagonists may interfere with allergy skin tests, resulting in a false-negative test.

DOSAGE ADMINISTRATION

Table 33.12a–2 outlines the commonly prescribed dosage of first-generation H_1R antagonists. Superficial administration of intramuscular formulations may result in local irritation. Hence deep injection is recommended. Most antihistamines are prescribed in doses that are divided to be administered over the day. However, when used as a hypnotic, a single evening dose is recommended.

33.13 Pharmacological Treatments of Substance Abuse

33.13a Opioid Receptor Modulators

33.13a.1 Opioid Maintenance Treatments: Methadone and Buprenorphine

Jonathan R. Buchholz, M.D., Kelly Barth, D.O., and Andrew J. Saxon, M.D.

It has long been recognized that after ongoing, regular use of opioids, a use disorder including maladaptive use, functional impairment, withdrawal symptoms, and tolerance may develop. Commonly misused opioids include heroin, fentanyl, morphine, hydromorphone (Dilaudid), codeine, meperidine (Demerol), oxycodone, tramadol, hydrocodone (Robidone), and kratom. The prevalence of opioid misuse, use disorder, and opioid-related overdoses has risen exponentially since the 1990s. The 2019 National Survey on Drug Use and Health reported that approximately 9.7 million Americans used prescription pain relievers for nonmedical reasons in the past year, a decrease from previous estimates. However, starting in the early 2010s, heroin use started to rise, with estimates of 745,000 having used in the last year in 2019, and since 2013, the use of fentanyl and its analogs has become a central contributor to the exponential rise in opioid-related overdoses in North America. Whereas early reports suggested unintentional or unknown use of illicit fentanyl through drugs laced with fentanyl or counterfeit prescription opioid tablets, recent reports suggest more individuals are knowingly using fentanyl and may prefer fentanyl over other opioids. Regardless of the primary opioid used, opioid use disorder (OUD) is associated with several negative outcomes, including early mortality, increased rates of hepatitis, HIV infection, sexually transmitted diseases, and other health problems, as well as criminal justice system involvement.

PHYSICAL DEPENDENCE AND WITHDRAWAL

If an individual is physiologically dependent on opioids, opioid discontinuation or diminution in the amount consumed often leads to the development of an opioid withdrawal syndrome. Physical signs and symptoms that frequently occur include sweating, piloerection, yawning, rhinorrhea, sneezing, lacrimation, pupillary dilation, nausea, vomiting, abdominal cramps, diarrhea, tremor, muscle aches or cramps, agitation, dysphoric mood, fever, and sleep disturbances. Although opioid withdrawal is not usually life-threatening, other than times where it exacerbates underlying serious medical conditions, it is highly physically and subjectively uncomfortable, such that an individual continues to use opioids to avoid withdrawal symptoms.

The goal of most medically supervised withdrawal (detoxification) protocols is to limit patient discomfort by decreasing or ameliorating withdrawal symptoms. Medications commonly used in the treatment of acute opioid withdrawal include α_2-adrenergic agonists clonidine (Catapres) and lofexidine (Lucemyra), cyclobenzaprine (Flexeril) or benzodiazepines for muscle cramps, the antispasmodic dicyclomine (Bentyl), antidiarrheals such as loperamide, antiemetics such as prochlorperazine (Compazine) or ondansetron (Zofran), and sedatives such as zolpidem (Ambien) or benzodiazepines. Another option is to convert the patient to an equivalent dose of another opioid, typically either methadone or buprenorphine, and then gradually reduce the dose to minimize withdrawal. If methadone is used, it must be done under the auspices of a federally licensed program, and if buprenorphine is used, it must be prescribed by a qualified, trained physician with a special Drug Enforcement Agency

(DEA) number. If the goal is to expedite the withdrawal process, especially in the case of a long-acting opioid, administration of an opioid antagonist such as naloxone (Narcan) or naltrexone (Revia) hastens the onset of the withdrawal syndrome. Caution must be taken when using this approach because of the abrupt onset of symptoms that can appear in precipitated withdrawal. Again, adjunctive medications, such as clonidine, cyclobenzaprine, and dicyclomine, may also be used for the symptomatic treatment of some opioid withdrawal symptoms. The use of ultrarapid opioid detoxification, which involves the administration of general anesthesia or heavy sedation in individuals undergoing withdrawal, although effective in reducing physiologic dependence, has been demonstrated to lead to a greater number of serious adverse events than the other approaches without superior outcomes, and so it is not recommended. Once a patient has been completely withdrawn from opioids, naltrexone, an orally and parenterally active μ-opioid antagonist, may also be used to help prevent relapse. Prior to starting naltrexone, a naloxone challenge test can be performed in situations where the clinician is unsure if residual physiologic dependence remains to avoid a potential prolonged, precipitated withdrawal episode induced by the inherently longer acting naltrexone. Oral naltrexone may be dosed at 50 mg/day or 100 to 150 mg two to three times a week. Positive results have been found with using naltrexone in highly motivated patients, but many patients experiencing OUD tend to drop out of naltrexone therapy. The long-acting injectable form of naltrexone (Vivitrol) provides blockade of the μ-opioid receptor for about 30 days, is also available for the treatment of OUD, and has been shown to retain people in treatment more effectively than the oral formulation in a recent randomized trial. Two randomized control trials have compared the effectiveness of injectable naltrexone to sublingual buprenorphine for OUD.

OPIOID AGONIST THERAPIES FOR OPIOID USE DISORDER

Outcomes for medically supervised opioid withdrawal are generally suboptimal, so the generally preferred approach is utilizing one of the three Food and Drug Administration (FDA)-approved medications for the treatment of OUD. The other two FDA-approved medications for OUD include the μ-receptor opioid agonist agents methadone or buprenorphine. The goal of treatment with opioid agonist therapy is to provide a physician-ordered or prescribed opioid (either methadone or buprenorphine) to deter and ideally eliminate the use of illicit opioids. Early researchers in this area speculated that an effective pharmacologic treatment for OUD must eliminate the euphoric appeal of heroin, withdrawal symptoms, and cravings that draw those using opioids back to use; it must be sufficiently free from toxic dysphoric effects that patients will continue with the treatment; it must be orally effective, long acting, medically safe, and compatible with a normal performance at work and at school and with responsible behavior in society.

Methadone (Dolophine) which came into widespread use in the 1970s, was the first medication to meet these requirements. Levomethadyl (ORLAAM) was available from 1993 until 2003 as opioid maintenance therapy; however, production of levomethadyl was discontinued by the manufacturer due in part to reports of prolonged QT intervals and risk of torsades de pointes. In 2002, buprenorphine and buprenorphine/naloxone (Suboxone, Zubsolv, Bunavail, Cassipa, Probuphine, Sublocade) became the first opioid maintenance medications approved for office-based treatment of OUD.

As of 2019, among the more than 1.6 million people aged 12 years or older with a past-year OUD, only 294,000 were receiving treatment for OUD. Barriers to patients entering licensed opioid treatment programs include state and federal regulations for program admittance, treatment costs, and inadequate expansion of treatment centers since the 1980s. The social stigma associated with methadone treatment also may deter individuals experiencing OUD from entering treatment. Office-based treatment with buprenorphine, which appears to have nearly comparable effectiveness to clinic-based treatment, is making opioid maintenance therapy more accessible. As of March 2021, 98,076 providers had obtained waivers to prescribe buprenorphine, but according to a recent study, only half of the waivered clinicians prescribed buprenorphine and most were treated at levels below their patient limits. No clear data exist on the total number of patients treated since FDA approval, but it certainly exceeds 1,000,000. The following discussion reviews the history and current status of methadone and buprenorphine. A discussion on the use of opioid agonists in the treatment of chronic pain is also included.

METHADONE

Neuroscience-Based Nomenclature (NbN)	
Opioid Receptor Agonist	
Pharmacologic Domain	Opioid
Mechanism of Action	Receptor antagonist (μ)

In response to high rates of heroin-related deaths in the 1960s, researchers began investigating the feasibility of opioid maintenance therapy. Vincent Dole, Marie Nyswander, and Mary Jeanne Kreek evaluated several short-acting opioids as possible replacement medications but found that patients were overly sedated by the narcotic effects and still craved heroin. Moreover, patients required frequent dosing—every 4 to 6 hours—to prevent the emergence of withdrawal symptoms. Searching for a longer-acting alternative, the researchers administered methadone, which had been previously shown to be useful in heroin withdrawal. They discovered that, with methadone, it was possible to maintain a patient experiencing heroin dependence "between the limits of narcosis and abstinence [where] there is a functional zone."

The rapid expansion of methadone maintenance programs occurred in the 1970s during the presidency of Richard Nixon. At this time, politicians were concerned about the high rate of heroin-related crimes and were encouraged by the decrease in illegal activities reported by individuals receiving methadone. However, initial rapid expansion was soon curtailed by government regulation in an attempt to maintain some control over the distribution of methadone. Today, the DEA and the Center for Substance Abuse Treatment, which is part of the federal Substance Abuse and Mental Health Services Administration, both have roles in regulating licensed opioid treatment programs. There remains substantial community resistance to the placement and existence of these programs, which limits the availability of services in some areas. Critics often suggest that methadone maintenance is, in essence, trading one chemical dependency for another and is therefore not an appropriate treatment. Finally, there is concern that methadone diversion may occur, further worsening OUD epidemics or contributing to opioid overdoses. In reality, evidence accrued thus far suggests that diverted methadone comes mainly from methadone prescribed to treat pain, not from methadone dispensed in licensed opioid treatment programs.

Chemistry

Methadone is a synthetic opioid of the phenylheptylamine class structurally unrelated to morphine (Fig. 33.13a.1–1). Methadone is comprised of a racemic mixture of two stereoisomers. R-(-)-methadone (levomethadone) is responsible for the drug's analgesic and other opioid agonist effects, while S-(+)-methadone (dextromethadone) exhibits substantially less analgesic activity and does not have respiratory depression activity or addiction liability, but does have antitussive effects.

Pharmacologic Actions

Pharmacokinetics. Methadone is rapidly absorbed after oral administration. It is highly plasma protein bound, with an approximate volume of distribution of 4 L/kg. Methadone is primarily metabolized in the liver by cytochrome P450 (CYP) enzymes, predominately by CYP2B6 and CYP3A4, while its inactive metabolite, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP), is excreted in the urine. Single nucleotide polymorphisms

(SNPs) located within the CYP enzymes may alter methadone metabolism. Carriers of CYP2B6*6/*6 may have a greater risk for adverse effects given the decreased metabolism and clearance of methadone in these individuals, while carriers of CYP2B6*4 have been observed with decreased plasma concentrations of methadone secondary to increased methadone clearance. Of interest, women may metabolize methadone more rapidly than men. After oral administration, methadone has a biexponential half-life with an initial phase range of 12 to 24 hours and a secondary phase of 55 hours. Methadone obviously crosses the blood–brain barrier as well as the placenta and is found in maternal milk. The benefits of breastfeeding far outweigh concerns about exposing infants to the methadone in breast milk, and mothers on methadone maintenance are encouraged to breastfeed.

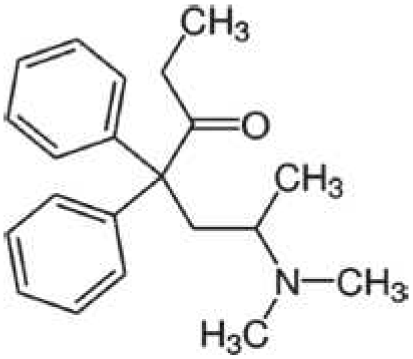

FIGURE 33.13a.1–1. Molecular formula for methadone.

Pharmacodynamics. The major pharmacodynamic action of methadone is agonism at the μ-opioid receptor, but methadone, unlike most other opioids, also acts as an antagonist at the N-methyl-D-aspartate receptor (NMDA) receptor and blocks serotonin and norepinephrine transporters. In addition, methadone inhibits the cardiac potassium channel, hERG, which can cause a prolonged QT interval on the Electrocardiogram (ECG). There is often not a clear linear relationship between methadone blood levels and its clinical effects. Therefore, it is rarely necessary to obtain blood levels during clinical care of patients on methadone maintenance. Suggested minimally therapeutic trough serum levels of methadone range from

100 to 400 ng/mL. Peak serum levels of methadone vary considerably in stable patients. A peak-to-trough serum ratio of greater than 2:1 is often considered indicative of inadequate pharmacologic coverage throughout the 24-hour dosing interval. Patients who display such a pattern may be rapid metabolizers of methadone who would ideally do best on a split-dosing regimen rather than on a higher single daily dose.

Design and Interpretation of Clinical Studies on Methadone

Although methadone maintenance treatment (MMT) was introduced in the 1970s, few randomized, controlled trials have evaluated its efficacy. Although these studies had small sample sizes and rarely followed patients for longer than 1 year, they reported positive results. The majority of data supporting the use of methadone maintenance comes instead from the many observational studies that have been conducted to evaluate this treatment modality. These studies support the findings of clinical trials in demonstrating that methadone treatment reduces heroin or other opioid use and criminal activity. Furthermore, MMT has been shown to decrease mortality among patients with OUD. Mortality estimates indicate that individuals who use heroin are one-fourth as likely to die if they are treated with methadone as those not in treatment. MMT also appears to decrease drug use practices, such as needle sharing, that are associated with the transmission of HIV and viral hepatitis. Methadone treatment appears to be cost-effective in that the cost per year of life saved is less than that incurred for other common medical therapies such as coronary bypass surgery or renal dialysis. A review that included seven randomized controlled trials and two quasi-experimental studies of MMT from 1995 to 2012 confirmed all the benefits described above, particularly when the dose of methadone exceeded 60 mg/day, and also confirmed improved maternal and fetal outcomes for pregnant women with OUD when provided MMT.

Adverse Effects

General. Because methadone shares the adverse effects and toxic potential of other opioid agonists, the usual precautions of opioid agonist therapy should be observed. Common side effects of opioids include sedation, constipation, sweating, nausea, dizziness, and hypotension. During methadone maintenance, most adverse effects disappear over the course of several weeks. However, constipation and excessive sweating often persist even with long-term methadone administration. Recent case reports also indicate that, as noted above, methadone, especially in high doses, although occasionally in moderate doses, can impair cardiac conduction, prolong the QT interval, and, in rare instances, lead to torsades de pointes. Like other opioids, methadone does suppress the hypothalamic–pituitary–gonadal axis and thus can cause hypogonadism with low testosterone levels in men and anovulation and lack of menstruation in women. A potential downstream effect of hypogonadism could be osteoporosis. Methadone does not cause chronic adverse effects on the heart, lungs, liver, or kidneys.

Overdose and Prevention. Severe intoxication or overdose with opioids constitutes a medical emergency. Miosis (known as pinpoint pupils) is a recognized effect of most opioids and can be used to identify opioid intoxication. Of most concern in opioid overdose is potentially fatal respiratory depression from direct suppression of respiratory centers in the midbrain and medulla. For severe cases, the administration of the pure opioid antagonist naloxone in combination with general supportive measures is indicated. Owing to the long half-life of methadone, repeat administration of naloxone may be necessary. An overdose of methadone may also involve other sedative agents that may affect treatment decisions. In 2006, the FDA issued a public safety advisory leading to a black box warning regarding risks of respiratory depression and QT prolongation associated with methadone. Center for Disease Control and Prevention opioid prescribing guidelines released in 2016 recommend considering naloxone and overdose prevention education for patients and household members of patients with a history of overdose, substance use disorder, those taking higher opioid dosages, or those with concurrent benzodiazepine use. Patients taking methadone or buprenorphine for OUD should be given naloxone rescue kits and counseled on proper use. There are multiple FDA-approved formulations of naloxone that are used in naloxone rescue kits: (1) injectable naloxone that is drawn up out of a vial with a needle into a syringe with a dose concentration of 0.4 mg/1 mL, (2) an autoinjector with audio prompts that administers a 0.4 mg intramuscular (IM) dose via a retractable needle, (3) a single-step nasal spray that administers a dose concentration of 4 mg/0.1 mL into one nostril, and (4) a multistep nasal spray assembled by combining a prefilled syringe with a nasal atomizer, that administers a dose concentration of 2 mg/2 mL, where 1 mL is administered to each nostril. Opioid overdose education and community naloxone distribution (OEND) programs have preferred intranasal, and IM autoinjector formulations as these are easier for a layperson to use. IM formulations tend to be more expensive and have insurance coverage variability.

Drug Interactions

Pharmacokinetic interactions are mainly related to methadone being a substrate for CYP450 2B6 and 3A4. Inducers of P450 enzymes such as the anticonvulsants, phenytoin and carbamazepine, the antituberculous medication rifampin, and antiretroviral medications, nevirapine and efavirenz increase the metabolism of methadone so that the patient could go into opioid withdrawal suddenly and become destabilized. Newer antiviral agents are generally well tolerated in patients taking methadone with routine monitoring. Inhibitors of the enzymes such as the antidepressant fluvoxamine, the antibiotic, erythromycin, and antifungal medications, like ketoconazole, have the potential to reduce methadone metabolism and lead to side effects or toxicity, though clinically meaningful effects are rarely observed with inhibitors. Pharmacodynamic interactions obviously can occur with opioid antagonists, such as naloxone or naltrexone, which would cause a patient on methadone maintenance to go into severe, precipitated withdrawal. Other opioids, sedative–hypnotics, and alcohol also have a pharmacodynamic interaction with methadone, leading to additive excess sedation and a greater risk of suppression of respiratory drive and overdose.

Laboratory Interference

None known.

Dosing

Federal eligibility requirements for MMT stipulate that individuals entering treatment have a minimum 1-year history of OUD. The minimum age requirement is 18 years of age; however, individuals between 16 and 18 years of age may enter methadone treatment under certain conditions. There is no upper age limit on program entry. Pregnant women with OUD may be accepted for methadone treatment. Individuals with major medical conditions are also eligible for treatment, as are those who use multiple substances where OUD is one component of their addictive disease.

Methadone dose determination should always be performed by an experienced physician based on their clinical assessment of the patient. Data indicate that adequate methadone doses are correlated with reduced illicit drug use and improved patient retention in treatment. A comparison by Eric C. Strain and colleagues of moderate daily doses of methadone (40 to 50 mg) and high doses (80 to 100 mg) showed significantly lower illicit opioid use in the high-dose group. Similar findings have been reported in regard to treatment retention, with one study showing that patients receiving 80 mg/day of methadone were twice as likely to remain in treatment as those receiving 60 to 79 mg, who were, in turn, twice as likely to remain in treatment as patients receiving less than 60 mg. The lowest effective dose of methadone is now widely accepted to be approximately 60 mg, with an optimum average dose for most patients of approximately 80 mg (±20 mg), although some patients require a dose higher than this range.

In general, methadone can be initiated in an individual with well-established current physiologic dependence at a dose of 20 to 30 mg. If there is any doubt as to the degree of an individual's tolerance to opioids, an initial dose of 10 mg is indicated. Under federal regulations, the maximum allowable first dose is 30 mg, and the maximum total dose for the first day of treatment is 40 mg unless the physician documents the fact that 40 mg is insufficient to suppress withdrawal symptoms. Dose escalation should be done in small increments (usually 5 to 10 mg at a time) under close physician supervision until an optimum maintenance dose is achieved. Given methadone's long half-life, it is advisable to observe the patient for at least 3 to 4 days before an additional dose increase is provided. The optimum dose is achieved when (1) the patient evidences no withdrawal signs or symptoms throughout the 24-hour dosing period, (2) the patient reports an absence of craving for opioids, (3) adequate tolerance is obtained such that the patient experiences little or no reinforcement from use of other opioids, and (4) self-report and urine testing indicate the absence of illicit opioid use. Ideally, these beneficial effects need to be balanced against side effects so that small dose decrements may be required if unpleasant or intolerable side effects occur.

The duration of maintenance therapy may range from a few months to an indefinite period. In general, methadone maintenance should be continued as long as the patient is continuing to benefit from and wishes to remain in treatment. It should be noted that methadone administration should ideally be combined with comprehensive counseling and rehabilitative services.

BUPRENORPHINE

Neuroscience-Based Nomenclature (NbN)

Opioid Receptor Modulator

Pharmacologic Domain	Opioid
Mechanism of Action	Receptor partial agonist (µ) and antagonist (κ, d)

Reckitt and Coleman Ltd. developed buprenorphine in the 1970s as an analgesic because of the widespread interest in developing mixed agonist and antagonist opioid agents for pain relief. It was hoped that these agents would offer analgesia with greater safety and less abuse liability than the pure opioid agonists. Buprenorphine is available in many countries, including the United States, as an analgesic. It was first marketed in the United Kingdom in 1978 for injection and in 1981 as a sublingual tablet.

The potential for the use of buprenorphine in the treatment of OUD was first recognized in the late 1970s when Donald Jasinski and colleagues demonstrated that buprenorphine substituted for morphine and suppressed opioid withdrawal while having few withdrawal symptoms. Human laboratory studies have demonstrated that buprenorphine suppresses heroin self-administration. A number of published clinical observations have also supported the usefulness and general safety of buprenorphine in clinical settings. However, in clinical practice, buprenorphine has been widely used as an injectable analgesic, and intravenous (IV) buprenorphine has been reported as a significant drug of misuse in Europe, New Zealand, Australia, and the Republic of Georgia. In 2002, the FDA approved the use of buprenorphine for the treatment of OUD (then termed opioid dependence). It is commercially available as a generic sublingual tablet containing buprenorphine only or a combination of buprenorphine and naloxone, which can come as a sublingual tablet, a sublingual film, or a buccal film. More recently, implantable and injectable formulations of buprenorphine have become available. In 2016, the FDA approved a 6-month subdermal formulation of buprenorphine requiring surgical implantation, but this formulation was discontinued in 2020 primarily due to low utilization. In 2017, a monthly subcutaneously injectable formulation of buprenorphine was approved for the treatment of moderate to severe OUD for individuals stable on transmucosal buprenorphine for at least 7 days, and another subcutaneous injectable formulation with weekly and monthly injection options is currently in the FDA-approval process.

Of note, there are also several formulations of buprenorphine that are specifically FDA approved for the treatment of pain, including an IV formulation for acute severe pain and transdermal patch and buccal film formulations for severe, chronic pain that requires long-term opioid treatment.

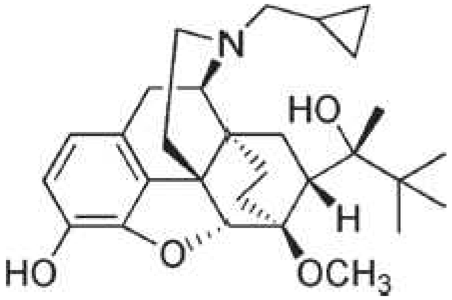

FIGURE 33.13a.1–2. Molecular formula for buprenorphine.

Chemistry

Buprenorphine is a semisynthetic derivative of the opioid alkaloid thebaine (Fig. 33.13a.1–2).

Pharmacologic Actions

Pharmacokinetics. Because of extensive metabolism by the intestine and liver, buprenorphine is poorly absorbed by the oral route and is, therefore, best administered using IV or sublingual, buccal, subcutaneous, or transdermal dosing. When administered by the IV route, buprenorphine is readily distributed into tissues, resulting in a large volume of distribution. The elimination is biphasic, with a rapid distribution phase ($T_{1/2}$ = 2 minutes) and a slower elimination phase ($T_{1/2}$ = 3 to 5 hours). The rate of absorption is slower by the sublingual route, with a time to reach maximum drug concentration (T_{max}) of approximately 60 minutes. It takes 3 to 5 minutes to dissolve, and sublingual bioavailability is approximately 55%. There is considerable between-subject variability in bioavailability, but the data suggest greater bioavailability of buprenorphine/naloxone versus buprenorphine alone. Buprenorphine has a variable range (3 to 44 hours) but typically has a long half-life. Following three-times-per-day dosing, steady-state levels of buprenorphine are reached at approximately 4 days. For the monthly extended-release buprenorphine injection, upon subcutaneous injection into the abdomen, a solid depot is created from which buprenorphine slowly diffuses as the depot undergoes biodegradation, resulting in sustained therapeutic plasma concentrations over the entire monthly dosing interval. Buprenorphine is 96% bound to plasma proteins. Buprenorphine undergoes both glucuronidation and N-dealkylation, with N-dealkylation catalyzed by the liver enzyme CYP450 3A4 producing an active metabolite, norbuprenorphine. The main route of elimination for both parent drug and metabolites is fecal, with lesser amounts excreted by the kidneys. Buprenorphine crosses the blood–brain barrier as well as the placenta and is found in maternal milk. The benefits of breastfeeding far outweigh concerns about exposing infants to the buprenorphine in breast milk, especially since buprenorphine has such low bioavailability by the oral route, so mothers on buprenorphine maintenance are encouraged to breastfeed.

Pharmacodynamics. Pharmacologic studies have shown that buprenorphine combines a strong affinity for the μ-opioid receptor with low intrinsic activity. As such, it is considered a partial μ-agonist. Buprenorphine is also an antagonist at the κ-receptor. Because buprenorphine is a partial agonist, it has a considerable margin of safety with little chance of lethal overdose.

While blood levels of buprenorphine and norbuprenorphine are generally proportional to dose, to date, no specific correspondence between blood levels and therapeutic effect has been demonstrated.

Design and Interpretation of Clinical Studies on Buprenorphine

A series of well-controlled clinical trials have clearly established the safety and clinical efficacy of buprenorphine for OUD. These trials have demonstrated the efficacy of buprenorphine, as compared to placebo, in decreasing illicit opioid use in individuals with OUD. Subsequent trials have established the safety and efficacy of buprenorphine in the maintenance treatment of OUD in doses ranging from 2 to 32 mg/day.

Controlled clinical trials have demonstrated that buprenorphine and moderate-dose methadone (50 to 60 mg/day) have similar effects on retention and illicit drug use in maintenance programs. Comparisons of buprenorphine with higher doses of methadone suggest that high-dose methadone may have a slight advantage in terms of treatment retention and suppression of illicit opioid use. One recent study suggests that higher buprenorphine doses are associated with better treatment retention. Studies by Walter Ling and colleagues have demonstrated successful implementation and use of buprenorphine in private physicians' offices. Further studies have indicated that buprenorphine works as well or better for patients who primarily misuse prescription opioids as opposed to heroin; that for patients without severe psychiatric illness, outcomes for buprenorphine are as good with quality medical management alone as compared to addiction-focused counseling or psychotherapy added to medical management; that outcomes with maintenance buprenorphine treatment are superior to outcomes when buprenorphine is tapered; and that initiating buprenorphine is more readily achievable than initiating extended-release naltrexone, which leads to lower relapse rates.

The Drug Addiction Treatment Act, which was signed into law in October 2000, marked the beginning of a process designed to allow qualified physicians to prescribe approved narcotic drugs for the treatment of OUD in office-based settings. There are a number of approved training programs in place to teach physicians about the use of buprenorphine in an office-based setting. This is the first time in modern medicine that physicians in the United States practicing in a variety of clinical settings, including office-based practice, are able adequately to treat OUD with pharmacotherapy. This initiative has increased access to treatment for some individuals with OUD, but in the face of an ongoing opioid overdose crisis that has worsened during the COVID-19 pandemic, a treatment gap still remains.

Adverse Effects

Because buprenorphine is a partial agonist rather than a full agonist at the μ-receptor and it is a weak antagonist at the κ-receptor, this agent produces a milder withdrawal syndrome and has a wider margin of safety than the full μ-agonist compounds generally used in treatment. Buprenorphine has a ceiling effect beyond which dose increases prolong the duration of action of the drug without further increasing the agonist effects. Because of this, buprenorphine has a high clinical safety profile, with limited respiratory depression, therefore decreasing the likelihood of lethal overdose. Buprenorphine does have the capacity to cause typical side effects associated with opioids, including sedation, nausea and vomiting, constipation, dizziness, headache, and sweating. Buprenorphine may have the potential to suppress the hypothalamic–pituitary–gonadal axis, but this possible adverse effect requires further study. Buprenorphine does not cause chronic adverse effects on the heart, lungs, or kidneys. Some small early studies and case reports raised a concern that it could be hepatotoxic, but more recent, larger studies show no evidence of a hepatotoxic effect.

Drug Interactions

Theoretical pharmacokinetic interactions have been proposed mainly related to buprenorphine also being a substrate for CYP450 3A4. However, to the extent that these theoretical interactions have been studied in the human laboratory, no clinically meaningful effects have been observed, and no isolated clinical case reports have surfaced. It has been proposed that because buprenorphine has a high affinity for and slow dissociation from the μ-opioid receptor, changes in plasma levels have little effect on efficacy. Pharmacodynamic interactions obviously can occur with opioid antagonists, such as naloxone or naltrexone, although because of buprenorphine's high affinity and slow dissociation, there is competition for the receptor, with the likelihood of precipitated withdrawal being low. Other opioids, sedative–hypnotics, and alcohol could also have a pharmacodynamic interaction with buprenorphine leading to additive excess sedation and a greater risk of suppression of respiratory drive and potential overdose. This risk is less than with full-agonist opioids, and overdoses in adults on buprenorphine alone are nearly nonexistent.

Dosing

To reduce the likelihood of misusing buprenorphine via the IV route, buprenorphine has been combined with the opioid antagonist naloxone for sublingual administration. Because naloxone is poorly absorbed by the sublingual route, when the combination drug is taken sublingually, there is no effect of the naloxone on the efficacy of buprenorphine. If an individual with OUD injects the combination medication, the naloxone may precipitate a withdrawal reaction and/or block the intended effects of the buprenorphine being sought, therefore reducing the likelihood of illicit injection use of the sublingual preparation.

Inducting and stabilizing a patient on buprenorphine is analogous to inducting and stabilizing a patient on methadone, except that, as a partial agonist, buprenorphine has the potential to cause precipitated withdrawal in patients who have recently taken full-agonist opioids. Thus, a patient must abstain from the use of short-acting opioids for 12 to 24 hours prior to starting buprenorphine and from longer-acting opioids such as methadone for 24 to 48 hours or longer. The physician must assess the patient clinically and determine that the patient is in mild to moderate opioid withdrawal with objectively observable withdrawal signs prior to initiating buprenorphine. In most instances, a relatively low dose of buprenorphine (2 to 4 mg) can then be administered with additional doses given in 1 to 2 hours if withdrawal signs persist. Alternatively, the induction can be done at the patient's home after sufficient education about when to begin the medication.

Certain groups can be at higher risk for precipitated withdrawal during buprenorphine induction, including those being transitioned from high-dose full-opioid agonists (including methadone and fentanyl) and those unintentionally or intentionally exposed to illicit fentanyl. There has been a growing literature showing early promise for several different clinical approaches to decrease the risk of precipitated withdrawal in these populations, including buprenorphine "microinductions." Buprenorphine "microinduction" entails introducing very low doses of buprenorphine (e.g., 0.5 mg sublingually) while an individual is still on full-agonist opioids or coming off high-affinity, slowly cleared full agonists such as fentanyl, and gradually tapering the full opioid agonists (as applicable) while gradually uptitrating buprenorphine, a process that generally occurs over several days. Additional prospective studies would clarify the early clinical and anecdotal success in this area.

Once induction is accomplished, the subsequent goal for the first 24 hours is to suppress withdrawal signs and symptoms, and the total 24-hour dose to do so can range from 2 to 16 mg on the first day. In subsequent days, the dose can be adjusted upward or downward to resolve withdrawal fully and, as with methadone, to achieve an absence of craving, adequate tolerance to prevent reinforcement from the use of other opioids, and ultimately abstinence from other opioids while minimizing side effects. Dose-ranging studies have demonstrated that doses of 6 to 16 mg/day are associated with improved treatment outcomes, as compared to lower doses of buprenorphine (1 to 4 mg). Sometimes, patients seem to need doses higher than 16 mg/day, although there is no evidence for any benefit of doses beyond 32 mg/day. For the treatment of OUD, a dose of approximately 4 mg of sublingual buprenorphine is the equivalent of a daily dose of 40 mg of oral methadone. It has also been demonstrated that daily, alternate-day, or three-times-per-week administration, all have equivalent effects in suppressing symptoms of opioid withdrawal in physiologically dependent individuals. The buprenorphine/naloxone combination formulations are recommended for most clinical purposes, including induction and maintenance. The buprenorphine monoproduct should be used only for pregnant patients or for patients who have a documented anaphylactic reaction to naloxone.

The newer forms of buprenorphine delivery include a long-acting monthly subcutaneous injection that provides therapeutic plasma levels for 28 to 30 days. This delivery system obviates the need for taking medications daily while virtually eliminating the risk of medication nonadherence or diversion. Administered in a health care provider's office, this formulation is indicated for those with moderate to severe OUD who have been stable on a transmucosal buprenorphine product for at least 7 days. The approved dosing regimen is 300 mg administered subcutaneously for the first 2 months, followed by maintenance doses of 100 mg monthly with the option to continue 300 mg monthly if clinically indicated.

OPIOID AGONISTS IN THE TREATMENT OF PAIN IN INDIVIDUALS WITH ADDICTIVE DISORDERS

Opioid agonists are efficacious agents for the treatment of acute pain and possibly for some individuals with chronic pain syndromes, although in randomized controlled trials, their long-term use in chronic pain has not been demonstrated to be superior to nonopioid medications, and the use of opioid agonists in the treatment of pain in individuals with substance use disorders is controversial. Untreated pain can be a powerful trigger for relapse. On the other hand, exposure to opioid analgesics for some individuals with addictive disorders could trigger reminders of past use and place them at risk for relapse. In addition, some of the physiologic aspects of addictive disorders may make pain more difficult to treat in the individual with a substance use disorder than in individuals without such a disorder. Finally, it can be difficult to distinguish distress related to pain from distress related to drug craving in individuals with OUD. In spite of these potential problems, individuals with substance use disorders develop both acute and chronic pain disorders that warrant treatment, and total prohibitions against the use of opioids are neither practical nor good medical practice. However, pain management in individuals with addictions must attend to the treatment of both the pain and the addictive disorder to be successful. Ongoing support for maintaining recovery is essential for patients with OUD taking opioids for pain, including nonpharmacologic treatments like recovery-oriented meetings and/or regular follow-up with a treatment professional who understands the issues involved in the treatment of pain in individuals with addiction.

Acute Pain Management

Undertreatment of pain associated with trauma and surgery has been demonstrated to increase morbidity and lengthen hospital stays. In individuals with addictive disorders, acute pain conditions increase distress and anxiety and may become a risk factor for relapse. Physicians treating patients in acute pain who have addictive disorders should reassure the patient that their addiction is not an obstacle to the appropriate and effective treatment of the pain condition.

For patients with OUD, the prescriber should not consider tapering or discontinuing opioid medications until the acute pain situation is resolved. The use of nonmedication pain treatment approaches, such as ice, heat, physical therapy, acupuncture, or a transcutaneous electrical nerve stimulation (TENS) unit, as indicated, should be optimized. When medications are necessary, it is best to use those least likely to alter mood or to produce physical dependence if they are effective. Nonsteroidal anti-inflammatory drugs, tricyclic antidepressants, anticonvulsants, and topical agents, all have demonstrated efficacy in certain pain conditions. However, when opioid agents are necessary to manage pain conditions, they should be used effectively. In the management of moderate to severe acute pain, opioids are generally the mainstay of treatment in addicted or nonaddicted individuals. Scheduled administration of opioids is preferred to as-needed administration in individuals with addictive disorders, providing several advantages. If the patient needs to ask for medications, this may be misconstrued as drug-seeking behavior. In addition, when drug administration is time dependent rather than symptom dependent, reinforcement of pain symptoms is minimized.

Individuals on methadone maintenance or physically dependent on other opioids should have their baseline opioid requirements met in addition to the medications provided for pain treatment. At times these individuals require more opioid pain medication than the average individual because of their opioid tolerance and associated hyperalgesia. When possible, patients on methadone should receive a different opioid medication for the control of acute pain or have additional methadone prescribed on a three- or four-times-daily basis. Although an increase in methadone in divided doses throughout the day is generally effective in acute pain management, this strategy makes it easy to confuse issues of pain treatment with issues of addiction treatment. When the acute pain condition resolves, the taper of methadone back to the original maintenance dose can at times prove difficult for the patient.

The management of patients on buprenorphine who develop an acute pain condition is somewhat more complex, with fewer data and clinical experiences to guide it. Although buprenorphine is an effective analgesic, it may not have the analgesic potency of a full-agonist opioid. There are essentially three options. One is to increase the dose of buprenorphine and give it in divided doses throughout the day. Alternatively, even on stable doses of buprenorphine, additional μ-opioid receptors still remain available for full-agonist opioids to bind and activate, so another option is to try adding to the regimen a full-agonist opioid with high intrinsic activity at the μ-opioid receptor, such as morphine, hydromorphone, or fentanyl. A third option is to discontinue buprenorphine and switch temporarily to a full-agonist opioid during the time acute pain treatment is needed. When the acute pain (whether from injury, illness, or postoperatively) subsides, the patient can be transitioned back to buprenorphine, with care taken not to administer buprenorphine too soon after ingestion of the full agonist to avoid precipitating withdrawal.

Similar considerations apply to perioperative pain management of patients on buprenorphine, and rather than discontinuing buprenorphine perioperatively, many medical centers now recommend continuing or dose-adjusting buprenorphine during the perioperative period.

Management of Chronic Pain

The treatment of chronic pain in individuals with addictive diseases also does not differ significantly from the treatment of these pain conditions in nonaddicted individuals. The goals of treatment are the reduction of pain, improvement in associated features, and restoration of function. In general, these goals are approached initially through the use of nonpharmacologic strategies, such as physical therapy/therapeutic exercise, TENS units, peripheral nerve blocks, and cognitive behavioral therapy. The mainstay of medication treatment for chronic, nonmalignant pain includes nonsteroidal anti-inflammatory drugs, tricyclic antidepressants, and anticonvulsants. Anticonvulsants (pregabalin) and antidepressant agents (duloxetine) have received FDA approval for specific chronic nonmalignant pain syndromes.

Even when medications, including opioids, are deemed necessary in the treatment of chronic pain syndromes, the treatment plan should be multidimensional. Specifically, it should include a careful history of the development of the pain problem, factors that contribute to the patient’s pain and distress, and a plan for dealing with each of these contributing factors. The treatment plan may include the physical treatments of pain mentioned previously (i.e., TENS unit, nerve blocks), as well as behavioral interventions, such as relaxation training, biofeedback, and changes in behavioral responses to pain. The use of long-term opioids as one component in the treatment of chronic pain is generally a reasonable approach when other treatment regimens have failed. Clinicians should be aware that long-term opioid therapy use may be associated with the development of opioid tolerance as well as an abnormal sensitivity to pain or hyperalgesia, conditions which can be related and manifest clinically as needing increased doses of opioids to maintain the same level of analgesia. Opioid dose escalation should be approached with caution in these scenarios, as, by nature of tolerance, a dose increase may temporarily provide relief and meet the goals of treatment (decreased pain, improved functionality), but several weeks, months to years later, the patient and provider may find themselves in the same predicament (inadequate pain relief despite previous positive response to increased opioid dose). When tolerance development is noticed after multiple dose adjustments, a discussion should be had regarding options to address tolerance because continued dose escalation is generally not the safest long-term option. Alternative approaches include opioid rotation to an agent with less potential for tolerance, such as buprenorphine or a trial of opioid tapering, though much more research in the area of opioid tolerance is needed. For individuals with or without addiction, when opioids are used for pain, it is important to document their benefit by observing that their functional status is improving. Particularly for those with a history of opioid or other substance use disorder, when considering long-term opioid therapy, one may consider an agent such as buprenorphine (patch or buccal film FDA approved for pain) even as an initial long-term opioid choice. The majority of chronic pain patients, with or without addiction, achieve relief of pain through multimodal approaches that usually do not include the use of opioids. For most patients, a trial period with the use of coordinated alternative treatments should be tried before long-term opioid therapy is used.

Most recently, Health and Human Services convened an interagency task force that released an updated guide for clinicians: “Pain Management Best Practices,” which reviews evidence-based medications, restorative therapies, interventional procedures, behavioral health approaches, and complementary and integrative approaches to chronic pain. This report highlights the importance of multimodal care, risk assessment, safe opioid stewardship, and regular re-evaluation for all patients with chronic pain to ensure pain is managed as effectively as possible while mitigating risks of undertreated pain and long-term opioid use.

FUTURE DIRECTIONS

The efficacy of opioid agonist medications in the treatment of OUD has been clearly established. In spite of the data demonstrating that maintenance on buprenorphine or methadone is effective in decreasing opioid use, improving employment and prosocial behaviors, and enhancing public health and safety, only a small percentage of individuals with OUD in the United States are in treatment. It is hoped that legislation making it possible to prescribe opioid agonist therapies in a variety of settings and the development of agonist agents with a greater margin of safety and less abuse potential will increase the number of individuals with OUD receiving treatment.

33.13a.2 Opioid Receptor Antagonists: Naltrexone and Nalmefene

Oluwole O. Jegede, M.D., M.P.H., Stephanie S. O'Malley, Ph.D., Tiffany Arnold, B.S., M.D., Katherine S. Pier, M.D., and Srinivas B. Muvvala, M.D., M.P.H.

INTRODUCTION AND HISTORY

Naltrexone is an opioid antagonist—synthesized in 1965 by H. Blumberg and H. B. Dayton—which proved to have several advantages over earlier opioid antagonists, including cyclazocine, nalorphine, and naloxone. Specifically, naltrexone had a relatively long half-life, was orally effective, was not associated with dysphoria, and could be administered once a day. Whereas earlier narcotic antagonists—principally naloxone—were used to reduce narcotic overdose, these characteristics of naltrexone made it suitable for preventing relapse to opioid use in detoxified individuals with opioid use disorder (OUD). In 1984, the U.S. Food and Drug Administration (FDA) approved naltrexone (under the original trade name Trexan) for providing blockade of the effects of exogenously administered opioids after detoxification.

Over the ensuing years, naltrexone has been tried for the treatment of a wide range of disorders, including, among others, alcohol use disorders, eating disorders, autism, self-injurious behavior, cocaine use disorder, gambling, and chronic pain syndromes.

Naltrexone (ReVia; Depade) was approved as an oral formulation to treat alcohol use disorder in 1994. Generic formulations of oral naltrexone have been available since then. In addition, an extended-release, once-a-month injectable suspension (XR-NTX, Vivitrol) was approved in 2006 to treat alcohol use disorder and in 2010 to treat OUD.

In 2014, the FDA approved an extended-release (XR) formulation combining naltrexone hydrochloride and bupropion (Contrave) to treat obesity.

Nalmefene (Revex) is indicated for the complete or partial reversal of opioid drug effects and managing known or suspected opioid overdose and alcohol use disorder (Europe). An oral formulation of Nalmefene is available in some countries but not in the United States. Naloxone, an opioid antagonist, has been FDA approved for reversal of opioid overdose. It is an effective medication in reversing respiratory depression and preventing fatalities secondary to opioid overdose.

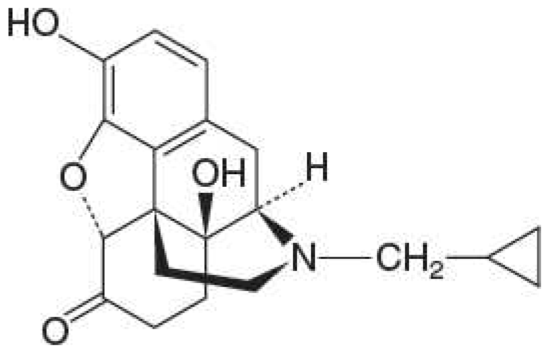

FIGURE 33.13a.2–1. Molecular structure of naltrexone (ReVia).

CHEMISTRY

Naltrexone, or 17-(cyclopropylmethyl)-4,5a-epoxy-3,14-dihydroxymorphinan-6-one hydrochloride, is a competitive opioid antagonist developed by substituting an N-methyl group on the opioid agonist oxymorphone with a methylcyclopropyl moiety. Naltrexone is a white, crystalline hydrochloride salt soluble in water, with a melting point of 275 °C and a pKa of 8.13 at 37 °C. Its molecular formula is $C_{20}H_{23}NO_4$•HCl. Nalmefene is a 6-methylene analog of naltrexone with a molecular formula $C_{21}H_{25}NO_3$, and it is also available as a hydrochloride salt with a pKa of 7.6 (Fig. 33.13a.2–1).

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Naltrexone is rapidly and completely absorbed following oral administration of a 100-mg dose, with peak plasma concentrations of 19 to 44 mg/L achieved within 1 hour. The oral bioavailability of naltrexone is 60%, with 20% of the drug bound to plasma proteins. A single dose of naltrexone has a volume of distribution of 16.1 L/kg, which decreases to 14.2 L/kg following repeated administration.

Naltrexone is primarily recovered in plasma, urine, and feces as conjugated naltrexone and conjugated and unconjugated 6β-naltrexol along with minor quantities of 2-hydroxy-3-O-methyl-6β-naltrexol and 2-hydroxy-3-O-methylnaltrexone. Approximately 60% of the drug is recovered in the urine 48 hours following oral administration and 72 hours following intravenous (IV) administration. Naltrexone has a plasma half-life of 10.5 hours regardless of whether it is administered via the oral or IV route. Conjugated 6β-naltrexol has been shown to have a plasma half-life of 14 to 19 hours. This metabolite may contribute to the longer duration of action of naltrexone. Studies indicate that after a 100-mg dose, naltrexone can be detected in plasma for 30 hours, whereas 6β-naltrexol can be detected for up to 125 hours. The XR injectable formulation (Vivitrol), containing 380 mg of naltrexone, was created using Medisorb drug-delivery technology for once-a-month intramuscular (IM) injections. Following administration of this formulation, an initial peak is seen within 2 hours, followed by a second peak 2 to 3 days later, with a slow decline in concentrations after 14 days. Thus, total naltrexone exposure is three- to fourfold higher than that observed with daily oral dosing over 28 days. The elimination half-life of both naltrexone and β-naltrexol in this form is 5 to 10 days.

Nalmefene, following administration of a 1-mg IV dose, has a volume of distribution of 8.6 L/kg and a terminal half-life of 10.8 hours. Nalmefene is completely bioavailable following IM and subcutaneous (SC) routes, with time-to-peak plasma concentrations of 2.3 (±1.1) and 1.5 (±1.2) hours, respectively. Because of variability in the speed of absorption of IM and SC doses, repeated dosing should be done with great care. Nalmefene is primarily metabolized through glucuronide conjugation in the liver and is excreted in the urine. Both the glucuronide and the dealkylated metabolite (formed in trace amounts) have minimal pharmacologic activity. Therefore, when administered orally, Nalmefene has a pharmacokinetic profile similar to that of naltrexone. In addition, a metabolite, nornalmefene, has been identified that also exists in glucuronidated and alkylated forms. Hepatic or renal impairment decreases the clearance of both naltrexone and nalmefene.

Pharmacodynamics

Naltrexone is a nonspecific opioid antagonist that binds to all three opioid receptor sites (μ, κ, δ) due to the dose administered. Naltrexone has minimal opioid agonistic effects, and its relative opioid antagonistic potency is 12 times that of nalorphine and 2.5 times that of naloxone or cyclazocine. The time course of action of oral naltrexone is about three times longer than naloxone in rodents. No significant species differences in the binding of [^{3}H] naltrexone have been documented. An oral 100-mg dose of naltrexone was found to almost completely antagonize the subjective and objective responses of 25 mg of IV heroin.

Similarly, following a 1-mg IV dose, nalmefene blocks greater than 80% of brain opioid receptors within 5 minutes after administration. Whereas nalmefene has been shown to have greater antagonistic potency at the δ-opioid receptors, it has also been shown following oral administration of a dose of 20 mg to produce complete and prolonged blockade of the μ-opioid receptors. Recent evidence based on the rapid onset of action, long half-life (>7 hours), and the high affinity of nalmefene at μ-opioid receptors has led to the development of an intranasal (IN) formulation as a rescue medication that could be useful in the context of synthetic opioid overdose. The pharmacokinetic profile of nalmefene was enhanced by the addition of the absorption enhancer dodecyl maltoside.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Naltrexone and nalmefene have demonstrated efficacy in blocking exogenously administered opioids and were used in protocols for rapid opioid detoxification. Both agents have also been extensively examined as aids in preventing relapse in patients with alcohol use disorder. Both agents, particularly naltrexone, have shown benefits in reducing heavy drinking in numerous studies. XR formulations of naltrexone have been evaluated to prevent relapse in both alcohol and OUDs. Naltrexone has also been evaluated to treat self-injurious behaviors in patients with intellectual disability and autism, based only on small studies and case reports. Case reports and small open-label trials have also examined naltrexone's utility in treating compulsive sexual behavior and kleptomania. Open-label and randomized controlled trials using relatively small samples have examined the efficacy of naltrexone in reducing binge eating. Randomized placebo-controlled trials have evaluated the extended-release combination of naltrexone and bupropion (NB) to treat obesity, resulting in FDA approval for this indication. Some randomized clinical trials support the use of nalmefene and naltrexone for pathologic gambling disorders. Naltrexone has been evaluated for cocaine use disorders without much success. Although randomized clinical trials suggest the possible utility for naltrexone as adjunctive therapy for smoking cessation, the effects are inconsistent and may vary by gender. Small Randomized Controlled Trials (RCTs) have also demonstrated a limited anti-inflammatory efficacy of low-dose naltrexone (LDN) in patients with chronic pain syndromes.

THERAPEUTIC INDICATIONS

Alcohol Use Disorders

The efficacy of naltrexone was initially demonstrated in the 1990s in two double-blind, placebo-controlled trials of naltrexone in alcohol-dependent patients. In each of these studies, treatment with an oral dose of 50 mg daily was initiated following a minimum of 7 days of abstinence or completion of medical detoxification and was provided with concurrent psychosocial interventions. In a combined analysis of these studies, naltrexone-treated patients were more likely to remain abstinent (54% vs. 31%), to experience fewer days of drinking (3.1% vs. 7.5%), and to report lower rates of relapse to heavy drinking (25% vs. 52%). Furthermore, participants who lapsed (i.e., were nonabstinent) were less likely to experience heavy drinking if they took naltrexone rather than a placebo. The COMBINE Study, a large multisite trial combining pharmacotherapy and behavioral interventions, conducted in 11 academic sites across the

United States showed that a 100-mg dose of naltrexone, with medical management, was more effective than medical management placebo in increasing percent days of abstinence and reducing heavy drinking days. In a meta-analysis of pharmacotherapies for alcohol use disorder, 53 trials studied the efficacy of naltrexone (*n* = 9,140), and treatment duration ranged from 12 to 52 weeks. Naltrexone was shown to have benefits in various consumption outcomes. Naltrexone is particularly shown to have efficacy in preventing the return to heavy drinking and reducing percent drinking days and percent heavy drinking days.

An XR formulation of naltrexone has also shown similar efficacy in reducing the rate of heavy drinking. A large multisite double-blind placebo-controlled study evaluated the efficacy and tolerability of IM long-acting naltrexone injections (one group was administered 380 mg and the other was administered 190 mg) versus placebo in alcohol-dependent patients. The long-acting preparation was well tolerated over 6 months, and the 380-mg injectable naltrexone preparation showed a 25% reduction in the number of heavy drinking days. In the subset of patients who were abstinent 4 or more days prior to treatment initiation, the 380-mg preparation also prolonged abstinence and reduced the number of heavy drinking days and drinking days. Subjects who received 380 long-acting naltrexone mg versus placebo and had lead-in abstinence were shown to have a greater effect size (HR, 0.20, *p* = .005) when compared to subjects who drank during the lead-in period (HR, 0.79, *p* = .05). This increase in effect size was also observed in subjects who received 190-mg long-acting naltrexone versus placebo (HR, 0.79, *p* = .05). Thus, while naltrexone effectively reduced the number of heavy drinking days in those using alcohol prior to commencing naltrexone, the treatment effects were greater in patients abstaining from alcohol consumption prior to treatment.

The dosing interval recommended for the administration of XR-NTX in the United States is 4 weeks. However, it should be noted that there may be variation in efficacy with this recommendation, and flexibility in dosing may need to be considered on a case-by-case basis. For example, a case report on a patient with cyclical relapse showed significant improvement when the dosing interval was shortened from 4 to 3 weeks, highlighting that flexibility in dosing intervals may be beneficial for some patients whose cravings and drinking behaviors return before 4 weeks have elapsed.

Despite substantial literature supporting the use of naltrexone to reduce drinking behavior, this agent's efficacy is modest. This evidence has motivated researchers to examine predictors of response to naltrexone. Recent evidence suggests that the efficacy of naltrexone may be more pronounced in specific subgroups of patients, such as those for whom alcohol use is primarily driven by the positive, rewarding effects of alcohol and those who smoke cigarettes. Individuals with high levels of alcohol cue–induced craving also seem to benefit from naltrexone. The predictive utility of the Asn40Asp polymorphism of the µ-opioid receptor (OPRM1) gene in treatment response is being debated, with some studies showing a stronger effect of naltrexone in Asp40 carriers while studies prospectively randomizing patients based on genotype do not. As a result, the data are still insufficient to recommend selecting patients for treatment with naltrexone based on these moderators.

Nevertheless, because of the good safety profile of naltrexone and support for its effectiveness in a range of patient populations, naltrexone should be offered as one of the treatment options to all patients with alcohol use disorder who do not have contraindicating conditions. Interestingly, there are small clinical studies that demonstrate increased responsiveness among patients that have an affinity for sweet taste (sweet-liking phenotype [SL phenotype]) versus patients who dislike sweet take (sweet-disliking phenotype [SDL]). It is also noted that the SL phenotype and high craving for alcohol both separately and especially in combination are associated with a positive response to naltrexone.

In 2013 a four-site randomized controlled trial known as the PREDICT study postulated that individuals whose drinking was driven by positive reinforcement (i.e., reward drinkers) would be more responsive to naltrexone, as a reward is thought to be partially mediated by the opioidergic system. Using the Inventory of Drinking Situations, a 30-item self-report questionnaire, subjects were categorized into high-reward/high-relief, high-reward/low-relief, low-reward/high-relief, and low-reward/low-relief phenotypes. The resulting data showcased that using naltrexone with predominantly reward drinkers produced significantly larger effect sizes than prescribing the medication to a more heterogeneous sample. In addition, the interaction between naltrexone and the reward subgroup significantly predicted any heavy drinking ($p = .03$). This finding was not replicated when the data from the COMBINE study were analyzed, however, which may be because, in this study, naltrexone was generally more effective for most patients with a significant main effect of medication.

Nalmefene was approved in 2013 by the European Medicines Agency to reduce alcohol consumption in patients with high-risk drinking who do have alcohol withdrawal symptoms and who do not require alcohol detoxification. The studies supporting the approval tested nalmefene taken as needed (i.e., in high-risk situations, when drinking is imminent, or as soon as possible after drinking) compared to placebo. Although fewer studies have been on nalmefene, a recent meta-analysis concluded that nalmefene led to a reduction in heavy drinking days per month and the number of drinks per drinking day.

Several small trials have also examined the combined use of opioid antagonists with other agents. For example, preliminary small placebo-controlled studies suggest that a combination of the 5-HT$_3$ antagonist ondansetron and naltrexone, when compared with placebo, may produce greater suppression of drinking outcomes in individuals with early-onset alcohol use disorders but not in those with late-onset alcohol use disorder.

Combining naltrexone with disulfiram has shown modest efficacy in increasing abstinence rates in concurrent psychiatric disorders and alcohol use disorder patients. A 12-week randomized clinical was conducted to evaluate the efficacy of disulfiram and naltrexone, alone and in combination, in participants with dual diagnoses. However, a large, multisite trial indicated no significant advantage of using naltrexone in combination with acamprosate to treat alcohol use disorder. A combination of LDN and prazosin has shown some promise in patients with comorbid post-traumatic stress disorder (PTSD). The addition of gabapentin to naltrexone has been shown to improve drinking outcomes than naltrexone alone in the first 6 weeks of abstinence, possibly secondary to beneficial effects with symptoms such as insomnia and mood instability.

Opioid Use Disorder Treatment

Although naltrexone was initially developed to treat opioid addiction, the value of oral naltrexone for this indication has been limited primarily by two issues: (1) the need for opioid detoxification prior to induction and (2) poor adherence compared to agonist therapy. The newer XR formulations address to a large extent the issue of adherence at least for the 30 days between injections.

As an opioid antagonist, naltrexone selectively competes with exogenous opioids for the central nervous system (CNS) and non-CNS opioid receptors and blocks their activity. This blockade lasts for up to 72 hours after oral naltrexone administration and prevents patients from achieving sought-after reinforcement from opioid use. This blockade can have positive psychological consequences, including reduced craving related to the reduced immediate availability of opioid effects and deconditioning of cue-related craving as patients are exposed to people, places, and things formerly associated with opioid use. The opioid antagonist properties of naltrexone do not appear to be subject to the development of tolerance because potency has been demonstrated after maintenance for 1 year or more. Thus, naltrexone does not have opioid agonist properties, and patients do not obtain a psychoactive reward ("high") from using naltrexone. It is also not associated with significant withdrawal symptoms if use is discontinued. However, patients may be more sensitive to lower doses of opioids once naltrexone is discontinued due to the loss of tolerance to exogenous opioids. This decrease in tolerance has been found in animal studies where chronic opioid antagonism with naltrexone results in an increased density of opioid receptors in the brain, thereby increasing sensitivity to opioid agonists relative to the pretreatment naltrexone state.

In certain highly motivated patients with OUD, it can be used as an alternative to maintenance treatment with opioid agonists, such as methadone or the partial agonist buprenorphine. As a nonscheduled medication without psychoactive or addictive properties, naltrexone can be administered as a treatment in various medical settings without any special licensing requirements. Because diversion is not an issue, take-home medications can be provided. As a drug without agonist effects that block the effects of opioids, naltrexone can be used only after completion of a 7- to 10-day period of complete opioid abstinence or after a rapid detoxification procedure to avoid precipitating opioid withdrawal. Hence, patients must start treatment to achieve total opioid abstinence and a willingness to undergo detoxification. Unlike patients maintained on opioid agonists, patients on naltrexone achieve no rewarding effects of taking medications and experience no withdrawal effects if doses are missed. It should be noted that oral naltrexone is not FDA approved for OUD, and maintenance treatment with naltrexone for OUD is with the long-acting formulation only. Retention in treatment is at least two times higher for subjects given XR preparations compared to oral.

Indeed, oral naltrexone has been associated with high rates of discontinuation. A Cochrane review of randomized controlled clinical trials of oral naltrexone maintenance treatments for opioid addiction suggested that oral naltrexone was not more effective than placebo or no pharmacologic agent in preventing relapse, mainly due to low adherence and retention rates. Greater success has been achieved with patients motivated by powerful contingencies such as opioid-dependent health care professionals for whom opioid abstinence is a condition for regaining medical licensure or incarcerated individuals for whom treatment is a requirement for probation or parole. Other strategies to enhance compliance include the use of voucher-based contingency management and the dispensing of naltrexone that is directly observed by either a medical professional or a significant other. The importance of retention in therapy for opioid addiction is highlighted by a review of coronial data in Australia in which those receiving oral naltrexone were 7.6 times more likely than those receiving opioid agonist treatments to experience an overdose. XR formulations, both injectable and surgically implantable, address some of the shortcomings of the oral naltrexone related to adherence and retention. The FDA approved the XR injectable formulation of naltrexone (XR-NTX) in 2010 to treat and prevent relapse after patients with OUD have undergone detoxification treatment. A double-blind placebo-controlled multicenter trial in Russia showed that XR-NTX in conjunction with psychosocial treatment is efficacious in preventing relapse on opioids in detoxified patients. The median proportion of weeks of abstinence was 90% in the 380-mg XR-NTX group versus 34% in the placebo group. In addition, treatment retention was much higher, and opioid craving was much lower in the active medication group. The 1-year open-label extension phase of this study showed that 62.3% of clients remained compliant, out of which 50.9% of patients remained abstinent from opioid use, and the safety of XR-NTX is further established during this phase. A recent study demonstrated the usefulness of XR-NTX as a therapeutic option in treating OUD in individuals involved with the criminal justice system. Opioid-dependent patients maintained on XR-NTX were shown to have lower inpatient substance use–related utilization and total cost of treatment than methadone. It should also be noted that where there is an external motivation for adherence, naltrexone may compare to opioid agonist medications.

Newer sustained-release formulations have been developed, such as naltrexone implants, but further research is needed to establish their safety and efficacy in clinical use.

The XR-NTX versus buprenorphine–naloxone for opioid relapse prevention (X-BOT) trial shows that XR-NTX was more difficult to initiate than sublingual buprenorphine–naloxone and associated with higher relapse rates in the overall sample; however, the two treatments were equally effective for those who were successfully inducted onto treatment. In addition, XR-NTX appears generally well tolerated, and concerns about hepatotoxicity have not been realized. No differences have been found between XR-NTX and placebo on the proportion of patients showing elevated liver enzymes, and XR-NTX is safe in patients with mild to moderate chronic Hepatitis C Virus (HCV) or HIV infections. Opioid detoxification is critical prior to naltrexone induction to avoid precipitating opioid withdrawal. This detoxification can be done by a gradual opioid or buprenorphine taper or by more rapid discontinuation with the help of adjunctive nonopioid medications for symptomatic relief. The latter is more suitable for patients with low physiologic dependence. For patients at risk of moderate to severe withdrawal symptoms, detoxification is best carried out in an inpatient detoxification setting or a partial hospital program with inpatient backup.

Other protocols that have shown promise in the induction of patients with OUD onto XR-NTX use small ascending doses of oral NTX in addition to adjunctive medications, including clonidine and benzodiazepines. In one example of a transition from buprenorphine, along with a brief buprenorphine taper, patients were started with 0.25 mg oral naltrexone twice daily on day 1, increasing gradually to 15 mg twice daily on day 7 and administering XR-NTX on day 8 following negative naloxone challenge. RCTs show that these methods can mitigate the period of relapse risk prior to XR-NTX by obviating the traditional requirement to maintain opioid abstinence before induction. For example, a 2017 randomized trial assigned 150 opioid-dependent adults in a 2:1 ratio to naltrexone-assisted detoxification or buprenorphine-assisted detoxification, followed by an injection of XR-NTX. Naltrexone-assisted detoxification lasted 7 days and included a single day of buprenorphine followed by ascending doses of oral naltrexone along with adjunctive medications for opioid withdrawal symptoms. Buprenorphine-assisted detoxification included a 7-day buprenorphine taper followed by a week-long delay before administration of XR-NTX, consistent with official prescribing information for XR-NTX. Participants from both groups received behavioral therapy focused on medication adherence and the second dose of XR-NTX.

Opioid Detoxification Protocols in Combination with Naltrexone

As a method for rapid detoxification, outpatient protocols have been developed combining naltrexone with clonidine, a selective α2-adrenergic antagonist initially used as an antihypertensive agent, and other adjunctive medication. This combined treatment allows patients to be completely opioid free from the first day of treatment, to have completed detoxification within 48 to 72 hours, and to be able to commence naltrexone maintenance at that time. As a method of initiating maintenance naltrexone treatment, this detoxification mode removes the need for an unprotected 7- to 10-day opioid-free period prior to starting naltrexone, a time when vulnerability to relapse is high. Because blood pressure may be substantially lowered by clonidine administration, patients must be monitored for up to 8 hours on the initial detoxification day, limiting this procedure to settings in which treatment rooms and adequate nursing staff are available. As this procedure may result in significant withdrawal symptoms, this method is best used in patients with a low level of physiologic dependence on opioids.

A variant method of “ultrarapid” inpatient detoxification involves administering naltrexone to opioid-dependent patients who are placed under light sedation or general anesthesia (including mechanical ventilation) followed by detoxification using full doses of naltrexone. However, this method was associated with more incidences of life-threatening adverse events, and therefore this form of “ultrarapid” detoxification cannot be recommended at this time.

Opioid Overdose Prevention

Deaths from opioid overdoses have reached epidemic levels in the United States. Naloxone hydrochloride (Narcan), a potent opioid antagonist, has been widely used in various health care settings and by emergency medical personnel to reverse an opioid overdose and the associated respiratory depression. Multiple routes can administer naloxone in a hospital setting, but it can be administered intramuscularly or intranasally in the community. Some community-based overdose prevention programs have been distributing naloxone to patients at risk of overdose since 1996. Subsequently, several agencies have trained clinicians to screen patients for overdose risk and educate them and their significant others in recognizing and responding to overdoses. With an increase in these initiatives focusing on naloxone distribution, there have been reports of thousands of overdose rescues in the United States. As of August 2020, all 50 states and the District of Columbia have some form of a naloxone access law, allowing individuals to obtain naloxone without a prescription in some capacity. A total of 17 states have a provision related to the co-prescribing of naloxone with an opioid. In nine of these states, the co-prescribing of naloxone is required in certain situations, such as prescribing opioids over a specific morphine milligram equivalent (MME), concurrent benzodiazepine use, or patient history of OUD or overdose. In addition, the FDA announced it would require labeling and prescribing information for opioid pain medicine and opioid agonist treatment to be updated to recommend that health care professionals discuss the availability of naloxone with patients and caregivers, both when beginning and renewing treatment. The FDA also recently approved higher doses of naloxone hydrochloride nasal spray to combat the escalating opioid overdose rates associated with highly potent fentanyl and its analogs.

Cocaine Use Disorders

Based on preclinical studies showing that opioid antagonists can attenuate many effects of cocaine, including acquisition and maintenance of self-administration, a randomized, placebo-controlled clinical trial evaluated its efficacy in an oral 50-mg/day dose alone and combination with relapse prevention therapy. Naltrexone was associated with modestly improved cocaine use outcomes only when combined with relapse prevention therapy. However, trials in patients with cocaine and alcohol use disorders found no benefit of oral naltrexone in reducing cocaine use. In addition, a prior open-label study and another double-blind placebo-controlled study found disulfiram to be superior to naltrexone for patients with combined cocaine and alcohol use disorders. Hence, the evidence does not justify a recommendation for oral naltrexone use in cocaine dependence.

Methamphetamine Use Disorder

Emerging evidence suggests the efficacy of XR-NTX in combination with XR bupropion for the treatment of individuals with moderate and severe methamphetamine use disorder. A randomized, double-blind trial designed to evaluate the efficacy and safety of XR injectable naltrexone (380 mg every 3 weeks) combined with oral XR bupropion (450 mg per day) as compared with placebo in adult patients (18 to 65 years old) with methamphetamine use disorder. This combination was associated with a small but significant negative methamphetamine urine drug screen compared to placebo. Adverse events with naltrexone–bupropion included gastrointestinal disorders, tremor, malaise, hyperhidrosis, and anorexia. However, serious adverse events occurred in only 3.6% who received naltrexone–bupropion during the trial.

Another randomized control trial investigated the use of XR-NTX on its own in reducing methamphetamine use and high-risk sexual behaviors among methamphetamine-dependent men who have sex with men compared with placebo. While initial studies showed possible promise for using naltrexone alone in treating methamphetamine use disorder, this study and others have cast significant doubt on these findings. Therefore, naltrexone in the absence of bupropion is not currently recommended for treating methamphetamine use.

Nicotine Use Disorders

Several lines of evidence suggest that the opioid system may be involved in tobacco use disorder. Nicotine administration is known to stimulate the release of endogenous opioids and attenuate pain perception via opioid mechanisms. Clinical laboratory studies examining the effects of opioid antagonists, including naloxone and naltrexone, on smoking behavior have been inconclusive, with some studies showing reductions in smoking and others finding no effect.

Prior clinical studies suggested that naltrexone may reduce urges or the desire to smoke and reduce weight gain following smoking cessation. The clinical utility of naltrexone as an aid for smoking cessation is supported by two randomized clinical trials, both of which tested the efficacy of naltrexone when used in combination with the nicotine patch for smoking cessation. One study found preliminary efficacy for 50-mg naltrexone primarily in women. The other trial, which combined naltrexone (25 to 100 mg/day) with a 21-mg nicotine patch, found some advantages for the 100-mg dose of naltrexone as an augmentation strategy for smoking cessation. However, a recent meta-analysis of opioid antagonists for smoking cessation concluded that naltrexone alone or as an adjunct to nicotine replacement has no beneficial effect in short- or long-term smoking abstinence. The two clinical trials mentioned above found significant reductions in weight gain following smoking cessation. A third trial in weight-concerned smokers found a modest weight reduction but somewhat lower smoking cessation success with 25 mg naltrexone combined with the nicotine patch.

Several studies have tested the effectiveness of naltrexone in combination with existing approved smoking cessation medications (bupropion or nicotine replacement therapy) to decrease the amount of weight gain following smoking cessation. The studies all measured outcomes within 52 weeks of cessation, a period consistently associated with the most significant postcessation weight gain. In addition, five out of seven studies looking at naltrexone as an adjunct to bupropion or nicotine replacement therapies found a reduction in post–smoking cessation weight gain, while this reduction was not statistically significant in two other studies. Thus, naltrexone may hold promise in moderating weight gain associated with smoking cessation.

Self-Injurious Behavior

Naltrexone has been proposed to treat self-injurious behavior and autistic behaviors in patients with mental retardation and autism. Clinically significant symptom reduction has been reported from numerous open case studies and trials with small sample sizes. However, more extensive studies using more rigorous experimental designs have failed to replicate these reports. Hence, naltrexone's utility for these symptoms is not established.

Eating Disorders/Obesity

Numerous studies in rodents have suggested an association between altered endogenous opioid activity and obesity and other eating disorders. Exogenous and endogenous opioid administration increases food intake, whereas opioid antagonists block the increase in food intake. The clinical data on the use of opioid antagonists in eating disorders is controversial, and the literature is replete with studies that demonstrate differential effects of these agents based on the type of eating disorder. For example, a laboratory study demonstrated that naloxone reduces the consumption of sweet, high-fat foods in both obese and lean binge eaters compared with obese and lean nonbingers suggesting a role of the opioid system in binge eating but not in obesity. In bulimia nervosa, a handful of small sample-controlled clinical trials have been conducted, with some, but not all, reporting reductions in binge symptomatology. Regarding anorexia nervosa, naloxone infusion produced a 10-fold increase in weight gain per week, an effect that was ended when the naloxone infusion was stopped in patients who were also concurrently treated with the antidepressant amitriptyline. Therefore, the role of naltrexone and other opioid antagonists in treating eating disorders remains unclear, and more extensive and definitive, controlled clinical trials are needed.

Naltrexone, when used alone, has failed to produce clinically significant weight loss in controlled studies. However, in translational studies, the combination of NB produced a synergistic reduction in rodent food consumption. This reduction was further proven by studies in overweight and obese individuals in which weight loss produced by the combination of bupropion and naltrexone was shown to be greater than the sum of individual monotherapies. A large, multicenter, randomized, double-blind, placebo-controlled trial showed that NB is a useful therapeutic option for treating obesity. The mean change in body weight was −6.1% in the sustained-release naltrexone 32 mg plus sustained-release bupropion 360-mg/day group (NB32) and −5% in the sustained-release naltrexone 16 mg plus sustained-release bupropion 360-mg/day group (NB16) as compared to −1.3% in placebo. Similarly, 48% of participants assigned to the NB32 group and 39% of participants assigned to the NB16 group had greater than 5% weight loss compared to only 16% in the placebo group. Another large 56-week, randomized, double-blind, placebo-controlled study in obese or overweight participants with dyslipidemia or hypertension compared NB32 to placebo. 55.6% of the participants treated with NB32 had greater than 5% weight loss compared to 17.5% in the placebo group. This study also showed that NB32 improved weight-related quality of life, control of eating, and various cardiometabolic risk markers without any increase in depression or suicidality. Another double-blind placebo-controlled study in overweight/obese type 2 diabetics showed that NB was associated with improvements in glycemic control and select cardiovascular risk factors, and promoting weight loss. FDA recently, in 2014, approved the combination of naltrexone hydrochloride and bupropion hydrochloride in an XR formulation for the treatment of obesity.

Naltrexone showed promise in reducing long-term smoking cessation–related weight gain in women. In addition, in recent pilot studies, naltrexone has shown promise in arresting antipsychotic-associated weight gain in patients diagnosed with schizophrenia and schizoaffective disorder. It is hypothesized that naltrexone could help reduce food cravings in this population by interacting with the dopamine–opioid system.

Few evidence-based psychopharmacologic treatments of eating disorders in adolescents exist. However, a case series in 2019 demonstrated that 50- to 100-mg naltrexone in 32 adolescents undergoing outpatient eating disorder treatment was well tolerated and reduced vomiting and urges to vomit in 52% of the patients. In addition, 18% of patients experienced a decrease in urge to binge/purge. Most importantly, naltrexone was well tolerated without significant adverse effects in this small sample treated for a median of 90 days. Given the paucity of effective pharmacotherapies for eating disorders in adolescence, the potential of naltrexone for this indication warrants further investigation.

Pathologic Gambling

Opioid antagonists can decrease dopamine release in the nucleus accumbens by disinhibiting GABAergic input to dopamine neurons in the ventral tegmental area. As such, it has been hypothesized that these agents might be effective in treating impulse control disorders in general and pathologic gambling in particular. Two open-label case series and a moderately sized, placebo-controlled, randomized, double-blind study supported the efficacy of naltrexone in the short-term treatment of pathologic gambling. In these studies, naltrexone was used at higher doses than generally used in treating alcohol or OUDs. For example, in the placebo-controlled, double-blind study, the dose of 250 mg/day was targeted, and completers had an end-of-study dose of 188 mg/day. Consistent with the use of these higher doses, adverse effects were not infrequently reported, the most significant of which included elevated liver function tests (LFTs). An examination of the individuals experiencing naltrexone-induced increases in LFTs suggested that concurrent use of nonsteroidal anti-inflammatory drugs (ibuprofen, aspirin) was associated with LFT increase. A double-blind placebo-controlled trial demonstrated that 50-, 100-, and 150-mg doses of naltrexone were equally efficacious in reducing gambling urges and behavior in pathologic gambling.

There has been more research examining the use of nalmefene for the treatment of pathologic gambling. Two multicenter investigations suggested that the use of 25 mg of nalmefene daily may effectively reduce the severity of gambling in those with pathologic gambling disorder; there was a 59% improvement in those who received nalmefene versus 34% in those who received placebo. However, higher doses of nalmefene (50 and 100 mg/day) were associated with intolerable side effects. Another double-blind placebo-controlled showed that at doses of 20 and 40 mg, nalmefene was not superior to placebo in the treatment of pathologic gambling.

Currently, there is no FDA-approved medication for the treatment of gambling disorders. A recent meta-analysis investigating the efficacy of pharmacologic treatments found that opioid antagonists have a small but significant benefit than placebo in treating pathologic gambling. However, the study did not support the use of the opioid antagonists, citing that some of the studies have not adhered to intent-to-treat principles. Further studies are needed to examine the safety and efficacy of nalmefene and naltrexone in treating pathologic gambling, especially in individuals with co-occurring substance use disorders and in combination with nonpharmacologic treatment modalities.

Chronic Pain

Long-term opioid treatment leads to a compensatory response from the brain, which increases pain drivers such as glutamate, dynorphin, corticotrophin-releasing factor, and substance P to compensate for chronic agonism of μ-opioid receptors. This brings about a paradoxical worsening of pain and diminished pain tolerance, resulting in the syndrome of opioid-induced hyperalgesia (OIH). Although this phenomenon of sensitization of nociceptors is known to be caused by exposure to opioids, the mechanism of action is still not fully understood. Consequently, although there have been numerous proposed theories about compensatory/allostatic changes of the pain receptors, no consensus has been reached about the exact mechanism. Some clinical research to date suggests that the mechanism of action is thought to involve inflammatory processes.

While the mechanism by which naltrexone restores endogenous opioid tone remains unknown, it is thought that LDN may impact neuroimmunomodulation by intermittent blockade of opioid growth factor receptor (OGFr), resulting in increased levels of opioid growth factor (OGF). The increase of OGF is associated with decreasing neuronal damage, inflammation, and proliferation of T and B cells. In addition, LDN may correct a disruption to the OGF-OGFr axis rather than simply increasing enkephalin levels alone. Case studies have shown that after 3 months of treatment with LDN, individuals with OIH had improved pain tolerance.

LDN has shown promise as a potential treatment for patients with fibromyalgia (FM). FM is a syndrome of chronic pain that is generalized yet intensified at multiple sensitive points and accompanies other somatic and cognitive symptoms. It is hypothesized that the endogenous opioid system plays a role in FM, as cerebrospinal fluid (CSF) studies of FM patients have shown elevated κ-opioid peptide, dynorphin, and met-enkephalin-Arg-Phe. These studies suggest that receptor modulation and desensitization may be contributory. Furthermore, Positron Emission Tomography (PET) scans of patients with FM showcase significantly decreased μ-opioid binding in the bilateral nucleus accumbens, left amygdala, and right anterior dorsal cingulate. Thus, FM involves an autoimmune process in which μ-opioid receptor dysfunction may cause a compensatory increase in endogenous opioids. Despite this compensation, the diminished binding of μ-opioid receptors results in brain-mediated pain experienced by patients as occurring diffusely over the body.

A recent case series found that low doses of naltrexone, up to 4.5 mg twice a day, restores endogenous opioid tone in OIH and improves it in FM to a lesser degree. The difference in response noted between OIH and FM may be due to FM having a distinct neuroimmunologic component from OIH. In addition, a case series suggested that the variation of an inflammatory component may indicate why FM patients have a significant but more minor response to LDN compared to OIH patients.

Immune System

Studies suggest that within a specific dosage window, LDN can act as an immunomodulator in malignant tumors and multiple autoimmune diseases, such as multiple sclerosis (MS), Crohn disease, FM, acquired immunodeficiency syndrome (AIDs), and type

1 diabetes. Currently, evidence supports the safety and tolerability of LDN in these diseases, but fewer studies support the efficacy of LDN, and most efficacy studies focus on subjective measures such as quality of life or self-reported pain.

The suggested mechanisms of action for LDN in autoimmune diseases are mainly related to endogenous opioid activity. Thus, naltrexone is thought to broadly stimulate immune cells by blocking the binding of endogenous opioids and opioid receptors, which may have a role in tissue repair and immunologic effects.

In a randomized controlled trial, 40 participants with moderately to severely active Crohn disease were randomized to receive naltrexone (4.5 mg daily) or a placebo. Eighty percent of patients treated with naltrexone had a 70-point decrease in Crohn’s Disease Activity Index (CDAI) score compared to 40% in the placebo group. Although promising, more extensive studies are needed before naltrexone can be recommended in patients with CD.

In MS, it is hypothesized that LDN reduces apoptosis in oligodendrocytes. A retrospective chart review of 215 patients’ charts found that almost 60% of the patients reported a reduction in fatigue, and 75% reported a subjective increase in quality of life. In addition, two placebo-controlled double-blinded crossover studies found significant effects on quality of life measures; however, a similar study from Iran found no effect.

A retrospective study was conducted that followed patients with relapsing–remitting MS on LDN versus placebo for 10 years and helped establish through serial MRIs and laboratory testing that LDN appeared to be nontoxic and safe in managing symptoms of MS without exacerbating the disease course. At this time, randomized clinical studies are needed to determine whether LDN has any beneficial effects in modifying the course of MS or not, but it may help reduce symptoms without causing significant deleterious effects.

A single 9-month randomized clinical trial compared the results of patients with AIDS on three antiretroviral treatments alone versus these three antiretrovirals plus LDN. This trial demonstrated that subjects randomized to treatment with LDN had a 37.06% higher recovery rate of CD4 count at 6 months (*p* = .041), and a 31.62% higher recovery rate of CD4 count at 9 months (*p* = .067) compared to placebo. Despite these promising results, further research is needed.

There is currently no FDA approval for this indication.

Anxiety and Depression

Currently, data on ultralow-dose naltrexone (ULDN) or LDN are scarce, but anecdotal evidence and clinical trials of LDN in different conditions have suggested beneficial mood effects. For instance, LDN reduces FM symptoms, many of which overlap with core symptoms of major depressive disorder (MDD). In cancer patients, naltrexone reduced depression-like side effects of treatment with interferon-α. In addition, preliminary evidence suggests that ULDN may prevent desensitization to D2/3 agonists, which may explain how ULDN, when combined with dopamine agonists in the treatment of restless leg syndrome, allows equivalent control of limb movements at half the last dose of D2/3 agonists.

In 2016, a small proof-of-concept randomized trial showed that in 12 depressed subjects who relapsed on prodopaminergic antidepressants, LDN reduced depression severity.

In 2018, a randomized clinical trial was conducted comparing the efficacy of XR-NTX versus buprenorphine–naloxone in alleviating symptoms of anxiety, depression, and insomnia among patients diagnosed with OUD. The study results demonstrated that both drug treatments were equally effective in reducing symptoms of anxiety and depression, but symptoms of insomnia were significantly further reduced by the XR-NTX treatment. In 2019, a meta-analysis of 26 studies demonstrated contradictory results, and naltrexone was found to have a higher risk of insomnia and somnolence than placebo.

A double-blind, placebo-controlled trial combining sertraline and naltrexone for the treatment of co-occurring depression and alcohol use disorder found that more patients taking the sertraline and naltrexone combination achieved abstinence from alcohol, delayed relapse to heavy drinking reported fewer serious adverse events, and tended not to be depressed by the end of treatment compared to placebo or either medication alone.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Although this section is explicitly written for naltrexone, the effects of nalmefene are similar except where noted.

Respiratory System

In opioid-dependent individuals, the administration of naltrexone has been shown to produce various nasal symptoms, such as nasal congestion, sneezing, rhinorrhea, sore throat, cough, and shortness of breath. In addition, in clinical trials with the injectable formulation Vivitrol, one diagnosed case and one suspected case of eosinophilic pneumonia were observed.

Heart

Naltrexone has increased blood pressure in opioid-dependent individuals, and it can also produce palpitations and tachycardia. Naltrexone has also been shown to decrease fibrinogen levels in opioid users.

Smooth Muscles

Naltrexone has produced muscle tension, tremors, and twitching in opioid-dependent subjects. In addition, incidences of back pain/stiffness, muscle cramps, and joint stiffness have also been reported with Vivitrol.

Liver

While naltrexone is not hepatotoxic when administered in the recommended dose of 50 mg/day, hepatotoxic potential has been documented for a sixfold higher dose of 300 mg/day in obese individuals and patients with Alzheimer disease. In an open-label safety study in which the typical dose was 50 mg, naltrexone was not associated with increased risk of hepatotoxicity in more than 500 alcohol-dependent patients treated for up to 12 weeks. However, in another trial, a daily dose of 100 mg was associated with a small but statistically significant increase in the number of patients who experienced elevated LFTs during 16 weeks. Thus, naltrexone is contraindicated in patients with acute hepatitis, liver failure, or significant liver disease. However, mild to moderate transaminase elevations associated with alcohol or drug use is not a contraindication. Similarly, XR-NTX is reported to have a lower likelihood of hepatotoxicity than previously suspected, even in individuals with HIV and HCV co-infection. Moreover, naltrexone has also shown some utility in the treatment of pruritus observed in cholestatic patients.

Endocrine System

Changes in baseline levels of some hypothalamic, pituitary, and gonadal hormones have been reported with naltrexone. In addition, naltrexone has been shown to produce significant increases in plasma luteinizing hormone (LH) and testosterone in opioid-dependent individuals and reverse heroin-induced decreases in such individuals. In healthy adult men, naltrexone has been shown to increase plasma prolactin, LH, testosterone, adrenocorticotropin (ACTH), and cortisol levels.

Studies have demonstrated that naltrexone has efficacy in treating different reproductive pathologic conditions, such as hypothalamic amenorrhea and polycystic ovary syndrome (PCOS). The studies note that the administration of naltrexone leads to the resumption of pulsatile gonadotropin secretion followed by restoration of menstrual cycles and pregnancies in patients with hypothalamic amenorrhea. In addition, pilot studies administering 50-mg daily naltrexone to women with PCOS and insulin resistance showed a dramatic decline in insulin levels after 3 to 7 weeks of treatment.

Gastrointestinal Symptoms

Abdominal pain and cramps have been documented following naltrexone administration in both opioid-dependent and nondependent individuals. Some individuals also report feeling nauseated or vomiting and suffering a loss of appetite and diarrhea or constipation. Naloxegol, methylnaltrexone, and naldemedin are peripherally acting μ-opioid receptor antagonists—PAMORA approved for opioid-induced constipation (OIC) in adults with chronic noncancer pain.

Carcinogenesis and Mutagenesis

Carcinogenicity studies with high doses in rats have documented a small increase in mesotheliomas and vascular tumors. No evidence of mutagenicity has been documented with naltrexone or nalmefene.

Pregnancy

Naltrexone, when administered at doses 140 times the therapeutic dose in humans, has been shown to decrease pregnancy rates in rats and to have an embryocidal effect in rats and rabbits. Doses of 100 mg per kg in rats and 60 mg per kg in rabbits have been shown to have similar effects. In preclinical studies, naltrexone has been shown to pass through the placenta to the fetus. There are no adequate or controlled studies of naltrexone in oral or injectable form in pregnant or nursing women. A 2017 retrospective cohort study compared the obstetric outcomes in women with OUD who were treated with either implant naltrexone, oral methadone, or sublingual buprenorphine. The study highlighted that rates of ectopic pregnancies in naltrexone-treated women occurred at more than four times the rates of the three other treatment groups. Similarly, preclinical reproduction studies with nalmefene indicate no evidence of impaired fertility or fetal harm. However, there are no adequate trials in pregnant women, and this drug should be used during pregnancy or in nursing women only if critically needed.

Genitourinary

Less than 10% of individuals have reported increased frequency of, or discomfort during, urination, increased frequency of erections, or altered sexual interest.

Psychiatric/Neurologic

Non–opioid-dependent individuals have reported feeling fatigued, tired, and listless following the administration of naltrexone. Some individuals have reported increasing irritability, restlessness, mental confusion, and slowing following naltrexone administration. Depression and dysphoria have been cited as adverse effects of naltrexone; however, a review of clinical studies concluded that naltrexone treatment does not produce dysphoria as a serious side effect. A recent meta-analysis of medications for alcohol use disorders found that both naltrexone and nalmefene have a higher risk of withdrawal due to adverse events like dizziness, nausea, and vomiting. However, the latter has a higher risk difference for incidence of dizziness than placebo and has higher rates of incidence of headache. In addition, substance users have an increased risk of suicide, and this risk is not reduced by naltrexone.

Skin/Local Injection Site

Vivitrol (XR-NTX) injections can result in pain, tenderness, induration, swelling, erythema, bruising, and pruritus at the injection site. Proper injection technique is essential as inadvertent SC administration may increase the likelihood of severe injection site reactions.

General Problems

Some individuals have also reported blurred eyes and increased light sensitivity, as well as tinnitus.

THERAPEUTIC INDICATIONS

FDA-approved indications for naltrexone include maintenance treatment for detoxified patients with OUD and preventing relapse in patients with alcohol use disorder. Naltrexone has established utility when combined with clonidine as part of outpatient detoxification protocols. An XR injectable formulation of naltrexone has been approved for maintenance treatment of both opioid and alcohol use disorder. In addition, a fixed-dose combination of NB in an XR formulation has been approved to treat obesity. In addition, the FDA has approved naloxone hydrochloride injection for opioid overdose reversal or suspected acute opioid overdose.

PRECAUTIONS AND ADVERSE REACTIONS

One of the most critical risks with this class of agents is the risk of precipitated withdrawal in those who have received high doses of opioids for therapeutic purposes or those who use opioids recreationally. As a result, patients should abstain from short-acting narcotics (e.g., heroin) for at least 5 to 7 days and from longer-acting opioids (e.g., methadone) for 10 days or more based on self-report and urine toxicology. Suppose there is a question of occult OUD in an individual who has a negative urine toxicology screen for opioids and is not showing signs of withdrawal. In that case, a naloxone challenge test is recommended: the patient receives an SC injection of up to 0.8-mg naloxone and is observed for withdrawal symptoms for 20 minutes. Otherwise, naltrexone is generally well tolerated, and most patients who do not react to a test dose of naloxone report no side effects. The profile of reported side effects has considerable similarity to the symptoms of opioid withdrawal and includes gastrointestinal distress (nausea, vomiting, diarrhea, and abdominal pain), anxiety and restlessness, dysphoria, mild hypertension, headache, and insomnia. These side effects are most prominent in the first several days of use and improve rapidly for patients remaining in treatment. However, a substantial minority of those with a diagnosis of OUD (5% to 10%) may refuse a second dose, and an additional 10% to 20% may discontinue medication in the first month of treatment, often citing continued discomfort reminiscent of opioid withdrawal throughout the first 1 to 3 weeks of treatment. Side effects can be minimized by ensuring an adequate interval between cessation of opioid use and initiation of naltrexone and by a graduated initial dose schedule starting with 12.5 or 25 mg daily for the first several days. A prior study that used naltrexone depot treatment showed that 32% of opioid-dependent patients discontinued treatment after the first injection. Six-month retention rates of oral naltrexone in opioid-dependent patients are generally less than 20% following induction. However, injectable naltrexone has been shown to have higher 6-month retention rates than placebo in a recent sizeable Russian study. Studies examining the medication refill persistence showed that injectable naltrexone is consistently associated with better adherence rates in alcohol-dependent patients than the oral agents.

Patients should be advised that taking large quantities of exogenous opioids to overcome the blockade provided by opioid antagonists can be extremely dangerous. Life-threatening opioid intoxication may result, including respiratory arrest or circulatory collapse. In addition, patients should be advised that once these agents are discontinued, they may be more sensitive to the effects of opioids due to loss of tolerance.

Nausea is the most common adverse reaction to naltrexone among alcohol-dependent patients. It can be mild or severe and typically occurs within 90 minutes of administration. In a large multisite safety study, side effects that occurred in more than 2% of patients included nausea (10%), headache (7%), dizziness (4%), nervousness (4%), fatigue (4%), insomnia (3%), vomiting (3%), anxiety (2%), and somnolence (2%). A similar side-effect profile was observed in a large clinical trial for alcohol use disorder with a 100-mg daily dose of naltrexone. The effect of naltrexone on acute alcohol withdrawal has not been investigated. The rate of early termination due to adverse events has been somewhat higher in studies in which naltrexone was administered to individuals with active alcohol use disorder. Women and younger patients appear to be at somewhat increased risk of side effects.

The potential for hepatotoxicity has been identified when naltrexone is administered at high doses. However, convincing reports of elevated LFT results have been limited to patients treated for eating disorders with doses of 250 to 300 mg daily, five to six times higher than the recommended maintenance dose for OUD. In a clinical trial of alcohol use disorder with a 100-mg/day dose, a 2% rate of increases in liver enzymes (aspartate or alanine aminotransferases) to greater than five times the upper limit of normal was observed; this increase resolved on discontinuation of naltrexone. Therefore, as a precaution, patients should receive a full battery of LFTs prior to receiving naltrexone, and naltrexone is contraindicated in patients with liver failure or acute hepatitis. The moderate transaminitis often seen in alcoholism and narcotic addiction is not a contraindication; however, baseline bilirubin, serum transaminases, and periodic monitoring of transaminases are indicated. If persistent elevations in liver enzymes occur, naltrexone should be discontinued. The possibility of medication noncompliance and continued alcohol or drug use should be ruled out when mild transaminase elevations (less than threefold) occur.

Because this class of agents is excreted through the kidneys and metabolized by the liver, caution should be used in patients with renal impairment or severe liver disease. Among patients with compensated and decompensated liver cirrhosis, a 5- to 10-fold increase in naltrexone levels has been found relative to individuals with normal liver function. The increased systemic availability of naltrexone, which is believed to be due to lower conversion rates of naltrexone to 6β-naltrexol, appears to be related to the severity of the liver disease.

Naltrexone has not been studied in pregnant or nursing women, and an embryocidal effect has been demonstrated in rats and rabbits when given a dose approximately 140 times the human recommended dose. As a result, naltrexone should be used during pregnancy only when the potential benefit outweighs the potential risks to the fetus. Similarly, there are no studies of nalmefene in pregnant women, and hence this agent should be used in pregnant women only when needed.

DRUG INTERACTIONS

Because naltrexone and nalmefene are opioid antagonists, they block the pain-relieving effects of opioid analgesics. Therefore, in patients maintained on these agents, nonopioid pain medications or approaches should be tried first when possible. For elective surgery, cessation of oral naltrexone treatment 72 hours prior to surgery is recommended. Naltrexone does not reverse the effects of nerve root blocks or spinal anesthesia and does not antagonize agents used for general anesthesia. IV nalmefene can be used to reverse respiratory depression produced by these agents without blocking the analgesic effects of subsequently administered opioids. In patients treated with opioid antagonists, if opioid medications are necessary to treat severe pain, the blockade can be overridden with a rapidly acting analgesic. However, treatment requires close monitoring in a setting equipped and staffed for cardiopulmonary resuscitation because the resulting respiratory depression may be deep and prolonged. Patients should be given a card identifying that they are on naltrexone to alert medical personnel in an emergency.

Recent trials of alcohol use disorder have combined naltrexone and disulfiram without any significant increase in adverse effects or hepatic dysfunction, and some clinicians use the two drugs concomitantly for brief periods. However, given the potential for hepatotoxicity with both these agents, frequent monitoring of hepatic function is recommended. Although formal drug interaction studies have not been conducted with antidepressant medications, the incidence of adverse events reported by patients who started naltrexone while ongoing antidepressant therapy was similar to that of patients receiving naltrexone only in a large safety study. However, simultaneous initiation of antidepressant therapy and naltrexone has resulted in higher rates of nausea than using naltrexone alone. In addition, increased lethargy and somnolence have been reported with the combined use of naltrexone and thioridazine. Combined use of high-dose naltrexone (e.g., 250 mg daily) with nonsteroidal anti-inflammatory agents (ibuprofen, aspirin) may be associated with elevations in LFTs.

IV nalmefene has been administered after benzodiazepines, inhalational anesthetics, muscle relaxants, and muscle relaxant antagonists administered in conjunction with general anesthetics without any adverse reactions. However, care should be taken when using flumazenil and nalmefene together, as both agents have induced seizures in preclinical studies.

LABORATORY INTERFERENCES

Thin-layer, gas–liquid, and high-pressure liquid chromatographic methods used to detect opioids in the urine do not interfere with naltrexone. However, the potential for false-positive urine for opioids using less specific urine screens such as enzyme multiplied immunoassay technique (EMIT) may exist, given that naltrexone and nalmefene are derivatives of oxymorphone.

DOSAGE AND ADMINISTRATION

Oral naltrexone is prepared in scored, 50-mg, capsule-shaped tablets. The recommended dose for adults is 50 mg/day for alcohol use disorder and maintenance of abstinence from opioids. Lower initial doses can be considered over the first few days for patients at increased risk of adverse effects, with the dose increased as tolerated. In a large multisite study of alcoholism treatment, effect sizes for the 100-mg dose (compared to placebo) were not larger than those observed in earlier studies with a 50-mg daily dose. Morning administration is recommended for improved medication compliance.

Although daily oral administration is effective for treating alcohol use disorder, there is some evidence that targeting naltrexone use to the days when drinking is anticipated may also be helpful for some patients. The injectable formulation Vivitrol is available in single-use kits that contain 380 mg of Vivitrol microspheres and a diluent. The microspheres must be suspended in the provided diluent before administration and administered as an IM gluteal injection once every 4 weeks or once a month.

Naltrexone should not be administered until there is no reasonable possibility of opioid use within the past 7 to 10 days or unless the patient has completed detoxification and abstinence has been verified with urine testing for opioids. If there is a question about continued opioid use, opioid-free status should be confirmed by a negative response to an IM naloxone test dose of 0.8 mg. If substantial opioid withdrawal symptoms do emerge, initiation of naltrexone should be delayed at least 1 additional day.

Nalmefene is available as a sterile solution for IV, IM, and SC administration in two concentrations, containing 100 µg/mL or 1.0 mg/mL of nalmefene. The dose of this agent is titrated to achieve the desired reversal of the opioid effects. The oral form of nalmefene is not available in the United States. Naloxone hydrochloride injection is available to be administered intravenously, intramuscularly, or subcutaneously. An initial dose of 0.4 to 2 mg can be administered in adults and may be repeated at 2- to 3-minute intervals to reverse opioid effects. If a reversal is not achieved after administering 10 mg of naloxone, the diagnosis of opioid overdose should be questioned. Although it is not yet FDA approved, naloxone hydrochloride is also available in IN preparations for opioid overdose reversal.

INVESTIGATIONAL DRUGS

Naltrexone and nalmefene are nonspecific opioid antagonists that have been shown to dose-dependently bind to all three types of opioid receptors. The highest antagonistic potency is at the μ-receptor, which is 5 to 10 times greater than that at the δ-receptor and 13 to 33 times greater than that at the κ-receptor. In addition, opioid antagonists with a specific affinity of specific opioid receptor types have been developed, which have enormous use as selective tools to identify specific receptor types involved in specific pharmacologic endpoints. Most of the new specific opioid antagonists are nonpeptides that can easily penetrate the blood–brain barrier and, therefore, be administered via peripheral routes. All of these are investigational and remain in the different phases of drug testing.

33.13b Disulfiram and Acamprosate

KATHERINE S. PIER, M.D.

DISULFIRAM

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Alcohol
Mechanism of Action	Enzyme inhibitor (mainly liver)

History

In 1937, Dr. E. E. Williams, a rubber company's family physician, serendipitously discovered disulfiram (DSF) for medical use. Dr. Williams observed that workers in the vulcanized rubber industry exposed to tetraethylthiuram disulfide became physically ill after alcohol consumption. The tetraethyl analog of the vulcanization chemical had also been used topically since 1942 to treat scabies. In 1945, while investigating this chemical to treat parasitic stomach infections, Erik Jacobsen and Jens Hald tested the compound on themselves, only to become ill after drinking alcohol. They observed and reported symptoms such as nausea, vomiting, facial flushing, headache, and dizziness. Two years later, they collaborated with Dr. Oluf Martensen-Larsen and designed a study for DSF as a treatment for alcohol dependence. In 1951, it became the first medication approved by the Food and Drug Administration (FDA) for that indication.

Over the years, it has been recognized that the very same properties that constitute DSF's main therapeutic effect (i.e., the ability to produce unpleasant symptoms after alcohol intake, also known as a DSF–alcohol reaction) may also have potentially dangerous consequences. These are frequently related but not limited to dehydration and electrolyte imbalance secondary to vomiting, a symptom of the DSF–alcohol reaction. In the most severe cases, serious clinical conditions such as respiratory depression, myocardial infarction, arrhythmias, heart failure, seizure, loss of consciousness, and death have been documented. These potential complications and the more recent development of alternative alcohol use disorder medications have limited some of DSF's initial popularity.

Chemistry

DSF, when it is in its pure state, is a white to off-white, odorless, almost tasteless powder soluble in water and alcohol. Its chemical name is bis(diethylthiocarbamoyl) disulfide; its structural formula is shown in Figure 33.13b–1.

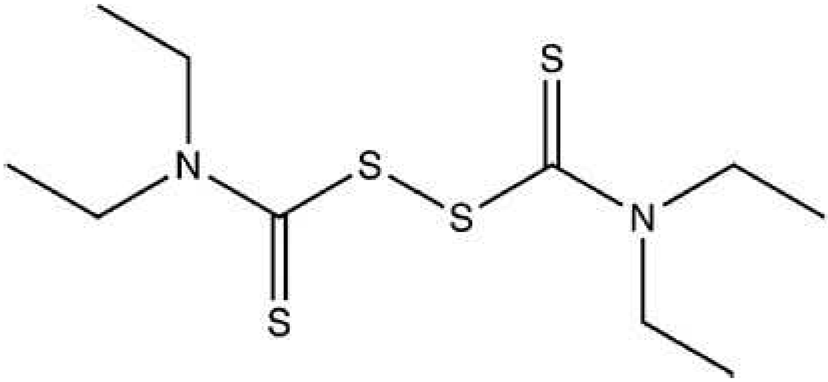

FIGURE 33.13b–1. Chemical structure of disulfiram.

Pharmacologic Actions

Pharmacokinetics

ABSORPTION. After ingestion, DSF rapidly converts to its diethyldithiocarbamate (DDC) copper complex. Subsequent absorption and distribution via the gastrointestinal (GI) mucosa into the bloodstream involve both the parent drug and the DDC copper complex. Absorption of DSF from the GI tract is rapid but incomplete (e.g., approximately 80% to 95% is absorbed through the GI tract). The concentration of DSF's active metabolite diethylthiocarbaminic acid methyl ester (Me-DTC) reaches its plasma peak about 4 hours after absorption. It is hypothesized that DSF tablets may be more bioavailable when taken with food. It can be crushed and mixed with water, coffee, tea, milk, soft drinks, or fruit juice.

DISTRIBUTION. Because of its high lipid solubility, DSF is widely distributed and accumulates in various fat deposits. Its safety during pregnancy has not been established, and it is labeled a Class C drug. In experimental animals, administration of DSF with ethanol potentiates the embryotoxic effects of ethanol. It is not clear whether the same potentiation occurs in humans. There are several case reports of normal pregnancy outcomes in humans exposed to DSF without exposure to ethanol. It is not known whether it is excreted in breast milk.

METABOLISM AND ELIMINATION. Due to partial absorption, approximately 5% to 20% of DSF is excreted in the feces. In the blood, DSF is rapidly metabolized to DDC, which is partly excreted as carbon disulfide in the expired air and is partly metabolized in the liver to diethyldithiomethylcarbamate (Me-DDC). Further metabolic changes result in the formation of the active metabolite Me-DTC. This metabolic cascade is not appreciably affected by a mild to moderate decrease in hepatic function. DSF's metabolites are chiefly excreted in the urine, and a part is expired as carbon disulfide. Overall, elimination of DSF is slow, and up to 20% of a single dose may remain in the body for 7 days or more.

Pharmacodynamics

MECHANISM OF ACTION. DSF is a prodrug. It has been shown to inhibit the hepatic enzyme aldehyde dehydrogenase (ALDH) in vitro.

However, in vivo, the drug is too short lived to inhibit the enzyme directly. The net effect of irreversible inhibition of ALDH is achieved by DSF's active metabolite Me-DTC.

The pharmacologic action of DSF and its metabolites is based on inhibiting enzymes involved in ethanol catabolism. DSF is a sulfhydryl (-SH, thiol) group reagent and inhibits enzymes concerned with oxidation of active (-SH group) sites on enzymes' protein molecules. Normally, ethanol is metabolized to carbon dioxide and water, but in the presence of DSF, the metabolic chain of reactions stops after the production of acetaldehyde, leading to the accumulation of this substance. The acetaldehyde concentration in the blood may increase 5 to 10 times more than without DSF. Acetaldehyde is an important factor for developing a DSF–alcohol reaction, which occurs within 10 to 30 minutes after the ingestion of alcohol. The clinical picture of the DSF–alcohol reaction includes several unpleasant symptoms: intense flushing of the face, a feeling of difficulty in breathing, palpitations, a throbbing headache, nausea, and vomiting. Ingestion of large amounts of alcohol may cause a significant fall in blood pressure, resulting in fainting and the risk of cardiovascular shock.

Re-establishment of the ALDH enzymatic activity depends on new synthesis, which occurs gradually for up to 2 weeks. Although the plasma half-life of DSF's active metabolite Me-DTC is about 10 hours, its inhibiting effect on ALDH may last considerably longer, persisting for 7 to 14 days after discontinuation. Prolonged use of DSF does not result in the development of tolerance; conversely, it has been shown to produce heightened sensitivity to alcohol.

In addition to its effect on ALDH, DSF and some of its metabolites (e.g., DDC) also inhibit the enzyme dopamine-beta-hydroxylase (DBH), thus reducing the synthesis of noradrenaline. This mechanism is suggested to play a role in the DSF–alcohol reaction. DSF also diffuses readily into cells and raises intracellular -SH levels; therefore, it can affect intracellular oxidation reactions. Notably, DSF has been shown to inhibit the enzymes xanthine oxidase and succinoxidase. DSF also possesses antithyroid properties as it reacts with free iodine to form a stable molecular complex.

BLOOD CONCENTRATIONS AND RELATION TO ACTION. Plasma concentrations of DSF may vary between individuals due to several factors, most notably age and hepatic function. In general, the severity of the DSF–alcohol reaction is proportional to the amount of the ingested DSF and alcohol. However, DSF plasma levels are rarely utilized in clinical practice. Mild effects may occur at blood alcohol concentrations of 5 to 10 mg per 100 mL. Symptoms will fully develop when alcohol levels reach 50 mg per 100 mL. Unconsciousness may occur when alcohol levels reach 125 to 150 mg per 100 mL.

Design and Interpretation of Clinical Drug Studies

To date, the Veterans Administration Cooperative Study remains the largest DSF treatment study, conducted in a cohort of 605 males diagnosed with alcoholism. Participants were randomly assigned to three treatment arms: 202 received DSF 250 mg daily, 204 were administered DSF 1 mg daily, and 199 were prescribed riboflavin. After 1 year of treatment, there was no difference in the percentage of patients from the three groups in terms of total abstinence, time to first drink, employment, or social stability. There was a significant relationship between adherence to drug regimens and complete abstinence. Among those who did drink, those in the DSF 250 mg group reported significantly fewer drinking days. Also, in the subpopulation of patients who attended all the scheduled follow-up research appointments, treatment with DSF 250 mg daily significantly decreased drinking days compared to low-dose DSF and riboflavin. In this large trial, adherence to the study medication was a notable barrier, with only 19% of patients taking DSF consistently. Ultimately, the study suggested that DSF was unlikely to be necessary for subjects who went on to achieve total abstinence but may be helpful in older males, who were socially stable, who relapse in terms of reducing the number of relapse days.

The first systematic meta-analysis of DSF's effectiveness was published in 2011. Eleven randomized controlled trials were included with a total of 1,527 patients. Studies were included from 1979 to 2010 in India, Denmark, the United States, Austria, Finland, and Italy. This review concluded that DSF had some short-term clinical benefits, including short-term abstinence, a fewer number of drinking days, and prolonged days until relapse. However, possible confounds were related to the fact that five of the six efficacious studies also had supervised DSF administration and that all studies were short-term treatment protocols. Others have pointed to possible selection bias since the authors included one nonefficacy study while five eligible trials were absent.

Moreover, the meta-analysis above utilized both open and blind studies. This issue was addressed by a second meta-analysis that compared blind versus open-label studies of DSF. The analysis, which included 2,414 participants from 22 studies, showed no difference between DSF and control groups when open studies were included. The authors explained this finding on the premise that the clinical effect of DSF is directly proportional to the expectation of a DSF–alcohol reaction, meaning a blinded placebo group has the same psychological threat as the treatment arm. Moreover, they point out that even in a blinded trial, the participants can unmask themselves easily with minimal alcohol. When analyzing data from only open-label studies, they found DSF had a significant effect size and, in fact, a greater one than naltrexone, acamprosate, and control group treatment conditions. Finally, the meta-analysis found that in randomized controlled trials where DSF administration was supervised, DSF performed significantly better than controls, while in unsupervised studies, DSF was not superior to controls on the main outcome.

There are no randomized controlled studies on long-term supervised DSF administration, and there have not been randomized controlled trials. One study, the Outpatient Long-Term Intensive Therapy for Alcoholics (OLITA), integrated supervised DSF administration into a 2-year comprehensive biopsychosocial approach to addiction treatment and achieved a 52% cumulative 9-

year abstinence rate. This does not isolate the effects of DSF from the effects of the psychosocial treatment but provides a model in which supervised DSF over 2 years may have contributed to long-term abstinence in some individuals.

By expert consensus, optimal DSF response is achieved when treatment is conducted in a specialized facility for substance use disorders (SUDs). Aspects of care that can increase DSF efficacy by adhering include using incentives, contracting with the patient and a significant other, providing regular reminders, patient behavioral training, and social support networks. The need for adherence and supervised administration of this medication provides some framework to understand that DSF has documented superior efficacy over placebo in treating alcohol use disorders in adolescents or in combination with spouse-observed administration. This also helps conceptualize why court-ordered DSF therapy promotes efficacy by increasing adherence to the regimen. Additional research indicates that, generally, older men involved in a structured social network like alcoholics anonymous (AA) are more likely to remain compliant to treatment regimens and thus, derive clinical benefit.

Spousal administration of DSF can be advantageous in increasing adherence to the treatment. Several studies have documented the benefit of behavioral marital therapy as an adjunct to DSF treatment. A pivotal component in this form of combined therapy is the DSF contract—a time-limited, renewable agreement by the couple to practice a behavioral interaction of observed DSF administration daily. It is believed that the contract aims to increase patient adherence to the medicine on an individual level. On the couple's level, the goal is to restructure the relationship dynamics of early sobriety behaviorally, often characterized by negative emotions like distrust, shame, and occasionally violence. Several trials have evaluated the efficacy of this approach as the couples received the combined treatment for periods of 10 to 24 weeks and were followed as long as 104 weeks after that. Overall, the combined treatment has produced greater DSF adherence, better drinking outcomes, higher marital satisfaction, and less domestic violence.

There are few comparisons between DSF and the other FDA-approved medications for the treatment of alcoholism, naltrexone, and acamprosate. Some of these trials are also confounded by the effects of frequent supervision for that administered DSF, which is not the case for those administered the other pharmacotherapies.

One randomized, open-label trial aimed to compare the effects in alcohol-dependent patients of three pharmacotherapies: DSF, naltrexone, and acamprosate. It included 243 voluntary treatment-seeking alcohol-dependent adult outpatients. It had two phases: a 12-week continuously supervised medication phase, followed by up to a year of unsupervised medication. Participants were followed for up to 2.5 years. All treatment arms included a brief manual-based cognitive behavioral therapy. The investigators found that all three medication interventions demonstrated a reduction in drinking from baseline to the end of the study. DSF was significantly superior to the other two agents (i.e., naltrexone and acamprosate) during the phase of supervised treatment; it demonstrated a greater reduction in heavy drinking days, reduction in weekly consumption, and increased abstinence days, and an increased time to the first drink. During the unsupervised period of the study, there were no significant differences between the groups in the heavy drinking days or time to first drink, although DSF displayed a significantly greater efficacy in the number of abstinence days.

Another study analyzed retrospectively collected data from 2002 to 2007 of 353 alcohol-dependent individuals in Germany and attempted to understand the relative efficacy of acamprosate and DSF. On the last week of 3-week inpatient detoxification, medical providers and patients mutually selected patients to be started on DSF versus acamprosate. Those receiving DSF were required to attend outpatient appointments three times weekly for supervised DSF, while those receiving acamprosate were required to attend a one-time, weekly appointment without the supervision of acamprosate administration. Abstinence was assessed using a breathalyzer, self-report, the reports of patients’ loved ones, urine and serum assays, and physician assessment.

Time before the first alcohol relapse, attendance in outpatient treatment, and cumulative alcohol abstinence achieved during a 12-month period were significantly higher in the DSF group. A longer duration of alcohol dependence predicted favorable treatment outcomes in the DSF group, while for the acamprosate group, the chances for a successful treatment increased with a shorter duration of alcohol dependence. The study has numerous limitations and confounding factors limiting the ability to draw true comparisons between acamprosate and DSF. That being said, the study provided a model wherein supervised DSF administration three times weekly contributed significantly to cumulative abstinence, adherence to outpatient treatment, and increased time to first relapse in patients with severe alcohol dependence compared to another treatment.

Efficacy of DSF has also been studied in individuals with addiction and co-occurring psychiatric disorders, including major depression, post-traumatic stress disorder (PTSD), bipolar disorder, schizophrenia, and schizoaffective disorder. One study enrolled 254 patients with alcoholism and a co-occurring Axis I disorder and randomized participants into four groups: (1) naltrexone alone, (2) placebo alone, (3) DSF and naltrexone, and (4) DSF and placebo. There was open randomization to DSF or no DSF and double-blind randomization to naltrexone or placebo. All patients were treated for 12 weeks in an outpatient setting. Participants treated with DSF or naltrexone as compared to placebo had significantly more consecutive weeks of abstinence and less craving than those treated with placebo, but there were no significant group differences in other measures of alcohol consumption (percent of days abstinent, percent of heavy drinking days, achieving total abstinence). There was no advantage to the combination of both medications. The study found that in subjects who chose DSF, medication adherence rates were as high as with naltrexone. Surprisingly, DSF-treated subjects reported lower levels of a craving than the naltrexone-treated subjects. Of interest, subjects taking any medication reported lower rates of paranoid ideation compared to placebo, contradicting other reports that DSF can actually precipitate psychosis.

DSF may be more effective in promoting short-term abstinence and treatment retention after detoxification than long-term relapse prevention. As such, some have suggested that this medication be solely used to assist in the initial period of abstinence to facilitate the client's involvement in psychosocial interventions. Because of the severe adverse effects of DSF in the event of relapse and some of the side effects of DSF itself, it has largely fallen out of favor in the United States. In general, DSF is considered an inappropriate treatment option for patients with severely impaired judgment, significant cognitive impairment, or those who are highly impulsive.

Effects on Specific Organs and Systems

Deaths from DSF treatment have become rare due to treatment with lower dosages and excluding patients with significant cardiac disease. DSF has a black box warning to never administer to a patient in a state of alcohol intoxication or without the patient's full knowledge.

GI and nervous system adverse effects can be prominent. DSF has been associated with hepatotoxicity. The symptoms of hepatotoxicity may be mild and reversible (e.g., jaundice, cholestasis, and altered liver function tests) or more serious and include acute hepatitis, hepatic necrosis, and liver failure, requiring transplantation. These effects may occur after many months of DSF treatment and have been documented in both individuals with and without prior history of abnormal liver function. Estimates of DSF-induced hepatitis are between 1 in 25,000 and 1 in 30,000 patients treated yearly.

DSF's effects on the nervous system may involve optic neuritis, resulting in eye pain or tenderness and vision changes, as well as peripheral neuropathy (i.e., paresthesias—numbness, tingling, pain, or weakness in hands or feet). The latter is mainly reported in patients on a relatively high dose of DSF (e.g., 500 mg daily). Peripheral neuropathy tends to improve with the discontinuation of DSF treatment. More rare side effects include the antithyroid effect of

DSF and skin eruptions that are usually controlled with antihistamine treatment.

Severe reactions (when DSF is used at very high doses or in individuals with cardiovascular disease) can include **myocardial infarction, cardiac arrhythmias, and congestive heart failure (CHF)**.

Therapeutic Indications

Alcohol Use Disorder. In clinical practice, DSF is recommended to aid in managing selected patients with alcohol use disorder. Selected patients should be highly motivated to maintain a state of sobriety. The agent has little effect on long-term drinking patterns once it is discontinued. It is most appropriate and efficacious in the short term after detoxification to assist in the initial period of abstinence to facilitate the client’s involvement in psychosocial interventions, including psychotherapy. Optimum response to DSF seems to be achieved in facilities specializing in treating SUDs.

The DSF–ethanol reaction is an aversive physiologic state that functions through negative reinforcement and behavioral counterconditioning to extinguish an unwanted behavior (alcohol consumption). When an individual takes this medication, they acknowledge that possible alcohol consumption will entail a severe adverse reaction, and this knowledge is the motivation for abstinence. Baseline blood tests include blood alcohol or breathalyzer (to confirm abstinence), liver function tests, a complete blood count, serum chemistries including blood urea nitrogen (BUN) and creatinine, and a pregnancy test. Follow-up liver function tests are recommended 10 to 14 days after therapy initiation, then monthly for 6 months, to monitor for possible hepatic dysfunction. After the first 6 months, liver function testing should be obtained every 3 months. Monthly pregnancy tests are indicated for women of childbearing age. An ECG should be obtained at baseline if clinically indicated in people with heart disease.

DSF should be prescribed for individuals abstaining from alcohol for at least 12 hours. On occasions, patients who appear to be on an adequate maintenance dose of DSF may report that they can consume alcohol without any negative reactions. In such cases, the physician should presume that patient’s compliance with the treatment has been compromised. Before the patient is observed to reliably administer the medicine (preferably crushed and mixed with water), it may not be concluded that DSF is ineffective.

Disulfiram Test Reaction. During the earlier use of DSF, it was thought advisable to have patients experience at least one supervised DSF–alcohol reaction, a so-called “alcohol challenge.” This practice is currently not recommended; moreover, it should never be considered for patients over the age of 50 years. It is believed that a clear, convincing, and detailed description of the DSF–alcohol reaction is considered sufficient.

Management of Disulfiram–Alcohol Reaction. The DSF–alcohol reaction is diagnosed when a patient with a history of DSF use and possible exposure to ethanol presents with symptoms of the characteristic hypotensive flushing reaction. Blood DSF levels are not of value in diagnosis or treatment. Blood acetaldehyde levels may be elevated during the DSF–ethanol reaction, but this information is of little value in acute management. In a severe reaction, all measures should be taken to stabilize the patient’s respiratory and cardiovascular systems. This may include supplemental oxygen, intubation, intravenous (IV) fluids, and/or pressor agents. Other interventions include IV use of vitamin C, ephedrine sulfate, and antihistamines. Since hypokalemia has been reported, potassium levels should be monitored, particularly in patients treated with digitalis. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, liver aminotransferases, and ethanol level. Some protocols include treating vomiting with metoclopramide. There is no specific antidote. A case series found that IV fomepizole safely and rapidly reversed vasodilation and toxicity related to alcohol ingestion with DSF.

Management of Disulfiram Overdose (Without Alcohol). DSF overdose (without alcohol ingestion) is rare, and its clinical presentation is one of the neurologic adverse effects of the medication: confusion, lethargy, headache, ataxia, seizures, and coma. Brain lesions in the basal ganglia have also been reported. Patients may also have a garlic-like breath odor, vomiting, and hypotension. The diagnosis of overdose is made based on history and presenting symptoms. In some circumstances, activated charcoal may be clinically indicated. The treatment is focused on maintaining a patent airway, stabilizing the cardiovascular system, and treating seizures.

Other Disorders. There is evidence that DSF could be efficacious for cocaine use disorder alone, co-occurring cocaine and alcohol use disorders, and cocaine and opioid use disorders. Initial research into DSF for cocaine addiction emerged based on evidence that alcohol and cocaine are often co-ingested. Researchers hypothesized that withholding alcohol from cocaine users through DSF administration would reduce cocaine use, which was found to be true in one initial study from 1993. A subsequent randomized 12-week pilot trial compared the effects of DSF administration to the effects of naltrexone. Both treatments were accompanied by cognitive behavioral therapy (CBT). DSF proved more effective than naltrexone at lowering the frequency of cocaine use. In a larger clinical trial, DSF treatment improved abstinence from cocaine compared to no treatment; DSF treatment in this larger trial appeared more effective for those outpatients who also received CBT. The beneficial effect of DSF on cocaine use was still evident a year later in a follow-up study.

Subsequent trials assessed the effects of DSF on cocaine in patients who were addicted to both cocaine and opioids and were maintained on methadone or buprenorphine. Those treated with DSF were better able to reduce their alcohol, cocaine, and opioid intake. DSF shortened the time necessary for patients to reach continuous cocaine, but not heroin abstinence. In these trials, alcohol consumption was minimal for all subjects, and baseline alcohol use did not predict responses to DSF. A 2004 randomized, placebo-controlled trial investigated cocaine use with and without concurrent alcohol use disorders, showing that the benefits of DSF therapy were most pronounced in patients who either were not alcohol dependent at baseline or who fully abstained from alcohol during treatment.

Whereas ALDH is the primary target in treating alcoholism, human laboratory, genetic, and preclinical animal studies indicate that its beneficial effects on cocaine use result from the inhibition of DBH, resulting in increased dopamine activity in the synaptic cleft. Given that cocaine also increases dopamine levels by blocking the reuptake of the dopamine transporter, the combination may produce a state of hyperstimulation, causing discomfort and aversion. In laboratory studies, people experiencing a DSF–cocaine interaction demonstrated increased heart rate and blood pressure and reported anxiety, paranoia, and restlessness.

People with low levels of the enzyme DBH have increased dopamine activity and tend to be more responsive to DSF. Hormones, as well as genes, may influence DBH levels. Researchers suspect that estrogen hormones increase DBH, attenuating the effect of DSF, which could explain why women seem to benefit less than men. A recent study showed that patients with genetically higher dopamine transporter levels had better treatment outcomes with DSF pharmacotherapy of cocaine dependence than those with lower DAT levels.

A 2010 Cochrane review included seven controlled studies with 492 participants receiving DSF, a placebo, no pharmacologic treatment, or naltrexone in addition to psychosocial treatment. One out of four studies comparing DSF to placebo found that DSF significantly affected the number of weeks of cocaine abstinence compared to placebo. Another study found DSF significantly affected maximum weeks of consecutive abstinence and the number of people achieving 3 or more weeks of consecutive abstinence compared to no treatment. Ultimately, the authors concluded that the evidence for DSF for cocaine dependence was low and warranted further randomized controlled trials.

The review showed “low evidence” in support of DSF for the treatment of cocaine dependence. Current investigations are examining safety profiles for the combination of DSF with alcohol and cocaine.

Starting in the 1970s, evidence accumulated that DSF had anticancer properties both through its direct actions and by reversing resistance to chemotherapeutic drugs. Its antitumor effect has been reported in many preclinical studies and on seven types of cancer in humans: non–small-cell lung cancer (NSCLC), liver cancer, breast cancer, prostate cancer, pancreatic cancer, glioblastoma multiforme (GBM), and melanoma. The mechanisms, particularly the intracellular signaling pathways, have yet to be fully elucidated.

Studies have found that DSF inhibits NF-kB signaling, proteasome activity, and ALDH activity. It induces endoplasmic reticulum (ER) stress and autophagy and has been used as an adjuvant therapy with irradiation or chemotherapy drugs. DSF kills the normal cancer cells and can target cancer stem cells, providing a new approach to preventing tumor recurrence and metastasis. Furthermore, other researchers have reported the ability of DSF to bind to nuclear protein localization protein 4 (NPL4), inducing its immobilization and dysfunction, ultimately leading to cell death.

Using Denmark’s cancer registry, examining more than 240,000 cases diagnosed between 2000 and 2013, along with data on the medications each patient took, a population-based cohort study found that of more than 3,000 patients taking DSF, the cancer death rate was 34% lower for the 1,177 patients who stayed on the drug compared to those who stopped taking it. Its benefits are held for prostate, breast, and colon cancer, as well as cancer overall. Studies have revealed that treatment with DSF and chemotherapy extends the lives of patients with metastatic breast and colon cancers. It has also been shown to slow the progression of small-cell lung cancer and GBM in small trials.

Cancer research into DSF’s mechanism has revealed that it may have anti-inflammatory properties more broadly by inhibiting nuclear factor-κB (NF-κB). Other research has also demonstrated that DSF can regulate FOXO1, leading to impaired hepatic gluconeogenesis, suggesting it may be involved in the hepatic regulation of metabolic function. Recent research has sought to investigate whether these properties of DSF might hold promise in treating obesity and metabolic syndromes. One study found that in mice fed high-fat diets, those treated with DSF had a 40% decrease in body weight and an increase in energy expenditure without a significant change in diet. DSF improved glucose tolerance and insulin sensitivity while preventing fibrosis and steatosis of the liver and hypertrophy of pancreatic islet cells. A follow-up study found that in cell culture, DSF was a potent activator of autophagy as well. While there have not been studies on the metabolic effects of DSF in humans yet, DSF may hold promise for treating human obesity and its metabolic sequelae.

Precautions and Adverse Reactions

Precautions. All patients prescribed DSF should be fully informed of the DSF–ethanol reaction and cautioned against the possible consequences of taking alcohol either surreptitiously or unwittingly. Patients receiving DSF should be strongly advised not to use any alcohol-containing preparations, for example, certain cough syrups, sauces, vinegar, tonics, foods prepared with wine, and should avoid the use of aftershave lotions and moisturizers containing alcohol. In addition, patients should be advised to obtain and carry an identification card describing the symptoms of DSF–alcohol reaction and containing contact information in emergency cases. DSF should not be coadministered with paraldehyde or metronidazole.

Candidates for DSF should be evaluated for hypersensitivity to other thiuram derivatives used in pesticides and rubber vulcanization. Concurrent conditions such as severe myocardial disease or ischemic heart disease, pregnancy, advanced hepatic and renal disease, psychotic states, and serious organic brain damage are contraindications of the use of DSF.

Adverse Reactions. The most common side effects associated with DSF include drowsiness, headache, fatigue, allergic dermatitis, stomach upset, dizziness, acneiform eruptions, halitosis, and impotence. A metallic or garlic-like aftertaste has been reported during the first 2 weeks of therapy. These complaints disappear spontaneously or by reducing the dosage.

Sensorimotor peripheral neuropathy, frequently associated with combined treatment with metronidazole or isoniazid, may present with numbness, tingling, pain, or weakness in hands or feet. In addition, symptoms of optic neuritis may occur, indicated by eye pain and vision changes. Most of these symptoms improve when DSF is discontinued.

More serious but rare side effects include DSF-induced hepatitis, with an incidence between 1 in 25,000 and 1 in 30,000 patient-years of treatment. Varying degrees of hepatotoxicity have been reported, including altered liver function tests, jaundice, and hepatic necrosis. Psychiatric side effects like mood liability and mental status changes have also been reported with the administration of DSF. DSF may also block DBH and increase dopamine concentrations, contributing to psychosis, particularly in patients with pre-existing psychotic disorders.

Drug Interactions

Concomitant ingestion of antacids containing divalent cations and large doses of ferrous salts may reduce the absorption of DSF. Other clinically salient drug–drug interactions of DSF may occur through several separate physiologic mechanisms (i.e., inhibition of hepatic enzymes). For instance, DSF may affect the metabolic rate of other drugs, in particular phenytoin and theophylline. The concomitant use of DSF with either of these two agents should be used with caution since it may result in elevated phenytoin or theophylline plasma level and possibly lead to phenytoin or theophylline toxicity. It is recommended that baseline phenytoin and theophylline levels be obtained before the initiation of DSF with subsequent regular monitoring of phenytoin and theophylline levels.

DSF may prolong prothrombin time when coadministered with oral anticoagulants (e.g., warfarin), as DSF inhibits warfarin’s metabolism, and regular assessments of anticoagulation profiles are recommended.

Another clinical interaction with a less understood mechanism occurs between isoniazid and DSF. Their coadministration may cause ataxia and even mental status changes, which usually resolve after discontinuation of DSF. Another antituberculosis agent, rifampin, also interacts with DSF, resulting in inhibition of rifampin's oxidation and renal excretion. Mental status changes (e.g., psychosis and confusion) have also been demonstrated with concurrent use of metronidazole.

DSF can differentially potentiate and prolong benzodiazepines' suppressing effect on the CNS—for instance, this effect is pronounced with coadministration of chlordiazepoxide and diazepam but not seen with oxazepam or lorazepam.

Animal research has documented that in the GI tract, DSF may interact with nitrates and form nitrosamine in the GI tract, which has been shown to cause stomach tumors. The toxicity of certain centrally acting drugs (e.g., morphine, pethidine, amphetamine, and barbiturates) has been potentiated by DSF in rats; however, the importance of this observation for humans is unclear.

Laboratory Interference

DSF is not known to interfere with any laboratory tests.

Dosage and Administration

Dosing for the first 1 to 2 weeks is 250 mg in the morning or the evening (based on whether the patient has sedation). The average maintenance dose is 250 mg daily, ranging from 125 to 500 mg. The dose of DSF should never exceed 500 mg per day.

The duration of DSF therapy should be determined on an individual basis.

Administration. DSF should be taken preferably upon waking in the morning, although in patients who experience a sedating effect, it may be taken at bedtime.

ACAMPROSATE

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Glutamate
Mechanism of Action	Yet to be determined

History

Acamprosate was developed in response to a growing literature demonstrating that chronic alcohol consumption and withdrawal fundamentally change neurochemistry and electrophysiology, thought to underlie some of the difficulty achieving initial abstinence from alcohol and regaining abstinence after relapse. Over 30 years ago in Europe, various pharmaceutical companies started synthesizing amino acid neuromediators, hoping to ameliorate the hyperglutamatergic state resulting from protracted alcohol use. In collaboration with several universities in France, pharmaceutical companies investigated several taurine and homotaurine compounds in the 1980s. An animal model of alcohol relapse conducted at the University of Rouen in France supported the utility of calcium acetyl-homotaurinate in reducing alcohol consumption in dependent rats. This initial preclinical trial was again validated in another animal model, which revealed a significant reduction in voluntary alcohol consumption.

These preclinical studies catalyzed the first multicenter, double-blind placebo-controlled study in 569 detoxified alcohol-dependent male patients in Europe, again showing decreased alcohol consumption in patients receiving calcium acetyl-homotaurinate compared to placebo. This compound, now known as acamprosate, was approved for the treatment of alcohol dependence in 1989 in France. Extensive clinical studies involving over 4,000 subjects throughout Europe demonstrated the safety and efficacy of acamprosate across clinical settings. By 1996, the medication became available in all European Union countries to treat alcohol use disorder, promulgating additional investigations into its utility in the pharmacologic treatment of alcohol use disorder.

In July 2004, the FDA approved acamprosate to maintain abstinence from alcohol in detoxified patients with alcohol use disorder. It became available for use in January 2005 under the trade name Campral. Since its introduction in 1989, acamprosate has been used to treat over 1.5 million patients worldwide.

Chemistry

Acamprosate is the calcium salt of *N-acetyl-homotaurine* (Ca-AOTA), a synthetic analog of the endogenous amino acid taurine with additional carboxyl and methyl groups in its chain. Acamprosate calcium is a white, nearly odorless powder readily soluble in water and practically insoluble in absolute ethanol. Its chemical name is calcium 3-acetylaminopropane-1-sulfonate, and its structure is shown in Figure 33.13b–2.

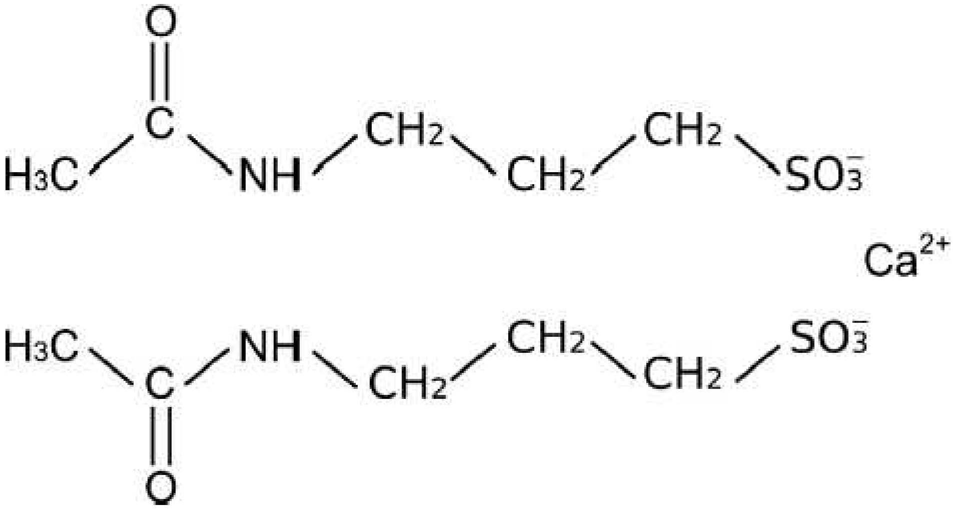

FIGURE 33.13b–2. Chemical structure of acamprosate.

Pharmacologic Actions

Pharmacokinetics

ABSORPTION. Acamprosate is a dimer of acetyl-homotaurine linked by a calcium salt formulated to assist in its absorption across the GI tract. However, the amount of acamprosate absorbed is quite low, with a bioavailability of ~11% in the fasting state. Food consumption reduces acamprosate absorption but not sufficiently to justify dose adjustments. Acamprosate is so slowly absorbed that it acts as if it were a modified-release medication. Peak plasma concentrations are usually reached within 3 to 8 hours after dosing, and steady-state levels are achieved by the fifth to the seventh day of dosing. Its terminal half-life ranges from 20 to 33 hours after administering a standard 666-mg enteric-coated formulation.

DISTRIBUTION. The amount of acamprosate that is protein bound is negligible, such that the active drug that permeates the intestinal mucosa is entirely dissociated in plasma. While its volume of distribution following IV acamprosate administration is high, estimated to be 72 to 109 L (approximately 1 L/kg), its oral bioavailability is relatively low. Only 6.5% to 11% of what is ingested crosses the GI tract, which explains why it must be given in high doses. In contrast to orally administered acamprosate, its concentrations are quite high when administered intravenously, but its half-life is approximately 3 hours compared to 20 to 33 hours when taken orally. This is an example of "flip-flop" pharmacokinetics in which the concentration and half-life are limited by the rate and extent of absorption rather than the volume of distribution or excretion.

Acamprosate has been assigned a Category C labeling in pregnancy. Teratogenicity has been demonstrated in rat and rabbit fetuses though there have been no large-scale studies in humans to date. It is also unknown whether the medication is excreted through breast milk, but in lactating rats given oral doses of acamprosate, the concentration in milk compared to the drug in blood was 1.3.

METABOLISM AND ELIMINATION. Importantly, acamprosate bypasses the liver and is eliminated unchanged in the urine and feces. Most of the acamprosate does not permeate the intestinal mucosa and is therefore removed through the feces. Once the medication is available via paracellular transport, renal clearance is expedient, occurring at approximately 6 mL/minute. The portion of the absorbed drug (ranging from 6.5% to 11%) does not undergo metabolism and is excreted in the urine as acamprosate. There is a linear relationship between renal clearance and plasma half-life of acamprosate and creatinine clearance values when taken orally. No significant pharmacokinetic differences between male and female subjects have been found for acamprosate.

Pharmacodynamics

MECHANISM OF ACTION. Acamprosate bears structural similarities to several amino acids, including gamma-aminobutyric acid (GABA), glycine, aspartate, and glutamate; its mechanism of action is therefore thought to be mediated, at least in part, through numerous neurotransmitter systems.

Initial studies focused on acamprosate's in vitro affinity for $GABA_A$ and $GABA_B$ receptors, which appears to decrease electrical excitability without changing the membrane potential of the neuron. It is postulated that the therapeutic effect of acamprosate is partially due to its potentiation of the GABA network, the main neuronal inhibitory system. Unlike other GABA agonists, however, acamprosate doesn't exert anxiolytic, hypnotic, or muscle relaxant properties.

Other research has shifted focus to the structural similarities between acamprosate and the excitatory neurotransmitter glutamate. It has been proposed that acamprosate may decrease the excitatory effects of glutamate, especially during the period after abrupt discontinuation of alcohol. Since alcohol inhibits the activity of the *N*-methyl-D-aspartate (NMDA) receptors, chronic alcohol consumption leads to the overexpression of these receptors. Chronic alcohol intake also affects the release of glutamate—in order to compensate for the alcohol-induced inhibition at the NMDA receptors, the amount of glutamate released into the synaptic cleft increases over time. Thus, abrupt discontinuation of alcohol results in unopposed neuronal excitation due to supranormal levels of glutamate acting on upregulated NMDA receptors, which may contribute to the pathophysiology of the alcohol withdrawal syndrome, including delirium tremens and seizures.

Other research supports the hypothesis that acamprosate interacts with NMDA receptors in a more complex way; for example, studies show that the drug is an NMDA partial co-agonist. This means that at lower concentrations, acamprosate activates NMDA receptors when receptor activity is low. Conversely, at higher concentrations and when NMDA receptor activity is high, acamprosate is inhibitory, thereby helping to restore equilibrium in this disrupted neuronal system.

Furthermore, it has been shown that acamprosate induces the release of taurine, an inhibitory neuromodulator, which also decreases neuroexcitability. In early alcohol withdrawal, the drug also decreases dopamine hyperexcitability in the nucleus accumbens, as well as the expression of brain *c-fos*, a gene expressed during early alcohol withdrawal.

Other research supports that by activating glycine receptors in the nucleus accumbens and nicotinic acetylcholine receptors in the ventral tegmental area, acamprosate elevates extracellular dopamine levels in the nAc. In rat models, acamprosate appears to elevate dopamine and simultaneously prevent ethanol from further increasing dopamine output. In these animal models, 10 days of treatment with acamprosate produced a loss of the ethanol intake–reducing as well as the dopamine-elevating effects of acamprosate, and the dopamine-elevating property of ethanol was restored, suggesting possible tolerance to the dopaminergic properties of acamprosate. In multiple studies, a significant shortcoming with acamprosate is about 50% of patients discontinue the medication before 6 months. It is possible that this is not only due to the three times daily dosing schedule but also due to the diminishing effects of acamprosate over time.

While it was previously thought that *N-acetyl-homotaurine* was the biologically active compound mediating acamprosate’s effects, recent literature has demonstrated that calcium may be the moiety responsible for acamprosate’s role in the treatment of alcohol use disorder. In fact, there is compelling evidence that acamprosate's efficacy does not stem from its direct interactions with glutamate receptors but rather from increasing calcium concentrations. Studies have demonstrated that treatment with calcium-acamprosate decreases voluntary drinking, while sodium-acamprosate is not superior to placebo in attenuating alcohol consumption. Sodium- and calcium-acamprosate have the same bioavailability, such that differences in pharmacokinetics are unlikely to render this finding. Human studies have shown that higher brain and plasma calcium levels correlate with acamprosate's efficacy parameters, such as time to first drink, time to severe relapse, and cumulative abstinence. This has led researchers to question whether *N-acetyl-homotaurine* is biologically active or whether the efficacy of naltrexone could be realized with calcium salts alone.

It is clinically important to emphasize that despite acamprosate's modulation of glutamate dysregulation in rodents, there is no clinical improvement in patients who begin acamprosate during acute detoxification. On the contrary, available research suggests that patients who receive acamprosate during the detoxification period drink more alcohol statistically in 10-week follow-up than those administered a placebo**.** Acamprosate does not eliminate or diminish withdrawal symptoms and is not indicated for the treatment of delirium tremens.

Acamprosate is most beneficial in maintaining abstinence and helping patients regain abstinence after relapse. The medication is thought to alleviate the negative affect associated with early stages of alcohol withdrawal, reverse alcohol-related changes in sleep architecture, and also decrease alcohol cravings once abstinence is achieved. It additionally decreases cravings in response to conditioned environmental cues. Unlike DSF, which relies on decreasing alcohol use by inducing distinctly unpleasant effects or naltrexone, which decreases the pleasurable effects of alcohol, acamprosate's primary mechanism appears to lie in its neuromodulatory effect—its ability to normalize disturbed brain chemistry and electrophysiology during acute and protracted withdrawal. Some studies suggest that it may reduce the rewarding effects of alcohol.

The medication has not traditionally been associated with the development of tolerance or dependence; however, in rodents, there does appear to be some tolerance toward the ethanol intake–reducing effect of the compound following prolonged exposure. The mechanism for this is discussed above. The clinical significance of this in humans awaits further research. Acamprosate does not cause alcohol aversion or produce a DSF-type reaction in the event of relapse.

Preclinical research provides evidence that acamprosate has neuroprotective properties in neurons exposed to alcohol. The hyperglutamatergic imbalance that takes place during alcohol withdrawal is associated with neuronal excitotoxicity, which acamprosate has been shown to mitigate. Results from cell culture and animal studies have demonstrated decreased cell death in alcohol-exposed neurons in the cerebral cortex and hippocampus. Research supports that excessive glutamate activity continues after acute withdrawal, inducing ischemia, as measured by lactate dehydrogenase levels. Furthermore, acamprosate has been shown to inhibit trans-ACPD, a metabotropic glutamate-type receptor (mGluR) agonist responsible for some of the neurotoxicity that glutamate exerts. The hyperglutamatergic syndrome that occurs during alcohol withdrawal is also thought to be mediated by calcium entry into neurons, which acamprosate alleviates. The relevance of these findings for treatment in humans awaits further research.

BLOOD CONCENTRATIONS AND RELATION TO ACTION. Plasma concentrations of acamprosate may significantly vary between individuals due to multiple factors, most notably individual rates of absorption. Pharmacokinetic studies indicate that the concomitant use of acamprosate and alcohol doesn’t result in any noticeable changes in the pharmacokinetics of either substance. At least one double-blind placebo-controlled randomized controlled trial in a sample of 56 patients seeking treatment for alcohol use disorder found a negative correlation between alcohol craving following a priming drink (i.e., first drink after 21 days of continuous acamprosate treatment) and acamprosate plasma levels. This suggests that higher acamprosate blood concentrations may increase the chances of regaining abstinence after mild relapse.

Design and Interpretation of Clinical Drug Studies

Since its inception, there have been more than 20 double-blind, placebo-controlled protocols investigating the utility and safety of acamprosate in the pharmacologic treatment of alcohol use disorders. The length of any individual trial ranged from 12 to 52 weeks, with some protocols offering additional follow-ups. With few exceptions, patients were detoxified prior to treatment; dosing was based on weight and ranged between four and six 333-mg tablets. The treatment took place in outpatient programs with concurrent psychosocial interventions. The subjects across trials were predominantly male, and the mean age fell in the fourth decade of life.

The cumulative sample size from a meta-analysis of eight positive randomized-controlled trials was 2,430, sufficiently powered to support some clinically relevant conclusions. Six of these protocols followed patients for over 52 weeks, providing a relatively long duration to study adverse effects over time. Acamprosate treatment separated from placebo most consistently when acamprosate was initiated after the acute withdrawal phase and in patients receiving concurrent psychosocial interventions. Acamprosate outperformed placebo in terms of continuous abstinence duration (time to first drink) as well as cumulative abstinence proportion (number of days abstinent out of the total days patients were in treatment) measured at 6 months. These results support the notion that acamprosate may help patients achieve complete abstinence and regain abstinence if relapse occurs. Another meta-analysis assessed acamprosate in 27 studies across 7,519 subjects. Sample sizes ranged from 21 to 1,383, treatment durations were 12 to 52 weeks, and the mean age was in the 40s. The participants met the Diagnostic and Statistical Manual of Mental Disorders (DSM) criteria for alcohol dependence, and the vast majority of studies included concurrent psychosocial interventions. This meta-analysis found that the number needed to treat to prevent a return to any drinking for acamprosate was 12, suggesting modest efficacy of acamprosate treatment. In this meta-analysis, the number needed to harm for withdrawal from trials due to adverse effects was 48 for naltrexone and not significantly increased for acamprosate.

In protocols that included patients who had not undergone detoxification or were acutely withdrawing from alcohol, acamprosate failed to demonstrate superiority over placebo. Further, in another study where patients initiated treatment 25 days after recovery from physical withdrawal symptoms, acamprosate was not more effective than placebo. One meta-analysis was designed to study differential outcomes as a consequence of the duration of detoxification and abstinence prior to initiating treatment. Nineteen trials were analyzed that used acamprosate alone and in combination with various other interventions (naltrexone with and without adjunctive psychotherapies). In the 5,559 subjects included in this part of the meta-analysis, detoxification prior to treatment was associated with larger medication effects. These data indicate that the outcome of acamprosate treatment is time sensitive and may depend on the timing of intervention in relation to acute detoxification.

Several studies have attempted to evaluate and compare the usefulness of different psychotherapies (e.g., dynamically oriented individual psychotherapy, cognitive behavioral individual coping skills therapy, group therapy, or various brief interventions) in the treatment of abstinence from alcohol when used in combination with acamprosate. To date, it remains unclear whether any particular psychotherapy is superior to another. The literature does substantiate that acamprosate is more effective when administered concurrently with psychotherapy. Brief *motivational enhancement therapy* (MET) is readily learned and can be implemented in psychiatric and primary care settings alike. This intervention focuses on improving a person’s motivation to achieve and sustain abstinence. Given that acamprosate has been shown to be more effective when abstinence is the goal of treatment, MET holds promise as a psychotherapeutic adjunct to acamprosate.

Additional studies have investigated the efficacy of acamprosate in comparison, or in conjunction with, naltrexone as compared to acamprosate alone, acamprosate + psychosocial interventions, and placebo. These studies haven't shown any efficacy of acamprosate over placebo with or without psychotherapy. Results from a 16-week randomized controlled trial, including 1,383 recently alcohol-abstinent volunteers, demonstrated no evidence of the efficacy of acamprosate alone or together with *combined behavioral intervention* (CBI) when compared to other treatments (e.g., naltrexone, CBI, and placebo alone or in various combinations). The largest limitation of this study was that subjects were only given 4 days for detoxification in an outpatient program. Studies that reported no additional benefit from the combined acamprosate + psychotherapy treatment had additional limitations, including the following: (i) lack of randomization in one open-label naturalistic study of 753 alcohol-dependent patients; and (ii) presenting the participants with the option to be randomized to the no psychotherapy arm, which may have created a selection bias against participants with a particular interest in receiving psychotherapy as documented in one randomized, multicenter study of 248 patients.

Using the structural clinical interview for DSM-IV and *International Statistical Classification of Diseases, Tenth Revision* (ICD-10), another protocol studied 426 subjects meeting DSM-IV criteria for alcohol dependence. All subjects were recruited from inpatient wards for medical detoxification to which their general practitioners had referred them. Following a mean of 18 days' inpatient detoxification, eligible patients were treated for 12 weeks in the outpatient setting with acamprosate, naltrexone, acamprosate + naltrexone, or placebo in conjunction with brief psychotherapy. Exclusion criteria included dependence or abuse of another substance other than cannabis or nicotine, a comorbid psychiatric disorder for which subjects were receiving medication, and unstable medical conditions. The study showed no effect on abstinence in those who received treatment as compared to those who received placebo. Limitations were related to higher acuity since participants were recruited from an inpatient setting, in addition to a relatively long detoxification period followed by a relatively short outpatient treatment duration. Furthermore, these data likely are not generalizable as patients with alcohol dependence often have comorbid psychiatric and medical conditions. Out of all the patients screened, for example, only 43% met inclusion criteria, and only 31% of all eligible patients chose to participate, which is suggestive that selection bias may have influenced the results.

One study investigated the efficacy of acamprosate with respect to gender using a gender-specific meta-analysis of individual patient data obtained from double-blind, randomized controlled trials with inpatients carrying diagnoses of alcohol dependence based on DSM-III or IV criteria. Records were obtained from 1,317 women and 4,793 men from 22 studies across 18 countries. Exclusion criteria were pregnancy, lactation, or refusal to use birth control in women of childbearing age and potential, significant comorbid psychiatric disorders for which patients were prescribed medication, medical disorders such as renal failure, and concurrent use of another pharmacologic intervention for alcohol use. Fourteen trials had durations of at least 6 months, and 5 lasted longer than 1 year. Patients needed to have at least one quantitative measure of drinking behavior to assess treatment efficacy. The four endpoint variables included the percentage of abstinent days, percentage of no heavy drinking days, rates of complete abstinence, and rates of no heavy drinking over the study's duration. There was an incremental gain of 10.4% in the percentage of abstinent days (95% confidence interval [CI] 7.1 to 13.7, $p < .001$), a gain of 11% in the percentage of no heavy drinking days, an odds ratio of 1.9 for complete abstinence rates (CI 1.6 to 2.2, $p < .001$), and an odds ratio of 1.9 (CI 1.6 to 2.3, $p < .001$) for a rate of no heavy drinking over the studies' durations. Importantly, outcomes in acamprosate efficacy, safety, or tolerability did not differ between men and women.

More recent studies have set out to investigate whether certain subtypes of persons with alcohol use disorder may respond preferentially to naltrexone or acamprosate. The central hypothesis of these studies is that individuals with significant alteration of the opioidergic system, who drink alcohol primarily in the context of positive reinforcement (reward drinkers), would benefit more from naltrexone, while individuals with significant glutamatergic dysfunction, who primarily drink alcohol in the context of negative reinforcement (relief drinkers) may benefit more from acamprosate. One of these studies utilized the data from a 16-week randomized controlled trial, including 1,383 recently alcohol-abstinent volunteers, comparing the efficacy of various combinations of pharmacotherapy and CBI. While the initial study did not find any significant difference in efficacy outcomes when combined with placebo alone, when subjects were stratified based on drinking for reward versus drinking for relief (i.e., preventing aversive effects from alcohol withdrawal), the data showed a significant effect for acamprosate. Specifically, the study found a significant interaction effect between the "high-relief/moderate-reward" class and acamprosate in the prediction of the percentage of drinking days at the end of treatment (week 16) and the percentage of heavy drinking days 10 weeks post-treatment (week 26) compared to placebo. These findings did not generalize to other "high-relief" classes, specifically those in the "high-relief/high-reward" class, suggesting that acamprosate may be more effective in treating persons who have higher relief temptation relative to reward temptation. Importantly, inpatient detoxification prior to initiating the medication in this study was 4 days.

Another study used data from a randomized controlled trial conducted in Germany testing the efficacy of naltrexone and acamprosate in the treatment of alcohol dependence. 426 participants were randomly assigned to naltrexone, acamprosate, or placebo over the course of 12 weeks. All participants were recruited from inpatient medical detoxification programs of 2 to 3 weeks' duration (on average, participants were abstinent for 22 days prior to initiating the study). In contrast to the data above, this study did not find an effect of acamprosate for the high-relief subgroup. The authors postulated that this discrepancy might be explained by the fact that after an average of 22 days' abstinent, hyperglutamatergic states may have already started to normalize. These studies may further highlight the importance of initiating acamprosate shortly after acute detoxification when glutamate dysregulation remains high.

Other studies have established that pretreatment commitment to abstinence could be an important moderator of treatment response to acamprosate. Abstinence prior to initiating acamprosate appears to be an important moderator of treatment, and shorter abstinence (usually 1 week or less) appears to be another moderator of responsiveness to acamprosate. Finally, it appears that acamprosate's effect may be dose dependent and that patients with low to normal body masses indices do better with acamprosate compared to their overweight or obese counterparts. This may, in part, explain the differential success of acamprosate in Japanese and European studies over ones conducted in the United States.

A 2018 meta-analysis set out to confirm the efficacy of acamprosate in reducing insomnia in subjects with alcohol use disorder. Twelve studies were found, including 3,508 patients. The main endpoint of the study was a change in Short Sleep Index (SSI), which was derived from answers subjects had provided in the Hamilton Depression and Hamilton Anxiety Scales. The questions included in the SSI are: (a) insomnia early (difficulty falling asleep), (b) insomnia middle (being restless and disturbed during the night), (c) insomnia late (waking in the early hours of the morning), and (d) difficulty in falling asleep, broken sleep, unsatisfying sleep and fatigue on waking, dreams, nightmares, and night terrors.

After 6 months of treatment with acamprosate, the mean SSI decrease over baseline was −26% and −45% for placebo and acamprosate, respectively (treatment effect = 19%, 12.5–25.5; $p < .001$). Using a univariate mediation model, the authors found that the mediating effect of abstinence on insomnia accounted for 55.7%. The remaining unexplained effect of acamprosate was 44.3%. Limitations of this study include that one of the included studies did not require subjects to have stopped drinking prior to initiating acamprosate and that many subjects had returned to alcohol use by the end of the 6-month investigation period. Other studies have shown that acamprosate improves sleep continuity and architecture measured by polysomnography. DSF, naltrexone, and nalmefene have been shown to have deleterious effects on sleep, so there is only low-level evidence thus far that acamprosate may improve insomnia in persons with alcohol use disorder; it may hold advantages for persons in whom insomnia is a primary concern.

Mild diarrhea or loose stool was the only statistically significant adverse event documented in a large meta-analysis. It is estimated that up to 10% of patients may experience mild diarrhea; importantly, those who suffered from diarrhea were no more likely than their counterparts to discontinue the medication.

These data are limited in that the randomized controlled trial with the highest power failed to demonstrate the medication's efficacy as compared to placebo or naltrexone and that many studies supporting acamprosate's efficacy are short. Taken cumulatively, however, acamprosate appears to be a safe and effective adjunct to psychosocial alcohol rehabilitation programs. It is most useful for patients receiving concomitant psychotherapy, and whose stated goal upon initiating treatment is abstinence.

Effects on Specific Organs and Systems

The most serious adverse effect of acamprosate may be related to the urogenital system since there have been several documented cases of patients developing acute renal failure while receiving acamprosate treatment. However, no causal relationship has been established between acamprosate and any specific physiologic mechanism that may result in acute kidney impairment. Less severe but more frequent are acamprosate's effects on the cardiovascular (palpitation and syncope), respiratory (increased cough, rhinitis, dyspnea), digestive (diarrhea, nausea, vomiting, and abdominal pain), musculoskeletal (myalgias and arthralgias), nervous (somnolence, amnesia, tremor), and dermatologic (pruritus) systems.

Therapeutic Indications

Acamprosate is an FDA-approved agent for maintenance of abstinence from alcohol in patients with alcohol dependence who are abstinent at treatment initiation. The efficacy of acamprosate in promoting abstinence has not been demonstrated in subjects who have not undergone detoxification and have not achieved alcohol abstinence prior to beginning acamprosate treatment. The efficacy of acamprosate in promoting abstinence from alcohol in patients with polysubstance abuse has not been adequately assessed. Treatment with acamprosate should be a part of a comprehensive management program that includes psychosocial support.

Other Disorders. Acamprosate is only FDA approved for the treatment of alcohol use disorder.

The literature on other uses for acamprosate over the last few years is expanding. The medication appears to hold promise in the treatment of *fragile-X-syndrome* (FXS)-associated *autistic spectrum disorders* (ASDs) and tinnitus.

Excessive glutamatergic and deficient GABAergic neurotransmission is found in patients with both FXS and with idiopathic ASD. Extensive literature supports a correlation between excessive mGluR5 and deficient $GABA_A$ neurotransmission in FXS-associated ASD. Preliminary studies showed that three adults with FXS and ASD who were treated with a mean dose of 1,221 mg/day of acamprosate for a mean duration of 21.3 weeks achieved clinical and statistical improvement in social–communicative language. A subsequent 10-week prospective open-label trial of acamprosate in 12 patients (mean age 11.9 years old) with comorbid FXS and ASD found improvement in social behavior and inattention/hyperactivity in 75% of the subjects. Moreover, the medication was well tolerated with no severe or serious adverse effects. It is currently the preferred agent in patients with FXS and co-occurring alcohol use disorders.

A derivative of amyloid-beta precursor protein (APP) secreted APPα (sAPPα), has neuroproliferative effects, and has been shown to be elevated in the plasma of persons with ASD compared to control subjects. A pilot study of 15 subjects treated with acamprosate for 10 weeks showed a significant decrease in sAPP-total and sAPPα in subjects with FXS-associated or idiopathic ASD ($p < 0.05$), proposing a mechanism by which acamprosate might treat these disorders on the molecular level. The largest limitation of this study was its very low power and that 13 of the patients enrolled were receiving other pharmacologic therapies. There were no adverse effects reported in patients receiving acamprosate. The medication may benefit patients with FXS and ASD, though no high-powered randomized controlled trials have been conducted to date.

A prospective, randomized, placebo-controlled, double-blind, cross-over study investigated the use of acamprosate in treating 40 subjects with sensorineural tinnitus. The patients were randomized to receive three 333-mg tablets of acamprosate daily or placebo for 45 days, followed by a washout period of 7 days and then crossed over to acamprosate or placebo for another 45 days. 92.5% of subjects receiving acamprosate demonstrated objective and subjective improvement in tinnitus as opposed to 12.5% subjective improvement seen with placebo. Objective improvement of tinnitus was measured by tinnitus matching for loudness by decibel. On this objective measure of tinnitus, 80% of the treatment group showed improvement as compared to 0.0% of the placebo group. Another randomized controlled trial divided 20 subjects with chronic tinnitus into either acamprosate or placebo. This study indicated subjective relief of tinnitus as well as some degree of electrophysiologic improvement at the level of the cochlear and the distal portion of the auditory nerve in the 9 subjects who received acamprosate versus the 11 who received placebo. Numerous case reports also reflect subjective improvement in tinnitus with acamprosate. Larger studies are needed for FDA approval, but evidence suggests some efficacy of acamprosate in the treatment of tinnitus.

There is insufficient data to determine acamprosate’s utility in the treatment of other SUDs. This may be because the medication is relatively new, and small pilot studies have failed to demonstrate superiority to placebo in the treatment of stimulant (cocaine) use disorder, while preliminary studies in rodents were promising. This topic awaits further research.

Precautions and Adverse Reactions

Precautions. The dose of acamprosate will need to be adjusted for patients with moderate renal impairment (i.e., creatinine clearance of 30 to 50 mL/minute). Patients with severe renal impairment (creatinine clearance of ≤30 mL/minute) should not be prescribed acamprosate. Because acamprosate does not rely on hepatic metabolism, it can be used in patients with mild to moderate hepatic impairment (Child–Pugh groups A and B). It has not been used in Child–Pugh C liver disease and is not approved for use in this population.

In placebo-controlled trials, adverse events such as suicidal ideation, suicide attempts, and even completed suicides were reported more frequently in acamprosate-treated patients than in patients who received placebo (1.4% vs. 0.5% in studies of 6 months or less; 2.4% vs. 0.8% in year-long studies). Completed suicides in the pooled acamprosate group were 0.13% (3 out of 2,272 patients) and 0.10% (2 out of 1,962) in the placebo group. Depression was reported at similar rates in both treatment groups. The interrelationship between alcohol dependence, depression, and suicidality is well recognized and complex, and since many of these adverse events occurred during the periods of addiction relapse, it was hard to determine any direct link between the clinical course of recovery from alcoholism and the emergence of suicidality. Patients with alcohol use disorders, regardless of whether or not they are treated with acamprosate, should be monitored for the development of symptoms of depression and suicidality since suicide attempts and completions occur more frequently in patients with alcohol use disorders.

Although the safety of acamprosate during pregnancy has not been determined, the agent has been shown to have a teratogenic effect on the fetus in rodents. The benefit of acamprosate use during pregnancy should be carefully weighed against possible adverse effects. It is also not recommended for use in nursing mothers.

Adverse Reactions. More frequent and less serious side effects may include headaches, insomnia, stomach upset with nausea, vomiting, and abdominal pain, as well as sexual dysfunctions (e.g., decreased libido, frigidity, and impotence). In clinical trials, the most commonly reported side effects were diarrhea and pruritus, though these adverse effects were usually transient, and in recent meta-analyses, patients with these adverse effects are no more likely than those receiving a placebo to discontinue the medication. Those who developed anxiety and depression while taking acamprosate were most likely to discontinue the medication, but it is difficult to parse out whether these mood symptoms are directly attributable to acamprosate or to underlying untreated mood disorders or mood disorders that developed as a result of prolonged alcohol use. More serious side effects include allergic reactions to the drug, arrhythmias, and fluctuations in blood pressure.

Drug Interactions

Because acamprosate does not rely on hepatic metabolism, it has relatively few drug–drug interactions. Coadministration of benzodiazepines, DSF, antidepressants, or alcohol does not change acamprosate's pharmacokinetic properties, which is fortunate, and these medications are commonly prescribed in patients with alcohol use disorders. However, coadministration of acamprosate with naltrexone may result in a 33% increase in the C_{max} of acamprosate, which requires no adjustment of the dosage. Similarly, the pharmacokinetics of naltrexone and its major metabolite 6-beta-naltrexol are unaffected when given concomitantly with acamprosate. Patients taking acamprosate with antidepressants more commonly reported both weight gain and weight loss in comparison to patients taking either medication alone.

The absorption of several agents (tetracyclines, quinolones, levothyroxine, atenolol, iron, alendronate, sodium fluoride, and zinc) may be decreased by the calcium component of acamprosate during concurrent administration. The absorption of acamprosate can also be decreased by food. Acamprosate has shown no inhibiting or inducing potential both in vitro and in vivo on the enzymes of the cytochrome P-450 system.

Laboratory Interference

Acamprosate is not known to interfere with any laboratory tests.

Dosage and Administration

Initiation of therapy should begin after alcohol detoxification has taken place and the patient has abstained from alcohol for 5 to 7 days. Just as it should not be initiated during acute detoxification, a review of the literature substantiates that it may not be superior to placebo if the medication is initiated more than 25-days post acute alcohol detoxification. Acamprosate treatment should not be interrupted if relapses occur and are recommended to proceed for 12 months.

Acamprosate is dosed by weight: patients >60 kg should receive 1,998 mg/day in divided doses with meals, while patients <60 kg should receive 1,332 mg/day in three divided doses with meals. The drug has not been sufficiently studied in pediatric and geriatric populations.

ACKNOWLEDGMENTS

The author would like to acknowledge Dr. Iliyan Ivanov and Dr. Alison Ungar for their contributions to earlier editions of this chapter.

33.14 Fast-Acting Pharmacologic Treatments

33.14a Esketamine and Ketamine

CARLOS A. ZARATE, JR., M.D., AND LAWRENCE T. PARK, A.M., M.D.

Neuroscience-Based Nomenclature (NbN)	
Pharmacologic Domain	Glutamate
Mechanism of Action	Receptor antagonist (NMDA)

HISTORY

The discovery that racemic (*R*,*S*)-ketamine (hereafter referred to as ketamine) has antidepressant properties has been described as the most significant development in the treatment of depression in the past 60 years. While the monoamine era of pharmacotherapy yielded a host of moderately effective, relatively slow-acting, mechanistically similar drugs, ketamine offers the prospect of rapid relief of symptoms via a novel mechanism of antidepressant action. Our understanding of this underlying mechanism has the potential to serve as a basis for reconceptualizing the neurobiology of depression as well as a platform for developing innovative pharmacotherapeutic strategies.

Ketamine was originally synthesized in 1962 as a safer anesthetic alternative to phencyclidine (PCP), which was associated with significant emergence delirium and other adverse effects. As a structurally related analog, ketamine shares PCP's neurochemical activity as an *N*-methyl-D-aspartate (NMDA) antagonist but is less potent and has a shorter duration of action. Ketamine received FDA approval in 1970 as an anesthetic for procedures that do not require skeletal muscle relaxation, as an induction agent for short procedures, and as a supplement to low-potency anesthetic agents. In contrast to other anesthetic agents, ketamine produces a dissociative state with relatively little sedation. It has excellent analgesic properties and a relatively large therapeutic index. Given these characteristics, it remains widely used in adult and pediatric anesthesia as well as in veterinary medicine. Ketamine is on the World Health Organization's list of essential medicines.

Trullas and Skolnick (1990) first postulated that substances capable of reducing neurotransmission at the NMDA receptor complex might have potential as a new class of antidepressants. Based on the theory that NMDA mediates behavioral changes associated with inescapable stress, they demonstrated that ketamine reduced depressive-like symptoms in stress-related animal models of depression. Berman and colleagues (2000) subsequently conducted the first controlled human study, which administered a single intravenous (IV) ketamine infusion (0.5 mg/kg) to a small group of individuals primarily diagnosed with major depressive disorder (MDD). Compared to saline placebo, ketamine demonstrated antidepressant effects within 72 hours of infusion. Zarate and colleagues (2006) subsequently conducted a larger, saline placebo-controlled trial using a randomized, within-subjects crossover design. The study confirmed ketamine's rapid antidepressant effects (onset within 24 hours) in individuals with treatment-resistant MDD (TRD) as well as those with treatment-resistant bipolar depression. Additional studies also confirmed that these rapid antidepressant effects peaked within 1 day of infusion and lasted 3 to 7 days postinfusion, as well as ketamine's effectiveness in both TRD and bipolar depression and the feasibility of a repeated-dose strategy to extend the duration of these effects.

The discovery of ketamine's antidepressant properties renewed interest in pharmacologic research of compounds with related mechanisms of action. Investigators examined ketamine's enantiomers in an attempt to reproduce ketamine's antidepressant properties but minimize its adverse secondary effects. Researchers initially focused on (*S*)-ketamine (esketamine), which demonstrates greater potency at the NMDA receptor than (*R*)-ketamine (arketamine). Developed for intranasal administration, esketamine was found to be safe and effective for treating TRD. Intranasal esketamine (Spravato) received FDA approval for TRD in March 2019 (ketamine itself does not have an FDA indication for depression) and for use in adults with MDD with acute suicidal ideation or behavior in August 2020. Because of concerns about dissociative adverse events and the potential for abuse, the FDA approval required that esketamine use be managed through a risk evaluation and mitigation strategy (REMS). REMS requires that esketamine be dispensed and administered only in a REMS-certified, medically supervised health care setting where patients are monitored for at least 2 hours postadministration. Several recent treatment guidelines now incorporate ketamine and esketamine into the treatment algorithm.

Interestingly, research with animal models suggests that (*R*)-ketamine has greater and longer-lasting antidepressant-like effects. In addition, a metabolite of the (*R*)-enantiomer, (2*R*,6*R*)-hydroxynorketamine (HNK), appears to be essential for achieving antidepressant-like effects without apparent dissociative-like symptoms or abuse potential. Phase I human trials with (2*R*,6*R*)-HNK have recently been completed, and Phase II trials are planned.

CHEMISTRY

Ketamine (and ketamine hydrochloride) is an arylcycloalkylamine and a synthetic derivative of cyclohexanone. Its chemical name is 2-(2-chlorophenyl)-2-(methylamino)cyclohexan-1-one (IUPAC nomenclature). The molecular formula is $C_{13}H_{16}C1NO$, and the molecular weight is 237.72. Ketamine is a white to off-white crystalline powder soluble in water and lipid solutions, freely soluble in methanol, soluble in alcohol, and sparingly soluble in chloroform. It is often supplied as a clear liquid. Ketamine has an asymmetric carbon at the C2 position and is made up of a mixture of (*S*) and (*R*)-enantiomers. (*S*)-ketamine has four times greater affinity at the NMDA receptor than (*R*)-ketamine. The molecular structure is shown in Figure 33.14a–1.

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Ketamine can be delivered orally, intranasally, rectally, IV, intramuscularly, subcutaneously, and epidurally. Bioavailability and time to maximum concentration ($T_{\max}$) differ by route of administration, with IV demonstrating 100% bioavailability ($T_{\max}$ 3 minutes), intranasal 8% to 45% bioavailability ($T_{\max}$ 10 to 20 minutes), and oral 17% to 29% bioavailability ($T_{\max}$ 30 minutes). Ketamine absorption is very rapid. The distribution half-life ($T_{1/2a}$) is on the order of 2 to 4 minutes, and 17% is absorbed after first-pass metabolism. Ketamine is 53.5% plasma protein bound. The elimination half-life ($T_{1/2b}$) of ketamine in adults is 2 to 4 hours, and the elimination $T_{1/2b}$ of esketamine is 5 hours. Ketamine and esketamine undergo mainly hepatic metabolism via cytochrome P450 (CYP) 3A4 and 2B6. Most of the elimination is via the urine in the form of metabolites. Norketamine is the principal initial metabolite and is further metabolized to 18 other distinct compounds, including (2*R*,6*R*)-HNK (see Fig. 33.14a–2).

Pharmacodynamics

Ketamine and its metabolites bind to a variety of biologic targets. Although its primary activity is as a noncompetitive NMDA receptor antagonist, ketamine also interacts with opioid receptors (e.g., kappa, mu, and delta subtype agonist; mu opioid 2 receptor antagonist), with the monoaminergic system (e.g., dopamine 2 receptor agonism), and with the serotonergic system (e.g., 5-HT1, 5-HT2 receptor antagonism, 5-HT3 receptor weak antagonism). It also weakly inhibits the dopamine- and sodium-dependent norepinephrine transporters, has noradrenergic effects on the cholinergic system (e.g., alpha-7-nicotinic receptor subunit antagonist, binds at the muscarinic receptor, cholinesterase inhibitor), is a glycine receptor agonist, and is a sigma receptor 1 and 2 agonist. Finally, ketamine also binds the voltage-sensitive calcium and voltage-gated sodium ion channels, is an antagonist at the neurokinin 1 receptor, an agonist at the D-serine site, and inhibits nitric oxide synthase receptors. Ketamine has no significant direct effects on gamma aminobutyric acid (GABA) receptors.

The precise mechanism of rapid antidepressant response associated with ketamine remains unclear, and this is a rapidly evolving area of research. A proposed schema of glutamatergic mechanisms of interest (not comprehensive) is presented in Figure 33.14a–3. Early theories postulated a “glutamate surge” resulting from NMDA receptor antagonism as a necessary component of the antidepressant response, and mounting evidence suggests that ketamine promotes neuroplasticity by facilitating synaptogenesis and synaptic potentiation. Increased synaptic glutamate release is thought to result from NMDA antagonism at the GABAergic inhibitory interneuron that decreases inhibitory tone on the presynaptic pyramidal neuron. This “disinhibition” of the presynaptic neuron increases synaptic glutamate release and also increases glutamatergic tone on the postsynaptic neuron.

FIGURE 33.14a–2. The metabolism of ketamine (KET). Ketamine is metabolized in vivo via P450 enzymatic transformations. **i**: (*R*,*S*)-KET is selectively demethylated to (*R*,*S*)-norketamine (norKET). **ii**: NorKET can then be dehydrogenated to (*R*,*S*)-dehydronorketamine (DHNK). **iii**: Alternatively, norKET can be hydroxylated to the hydroxynorketamines (HNKs). **iv**: (*R*,*S*)-KET can also be hydroxylated at the 6 position to give either the *E*-6-hydroxyketamine ([2*S*,6*R*;2*R*,6*S*]-HK) or *Z*-6-hydroxyketamine ([2*S*,6*S*;2*R*,6*R*]-HK). **v**: Demethylation of (2*S*,6*R*;2*R*,6*S*)-HK produces (2*S*,6*R*;2*R*,6*S*)-HNK. **vi**: Demethylation of (2*S*,6*S*;2*R*,6*R*)-HK further gives (2*S*,6*S*;2*R*,6*R*)-HNK. (Reproduced from Zanos P, Moaddel R, Morris PJ, et al. NMDAR inhibition-independent antidepressant actions of ketamine metabolites. *Nature*. 2016;533:481–486. doi: 10.1038/nature17998.)

Several other NMDA-related processes have also been implicated in promoting neuroplasticity and, thus, mediating antidepressant response. These include blockade of spontaneous synaptic NMDA receptor activation, which inhibits eukaryotic elongation factor 2 kinase (eEF2K), leading to brain-derived neurotrophic factor (BDNF) translation and protein synthesis; inhibition of extrasynaptic NMDA receptors, which suppresses mechanistic target of rapamycin (mTOR) function and induces protein synthesis; and inhibition of NMDA receptor-dependent excessive burst firing activity of lateral habenula neurons. Other non-NMDA glutamate-related mechanisms of ketamine's rapid antidepressant effect have also been proposed. For instance, increased postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) activation has been shown to mediate antidepressant-like response in animal models. AMPAR activation may result from increased synaptic glutamate release and/or ketamine metabolites (i.e., [2*R*,6*R]*-HNK). AMPAR activation may also increase BDNF release, activation of the tropomyosin receptor kinase B (TrkB) receptor, and activation of the mTOR complex, with the subsequent promotion of protein synthesis. Animal models and human trials also suggest that the presynaptic group 2 metabotropic glutamate receptor (mGlurR2) may play a role in antidepressant response; mGluR2 antagonism has been shown to enhance glutamate release and subsequent AMPAR activation, and mGluR2 antagonists are currently in Phase II trials. Another recently proposed mechanism of action concerns focal glutamatergic hyperactivity in the ventral anterior cingulate cortex (vACC), which is thought to potentially lead to global reductions in monoaminergic activity, resulting in depressive symptoms.

Nonglutamatergic mechanisms have also been hypothesized to contribute to ketamine's antidepressant properties. Recent attention has focused on the opioid system. In particular, mu opioid receptor agonism may mediate antidepressant response to ketamine based on observations that naltrexone, a primarily mu opioid antagonist, blocked ketamine's effects in animals and humans. Kappa opioid receptor involvement has also been implicated, given evidence that kappa receptor antagonists have been found to block the behavioral effects of ketamine in rodents.

CLINICAL DRUG STUDIES

Ketamine for MDD

Ketamine is available on the U.S. market with an anesthesia indication but is not FDA-approved for a psychiatric indication. While multiple formulations and routes of administration are available, IV ketamine administration has been the most widely studied in TRD and has generated the greatest body of evidence; to date, ketamine administered via other routes has been studied in only limited fashion, and insufficient data currently exist to support its safety and effectiveness. In addition, evidence for its use for indications other than TRD and suicidal thoughts and behaviors is preliminary and in need of replication.

Adequate scientific evidence supports the rapid, though short-term, effectiveness of ketamine for TRD. Zarate and colleagues (2006) found that a single dose of IV ketamine (0.5 mg/kg) had rapid antidepressant effects (within 24 hours of administration). This first adequately-powered, placebo-controlled trial examined single-dose IV ketamine (0.5 mg/kg) versus saline placebo infused over 40 minutes. The study used a within-subjects crossover design where participants were randomized to receive ketamine infusion then placebo infusion, or vice versa, 1 week apart. Eighteen individuals with TRD (defined as nonresponse to at least two previous antidepressant trials) were tapered off psychotropic medications and underwent a 2-week washout period. Depressive symptoms were measured with the 21-item Hamilton Depression Rating Scale (HAM-D). Ketamine infusion significantly reduced depressive symptoms within 2 hours compared to placebo, with maximal effects seen at 24 hours. Improvement lasted 3 days and symptoms typically returned to baseline by 7 days. Subsequent single-infusion ketamine trials reproduced this initial finding.

FIGURE 33.14a–3. Proposed Mechanisms of Action of Ketamine and Esketamine; (1) **Disinhibition hypothesis**: i.e., blockage of N-methyl-D-aspartate (NMDA) receptors on gamma aminobutyric acid (GABA)-ergic inhibitory interneurons, leading to disinhibition of pyramidal neurons and enhanced glutamatergic firing; (2) **Inhibition of spontaneous synaptic NMDA receptor activation** inhibits eukaryotic elongation factor 2 kinase (eEF2K), leading to brain-derived neurotrophic factor (BDNF) translation and protein synthesis; (3) **Inhibition of extrasynaptic NMDA receptors** suppresses mechanistic target of rapamycin (mTOR) function and induces protein synthesis; and (4) **Inhibition of NMDA receptor-dependent excessive burst firing activity of lateral habenula (LHb) neurons**. Other proposed glutamate-related mechanisms of ketamine's rapid antidepressant effect include: (5**) Increased postsynaptic alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) activation** from increased synaptic glutamate release and/or ketamine metabolites ([2*R*, 6*R*]-hydroxynorketamine [HNK]); (6) **Presynaptic metabotropic glutamate receptor (mGluR) (group 2) antagonism** leading to enhanced glutamate release and subsequent AMPAR activation. AMPAR activation leads to

increased release of BDNF, increased activation of the tropomyosin receptor kinase B (TrkB) receptor, increased activation of the mTOR complex, and subsequent promotion of protein synthesis. (Adapted from Henter ID, Park LT, Zarate CA Jr. Novel glutamatergic modulators for the treatment of mood disorders: current status. *CNS Drugs.* 2021;35(5):527–543. doi: 10.1007/s40263-021-00816-x.)

Multiple ketamine infusions have also been studied to address the short duration of ketamine's antidepressant effects. Several studies demonstrated the feasibility of up to six repeated infusions of IV ketamine administered two to three times per week. These studies found a comparable antidepressant response to ketamine as the single-dose studies, noting that effects typically lasted 2.5 to 3 weeks; ketamine was generally well tolerated. One study that compared twice-weekly versus thrice-weekly IV ketamine infusions over 4 weeks found no significant difference in response rates over a 15-day follow-up period. Another study that reviewed two Cochrane reviews, 14 meta-analyses, and 15 clinical trials concluded that 0.5 mg/kg of IV ketamine had rapid and robust antidepressant effects in MDD and bipolar depression. Lower doses were not efficacious. Interestingly, the treatment effect was observed to last longer for individuals with MDD rather than those with bipolar depression and for those who received repeated doses compared to a single dose.

Esketamine for MDD

In 2019, esketamine, administered in conjunction with oral antidepressants, received FDA approval for TRD in adults. The pivotal trials supporting the FDA application comprise a short-term and a long-term study. In the short-term study, 223 adult patients with TRD (defined as inadequate response to at least two different antidepressants in the current episode) were evaluated in a randomized, placebo-controlled, double-blind fashion over a 4-week period. Patients were tapered off their existing antidepressant medications and randomized to receive twice weekly intranasal esketamine (flexible dosing of 56 or 84 mg) or placebo in conjunction with open-label concomitant treatment with a newly initiated daily oral antidepressant (duloxetine, escitalopram, sertraline, or extended-release venlafaxine). As assessed using the Montgomery-Asberg Depression Rating Scale (MADRS), esketamine plus the newly initiated oral antidepressant significantly improved depressive symptoms (mean difference of four points) compared to placebo plus the newly initiated oral antidepressant. In the esketamine groups, most improvement was realized within 24 hours and continued over time through Day 28.

In the long-term study, 297 adults who were known remitters and responders to intranasal esketamine were enrolled in a randomized, double-blind, parallel-group, maintenance-of-effect study. In this 16-week initial trial of intranasal esketamine and an oral antidepressant, stable remitters (MADRS ≤ 12) and stable responders (MADRS reduction ≤ 50%) combined were randomized to receive intranasal esketamine or placebo maintenance treatment (weekly or every other week) in addition to an oral antidepressant. Of 176 patients who achieved stable remission, 24 (26.7%) in the esketamine group and 39 (45.3%) in the placebo group experienced relapse by week 80.

Three other Phase III trials have been conducted with intranasal esketamine. One randomized, double-blind, placebo-controlled trial of 346 adult patients with TRD receiving standard oral antidepressants found that twice-weekly intranasal esketamine was superior at the 4-week time point for the 56 mg dose but not the 84 mg dose. The other large, randomized, double-blind, placebo-controlled trial of 138 older adult TRD patients (≥65 years) receiving standard oral antidepressants found no significant change in the primary outcome measure, change in MADRS score at Day 28. In a long-term safety and efficacy study assessing treatment-emergent adverse events in patients treated with intranasal esketamine, 90% of patients reported such events over a period of 56 weeks, including dizziness (22%), headache (19%), dissociation (19%), renal and urinary tract symptoms (17%), somnolence (14%), and viral upper respiratory tract infections (12%).

Bipolar Depression

Two initial studies of single-dose IV ketamine (0.5 mg/kg) infused over 40 minutes were conducted in adult patients with treatment-resistant bipolar I or II depression who had not responded to an adequate trial of lithium or valproate (study one, *n* = 18; study two, *n* = 15). Both studies were randomized, saline placebo-controlled, crossover, add-on trials with a therapeutic mood stabilizer. Patients were tapered off psychotropic medications other than lithium or valproate and underwent a 2-week washout period. Order of condition was randomized, with a 2-week period between each condition. The MADRS was the primary outcome measure. In both studies, depressive symptoms improved significantly in the ketamine condition compared to the placebo condition and, in both studies, over 70% of participants responded to ketamine (compared to 0% to 6% to placebo). Significant improvement was seen within 40 minutes and lasted through Day 3.

In addition, a recent systematic review examined 6 published studies of 135 individuals with bipolar depression (including the two studies discussed above) who received add-on IV ketamine (0.5 mg/kg over 40 minutes). The authors found an average response rate of 61% for IV ketamine versus 5% for placebo, and the overall response rates ranged from 52% to 80% across the six studies. Notably, two participants in the review (one receiving ketamine and one receiving placebo) developed manic symptoms. The authors concluded that there is preliminary evidence that IV ketamine administration has rapid, though short-term, effects as an adjunctive treatment to conventional mood stabilizers. Additional studies are needed to firmly establish this finding and explore longer-term outcomes.

Suicidality Associated With TRD

One systematic review and meta-analysis of 10 controlled trials (n = 167) of single-dose IV ketamine versus saline placebo or active midazolam control concluded that ketamine rapidly (within 1 day) reduced suicidal ideation with moderate to large effect sizes (Cohen's d = 0.48–0.85) up to 1 week posttreatment. Another systematic review of 25 reports from 15 independent trials (n = 572) concluded that there was moderate to low evidence that ketamine had antisuicidal effects, though the study noted significant heterogeneity in the results and the lack of data on actual suicidal behavior.

Intranasal esketamine also received an FDA indication for depressive symptoms in adults with MDD with acute suicidal ideation or behavior. Two randomized, double-blind, placebo-controlled studies of adults with moderate to severe MDD with active suicidal ideation and intent compared intranasal esketamine (56 or 84 mg) versus placebo twice weekly for 4 weeks, in addition to comprehensive standard of care. In both studies, the intranasal esketamine group demonstrated statistically greater improvement in MADRS scores than the placebo group (study one [n = 223] average difference in improvement = 3.8 points on MADRS; study two [n = 226]) average difference in improvement = 3.9 points on MADRS). Notably, neither study demonstrated the superiority of intranasal esketamine over placebo in a clinician assessment of suicide severity (Clinical Global Impression of Suicidal Severity–Revised [CGI-SS-r]).

Subtypes and Comorbidities

Investigations into the effectiveness of ketamine and esketamine for treating certain subtypes of depression, comorbid symptom constellations, or other diagnoses have only recently begun. Initial evidence suggests that some subtypes of depression (i.e., anxious, anhedonic, or atypical), as well as social anxiety, posttraumatic stress disorder (PTSD), obsessive compulsive disorder (OCD), and some types of substance use disorders may respond to ketamine infusion. However, these data should be considered preliminary and require further study and replication.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

While serious adverse effects may occur with any ketamine dose, they are generally dose-dependent, being more frequent and more severe at higher dosages and with longer durations of use. Indeed, much of the existing information regarding ketamine's effects is drawn from over 50 years of its use as an anesthetic agent, and the adverse effects reviewed in this section are thus associated with doses that are typically several times higher than those recommended for psychiatric indications. The lower ketamine doses associated with antidepressant use (e.g., 0.5 mg/kg IV infused over 40 minutes, administered twice daily over 4 to 6 weeks) are associated with less severe and less frequent adverse effects that are generally transient in nature.

One theoretical concern with ketamine (and other glutamatergic agents) is the possibility of neurodegenerative changes. Neurodegenerative changes, specifically neuronal vacuolization or "Olney lesions," have been reported in animal models administering high doses of NMDA receptor antagonists such as PCP, MK-801, or ketamine. However, a recent animal study found dose-dependent induction of "Olney lesions" for MK-801 (up to 0.8 mg/kg subcutaneous) but not for ketamine (up to 20 mg/kg IV or 60 mg/kg intraperitoneally) or its metabolite (2*R*,6*R*)-HNK (160 mg/kg IV). Olney lesions from ketamine exposure have not been documented in human studies.

Central Nervous System

Ketamine and esketamine's most common adverse effects are neuropsychiatric in nature. Dissociative symptoms, which over 70% of patients report experiencing, are the hallmark of IV ketamine administration. Dissociative symptoms include perceptual disturbances, abnormal and vivid sensory experiences, hallucinations, derealization (feeling detached from your surroundings), and depersonalization (loss of identity, feeling separate and/or outside of one's body). They may be accompanied by emotional dysregulation, sedation, agitation, confusion, and memory disturbance. If dissociative symptoms are severe, they may lead to a condition of complete disconnection and nonresponsiveness. Dissociative symptoms are generally experienced at the time of administration, are transient, and typically resolve with 2 hours postadministration. Psychotomimetic effects (nondissociative psychotic symptoms) may also emerge, particularly in patients with a history of schizophrenia.

At anesthetic doses, emergence reactions have been reported in approximately 12% of patients. Emergence reactions include confusion, severe psychomotor agitation, and amnesia that may begin shortly after administration and last 2 to 4 hours postadministration, though recurrence has been reported up to 24 hours postadministration. When emergence reactions occur, they may be treated with low-dose benzodiazepines or barbiturates.

Increased intracranial pressure has also been reported following ketamine administration. Finally, in pediatric populations, long-term cognitive deficits have been noted when ketamine is used for longer than 3 hours in children 3 years old or younger.

Cardiovascular System

At antidepressant doses, both ketamine and esketamine have been associated with transient hypertension and tachycardia. Rare reports of hypotension, bradycardia, arrhythmias, and cardiac decompensation have also been associated with ketamine administration. Thus, it is recommended that vital signs and cardiac function be monitored during ketamine and esketamine administration; both agents are contraindicated in patients with uncontrolled significant hypertension.

Gastrointestinal System

Gastrointestinal symptoms of nausea, vomiting, and anorexia are relatively common with ketamine and esketamine administration, including with antidepressant doses. If gastrointestinal symptoms are present, postponing treatment should be considered. Symptoms that develop over the course of treatment may require antinausea or antiemetic intervention. Airway management to prevent aspiration may be required if vomiting occurs during treatment.

Hepatic System

Short-term use of ketamine for anesthesia has been associated with rare instances of transient and clinically nonsignificant serum enzyme elevations. Longer-term recurrent use has been associated with hepatobiliary dysfunction (most often cholestatic pattern) with dilation and irregularity of the bile ducts. Patients may develop right upper quadrant discomfort and tenderness along with elevated serum alkaline phosphatase and aminotransferase levels and minimal or no increases in bilirubin levels. Monitoring baseline and follow-up liver function panels during treatment is recommended. If issues persist, discontinuation of ketamine administration is recommended.

Pulmonary System

Though rarely seen with antidepressant doses, risk of respiratory depression may occur with ketamine overdosage or too rapid a rate of administration. Maintaining adequate oxygenation and ventilation is recommended.

Urologic System

Long-term chronic ketamine use has been associated with inflammation and irritation of the urinary bladder and urethra. Symptoms may include dysuria, increased urinary frequency, and increased urinary urgency, urge incontinence, and hematuria. Diagnostic studies have identified cystitis, hydronephrosis, and reduced bladder capacity.

Immunologic Effects

Anaphylactic reactions are rare but have been reported with ketamine and esketamine administration.

Pregnancy

No controlled studies have examined the safety of ketamine use in human pregnancy. In rats and nonhuman primates, ketamine use during pregnancy was associated with altered neurodevelopment and neurodegeneration. In rat studies, esketamine similarly demonstrated adverse effects in offspring. Animal studies also suggest that ketamine is excreted in breast milk. Ketamine and esketamine have not been assigned a pregnancy risk category by the FDA, and their use is not recommended during pregnancy or breastfeeding.

Therapeutic Implications

IV ketamine is FDA-approved as a sole anesthetic agent for diagnostic and surgical procedures that do not require skeletal muscle relaxation, for the induction of anesthesia prior to the administration of other general anesthetic agents, and as a supplement to other anesthetic agents.

Intranasal esketamine is FDA-approved in adults to treat TRD or MDD with acute suicidal ideation or behavior.

Precautions and Adverse Reactions

Adverse effects associated with ketamine and esketamine are largely dose-dependent. Given that doses for psychiatric indications are typically several times lower than anesthetic doses, the adverse effects seen with anesthetic or illicit use of ketamine are greatly reduced. Common adverse events associated with anesthetic ketamine include emergence reactions and elevated blood pressure and pulse. The primary concerns with ketamine and esketamine administered at doses suggested for psychiatric indications include: dissociative symptoms, confusion, memory dysfunction, hypertension, tachycardia, emergence reactions, and risk of abuse and dependence. The most common adverse events at doses suggested for TRD include: dissociation, visual distortions, difficulty speaking, numbness, confusion, dizziness, faintness, drowsiness/sedation, euphoria, blurred vision, and hypertension. For intranasal esketamine, the most common adverse events include dissociation, dizziness, nausea, sedation, vertigo, hypoesthesia, anxiety, lethargy, increased blood pressure, vomiting, and feeling drunk. Common and other potentially serious adverse events are listed in Table 33.14a–1.

Table 33.14a–1.
Adverse Events Associated With Ketamine and Esketamine

Drug	Common Adverse Events at Antidepressant Doses	Other Potential Serious Adverse Events (including at higher doses)
Ketamine	Dissociation, visual distortions, difficulty speaking, numbness, confusion, dizziness, faintness, drowsiness/sedation, euphoria, blurred vision, and hypertension.	Hemodynamic instability, emergence reactions, risk of respiratory depression, risk of use of ketamine alone for procedures of the pharynx, larynx, or bronchial tree (as pharyngeal and laryngeal reflexes are not suppressed by ketamine), and pediatric neurotoxicity.[a]
Esketamine	Dissociation, dizziness, nausea, sedation, vertigo, hypoesthesia, anxiety, lethargy, increased blood pressure, vomiting, and feeling drunk.	Risk of sedation and dissociation, potential for abuse and misuse, availability only through REMS, and increased risk of suicidal thoughts and behaviors in pediatric and young adult patients taking antidepressants.

[a] Rates and type of side effects vary depending on dose and duration of administration. These serious adverse events are rare at doses and durations used for psychiatric indications.

The FDA label for ketamine (approved for anesthetic indications) has warnings and precautions for hemodynamic instability, emergence reactions, risk of respiratory depression, risk of use of ketamine alone for procedures of the pharynx, larynx, or bronchial tree (because pharyngeal and laryngeal reflexes are not suppressed by ketamine), and pediatric neurotoxicity. It is contraindicated in patients for whom a significant elevation of blood pressure would be a serious hazard and for those with known hypersensitivity to ketamine or to any excipient.

Esketamine (approved for psychiatric indications) is contraindicated in aneurysmal vascular disease (including thoracic and abdominal aorta, intracranial, and peripheral arterial vessels) or arteriovenous malformation, intracerebral hemorrhage, and hypersensitivity to esketamine, ketamine, or any of their excipients. Esketamine has a boxed warning for risk of sedation and dissociation, potential for abuse and misuse, availability only through REMS, and increased risk of suicidal thoughts and behaviors in pediatric and young adult patients taking antidepressants. The risk/benefit ratio for patients at higher risk of abuse should be considered prior to prescribing, and patients should be monitored for signs and symptoms of abuse and misuse as well as for clinical worsening and emergence of suicidal thoughts and behaviors. Additional warnings and precautions for esketamine include increased blood pressure, cognitive impairment, impaired ability to drive and operate machinery, and embryo–fetal toxicity.

Ketamine is classified as a Schedule III controlled substance under the Controlled Substance Act. According to the Surgeon General’s Report on Alcohol, Drugs, and Health, recreational misuse of ketamine has been increasing. In 2015, an estimated 3 million individuals (1.1%) aged 12 or older had tried ketamine in their lifetime. Ketamine, also known as K, Special K, Vitamin K, or Cat Valium, can be injected, snorted, smoked (added to tobacco or marijuana cigarettes), or ingested to induce a feeling of detachment and altered perception and consciousness. In abuse, ketamine is typically administered in higher doses than those recommended for psychiatric indications, often approaching anesthetic doses of 50 to 100 mg. These higher doses may generate a state of noncommunicativeness (termed the “K-hole”) that is experienced as extreme disconnectedness, lack of awareness of self and surroundings, and unresponsiveness to external stimuli; accidental overdoses may also occur. Repeated use of ketamine may result in the development of tolerance and a dependency syndrome, and psychological withdrawal symptoms may occur when use is curtailed.

For both ketamine and esketamine, side effects may be monitored during administration using a questionnaire such as the Ketamine Side Effect Tool (KSET).

DRUG INTERACTIONS

Ketamine and esketamine interact with many other drugs. Both undergo hepatic metabolism via CYP 3A4 and 2B6, and inhibitors of these isoenzymes may increase ketamine and esketamine drug levels while inducers may decrease levels. Both ketamine and esketamine also act as CPY 3A4 inducers and may decrease levels of drugs metabolized by this route. It is recommended that interactions be checked before using ketamine or esketamine in combination with other drugs.

Notable interactions include:

- Benzodiazepines and other GABA agonists: Administration of concomitant benzodiazepine and other GABA agonist drugs (such as barbiturates) may attenuate or delay antidepressant response.
- Lamotrigine: Concomitant lamotrigine administration may also attenuate antidepressant response, given that it decreases glutamate release.
- Sympathomimetics and vasopressin: Vital signs should be closely monitored when these agents are coadministered with ketamine. Consider dose adjustment individualized to the patient's clinical situation.
- Opioid analgesics or other central nervous system (CNS) depressants: Concomitant use of ketamine with opioid analgesics, benzodiazepines, or other CNS depressants, including alcohol, may result in profound sedation, respiratory depression, coma, and death. Concomitant use of opioid analgesics may prolong recovery time.
- Monoamine oxidase inhibitors (MAOIs): Given the risk of hypertension associated with MAOIs, coadministration of these agents with ketamine should be done with caution and close monitoring of vital signs.
- Theophylline or aminophylline: Concomitant administration of ketamine and theophylline or aminophylline may lower the seizure threshold.

Table 33.14a–2.
Dosing of Ketamine and Esketamine

Drug	Indication	Dose
Ketamine	Anesthesia induction	IV: 1–4.5 mg/kg slow IV, single dose IM: 6.5–13 mg/kg IM, single dose
	Anesthesia maintenance	50% of IV ketamine induction dose PRN, or 0.1–0.5 mg/minute IV continuous infusion
	TRD (off label)	IV: 0.5 mg/kg over 40 minutes up to twice weekly; not to exceed 6 weeks
Esketamine	TRD	Intranasal
	Induction	Weeks 1–4: 56 mg (starting dose), may titrate to 84 mg twice weekly
	Maintenance	Weeks 5 to 8: 56 or 84 mg once weekly Week 9 and thereafter: 56 or 84 mg once weekly or once every 2 weeks

TRD, treatment-resistant major depressive disorder; IV, intravenous; IM, intramuscular; PRN, as needed.

DOSAGE AND ADMINISTRATION

Typical doses for the given indications are presented in Table 33.14a–2. For psychiatric indications, the IV ketamine dose is 0.5 mg/kg, given over a 40-minute infusion. Other dosages and routes of administration have not been adequately studied.

The intranasal esketamine dose is either 56 or 84 mg. In the induction phase (weeks 1 to 4), dosing begins twice weekly with a starting dose of

56 mg. After the first administration, the dose may be titrated up to 84 mg as clinically indicated. In the maintenance phase, dose administration is reduced to once weekly for 4 weeks and then continues at once weekly or decreases to once every other week. As noted above, due to concerns about sedation, dissociation, and abuse potential, intranasal esketamine is currently being administered only under an FDA-required REMS program. The drug must only be distributed to REMS certified hospitals and clinical settings and administered by patients under the direct observation of a health care provider who must observe the administration, and the patient must be monitored for at least 2 hours postadministration. Intranasal esketamine may impair the ability to drive or operate machinery; patients should not engage in these activities on the day of administration or the following day.

FUNDING AND DISCLOSURES

Funding for this work was provided by the Intramural Research Program at the National Institute of Mental Health, National Institutes of Health (IRP-NIMH-NIH; ZIAMH002857). Dr. Zarate is listed as a co-inventor on a patent for the use of ketamine in major depression and suicidal ideation; as a coinventor on a patent for the use of (2*R*,6*R*)-HNK, (*S*)-dehydronorketamine (DHNK), and other stereoisomeric dehydroxylated and hydroxylated metabolites of (*R,S*)-ketamine metabolites in the treatment of depression and neuropathic pain; and as a coinventor on a patent application for the use of (2*R*,6*R*)-HNK and (2*S*,6*S*)-HNK in the treatment of depression, anxiety, anhedonia, suicidal ideation, and PTSD. He has assigned his patent rights to the U.S. government but will share a percentage of any royalties that may be received by the government. Dr. Park has no conflict of interest to disclose, financial or otherwise.

ACKNOWLEDGMENTS

The authors thank the 7SE research unit and staff for their support. Ioline Henter (NIMH) provided invaluable editorial assistance.

33.14b MDMA, Psilocybin, Ayahuasca, and Ibogaine

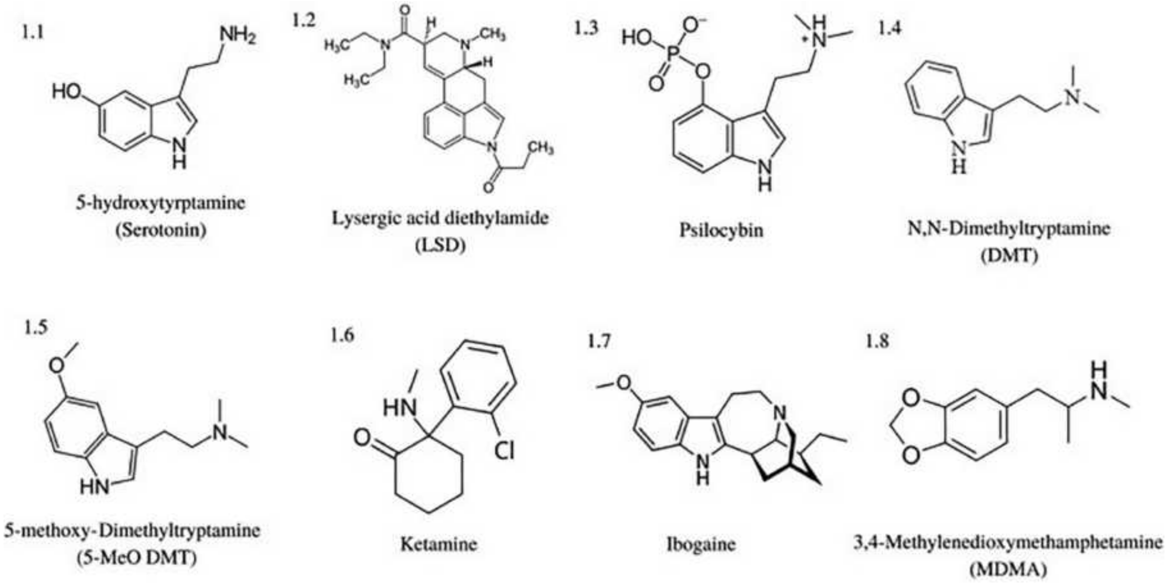
DAVID NUTT, F.R.C.P., F.R.C.PSYCH., F.B.PH.S., F.MED.SCI., D.LAWS., AND DAVID ERRITZOE, M.D., PH.D., M.R.C.PSYCH.

In this chapter, we cover the resurgence of clinical research in the use of serotonergic psychedelic drugs such as psilocybin and the synthetic entactogen MDMA (methylenedioxymethamphetamine). These are currently classified as “illegal” under the UN conventions on psychotropic drugs on the grounds that they are harmful and have no special medical value. These assertions are not evidence-based, as psilocybin, LSD, and MDMA all had significant evidence of medical benefit before being made illegal. The ban has very significantly impeded research for several decades, but a few centers have begun to revisit clinical research with these compounds. This research is underpinned by neuroimaging studies that have revealed their unique modes of action on the brain. This chapter focuses on the new clinical data with some reference to the earlier research and relevant preclinical and neuroimaging studies of mechanisms. Note: Ketamine can have psychedelic properties, but its pharmacologic target is glutamate and is covered in a separate chapter.

BACKGROUND AND EARLY STUDIES PREBANNING

Psychedelics

Most psychedelics are agonists of the 5-HT2A receptor and many are structural analogues of serotonin (see Fig. 33.14b–1). They include plant products such as ergot, mescaline (peyote cactus), DMT (ayahuasca) and ibogaine, plus psilocybin (magic mushrooms), and some of animal origin, for example, 5-MEO-DMT. They have been used for millennia in different cultures across the globe. LSD a derivative of ergot was made in 1943 by Albert Hofmann at Sandoz. Sandoz made LSD available to researchers across the world under the trade name *Delysid*. Research with LSD (and to a lesser extent psilocybin) flourished with the U.S. NIH funding over 130 grants for clinical LSD studies (though none since the 1967 ban). This research led to hundreds of papers. LSD trips were used to model psychosis as they mimicked some of the symptoms of acute psychosis, particularly ego-dissolution thought disorder and misperceptions. Lower doses were used to “unblock” psychological resistance in psychotherapy. One interesting area was in the treatment of alcohol use disorder. Bill Wilson, the founder of Alcoholics Anonymous, reported he “escaped” from the chains of his addiction as a result of a trip. Wilson’s own experience led him to promote the use of LSD in the treatment of alcohol use disorder, and six trials were conducted before the drug was banned. A modern meta-analysis of these data by Krebs and Johansen found this to be more efficacious than any current therapies.



1.1 5-hydroxytyrptamine (Serotonin)

1.2 Lysergic acid diethylamide (LSD)

1.3 Psilocybin

1.4 N,N-Dimethyltryptamine (DMT)

1.5 5-methoxy-Dimethyltryptamine (5-MeO DMT)

1.6 Ketamine

1.7 Ibogaine

1.8 3,4-Methylenedioxymethamphetamine (MDMA)

FIGURE 33.14b–1. Chemical structures.

For political reasons, rather than real evidence of harm, in 1967, the U.S. government banned LSD and related hallucinogens question ban consolidated internationally under the 1971 UN convention on narcotic drugs. They were all put into Schedule 1, which is for drugs defined as having no accepted special medical use plus significant potential for harm and dependence. This scheduling effectively stopped research on psychedelics for over 40 years, and only in the past decade have attempts been made to reverse this.

Methylenedioxymethamphetamine

MDMA is a synthetic molecule related to methamphetamine that in the 1960s was synthesized and tested by Alexander Shulgin, who reported it to have unique proempathy (entactogenic) properties. MDMA was widely used on the west coast of the United States by psychotherapists, especially in couples counseling, where its entactogenic effects allowed couples to regain the affection that was present when they fell in love and so helped them rebuild their failing relationships. At that time, it was called empathy and was legal, whereas other amphetamine-like drugs were banned. Because it was legal, MDMA became sold for recreational purposes, especially in clubs and raves where its name was changed to ecstasy. This led to a media and political backlash that resulted in MDMA being banned, and treatment stopped.

THE TWENTY-FIRST–CENTURY RESURRECTION OF PSYCHEDELICS AND MDMA IN PSYCHIATRY

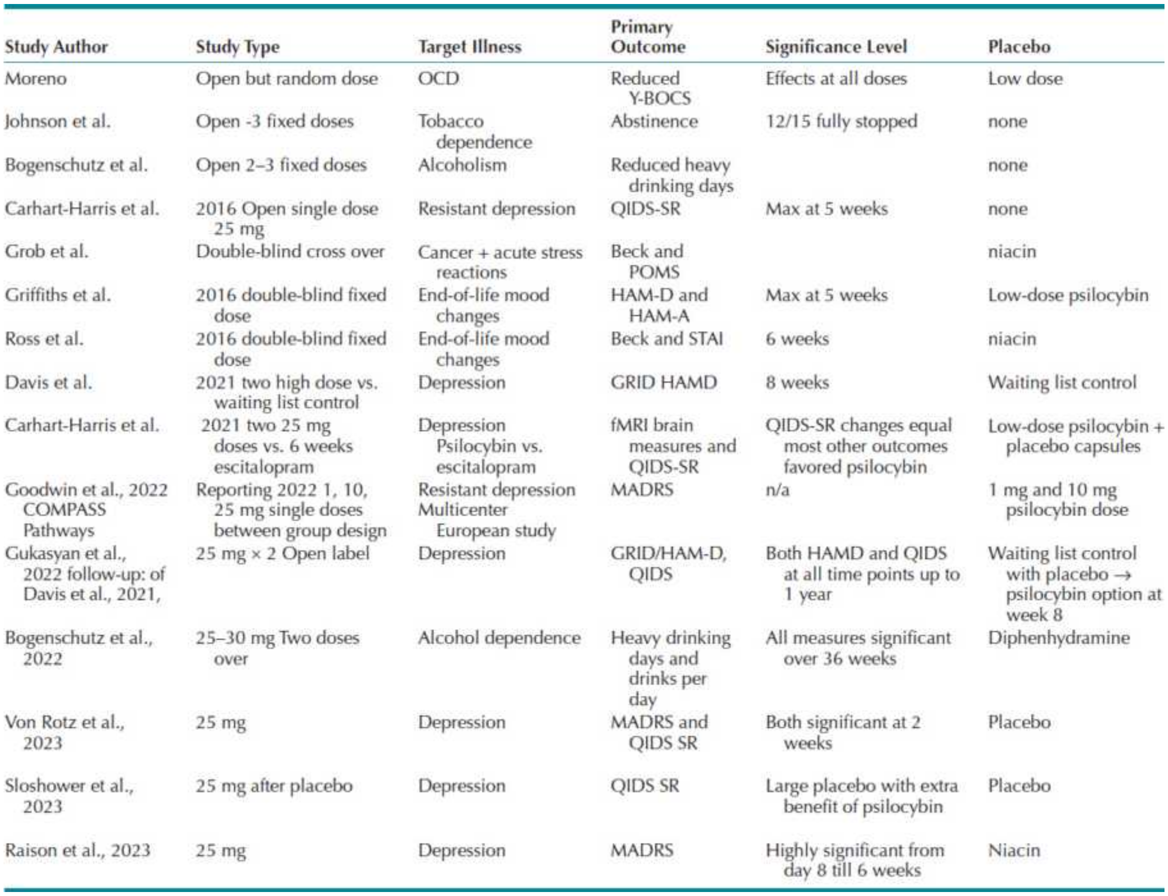
Over the past two decades, research on psychedelics has resumed due to persistence from a small group of researchers. Two themes drove this. One was the discovery, using neuroimaging techniques, of their very novel effects on the brain. The other was from some small exploratory clinical studies. The neuroimaging results with both fMRI and MEG were unexpected and surprising, revealing a reduction in brain activity in many regions but particularly the default mode network (DMN), including in the subgenual cingulate cortex (SGC). Many different treatments for depression have been found to reduce SGC activity, and other imaging studies have found the DMN overactive in depression.

PSILOCYBIN TRIALS

The first modern clinical trial of a psychedelic was by Moreno and colleagues, who gave nine subjects with treatment-resistant OCD up to four different doses of psilocybin in an open-label design (Table 33.14b–1). Then Grob and colleagues gave 12 subjects with advanced cancer diagnoses that resulted in DSM-IV-defined acute stress or anxiety disorders a moderate (0.2 mg/kg) dose of psilocybin and an active placebo (niacin 250 mg) in a double-blind within-subject design. The Johnson/Griffiths team at Johns Hopkins has subsequently conducted several clinical trials. The first was an open study on 15 people trying to quit tobacco smoking. They were given psilocybin 25 mg three times during a 20-week tobacco quitting course. Outcomes were assessed by urinary cotinine level plus smoking craving and urge for up to 6 months. Twelve and 10 of the 15 subjects became and remained smoking-free at 6 and 12 months, respectively, a very significant outcome.

The other addiction study with psilocybin was conducted by Bogenschutz and colleagues at the University of New Mexico, who gave two psilocybin sessions to 10 alcohol-dependent patients in addition to a standard psychotherapy course. They found a marked reduction in the percentage of heavy drinking days, and the psilocybin was well-tolerated.

Table 33.14b–1.
Psilocybin Studies



Study Author	Study Type	Target Illness	Primary Outcome	Significance Level	Placebo
Moreno	Open but random dose	OCD	Reduced Y-BOCS	Effects at all doses	Low dose
Johnson et al.	Open -3 fixed doses	Tobacco dependence	Abstinence	12/15 fully stopped	none
Bogenschutz et al.	Open 2–3 fixed doses	Alcoholism	Reduced heavy drinking days		none
Carhart-Harris et al.	2016 Open single dose 25 mg	Resistant depression	QIDS-SR	Max at 5 weeks	none
Grob et al.	Double-blind cross over	Cancer + acute stress reactions	Beck and POMS		niacin
Griffiths et al.	2016 double-blind fixed dose	End-of-life mood changes	HAM-D and HAM-A	Max at 5 weeks	Low-dose psilocybin
Ross et al.	2016 double-blind fixed dose	End-of-life mood changes	Beck and STAI	6 weeks	niacin
Davis et al.	2021 two high dose vs. waiting list control	Depression	GRID HAMD	8 weeks	Waiting list control
Carhart-Harris et al.	2021 two 25 mg doses vs. 6 weeks escitalopram	Depression Psilocybin vs. escitalopram	fMRI brain measures and QIDS-SR	QIDS-SR changes equal most other outcomes favored psilocybin	Low-dose psilocybin + placebo capsules
Goodwin et al., 2022 COMPASS Pathways	Reporting 2022 1, 10, 25 mg single doses between group design	Resistant depression Multicenter European study	MADRS	n/a	1 mg and 10 mg psilocybin dose
Gukasyan et al., 2022 follow-up: of Davis et al., 2021,	25 mg × 2 Open label	Depression	GRID/HAM-D, QIDS	Both HAMD and QIDS at all time points up to 1 year	Waiting list control with placebo → psilocybin option at week 8
Bogenschutz et al., 2022	25–30 mg Two doses over	Alcohol dependence	Heavy drinking days and drinks per day	All measures significant over 36 weeks	Diphenhydramine
Von Rotz et al., 2023	25 mg	Depression	MADRS and QIDS SR	Both significant at 2 weeks	Placebo
Sloshower et al., 2023	25 mg after placebo	Depression	QIDS SR	Large placebo with extra benefit of psilocybin	Placebo
Raison et al., 2023	25 mg	Depression	MADRS	Highly significant from day 8 till 6 weeks	Niacin

Two studies of psilocybin in major depressive disorder have been conducted by the Imperial College group of Nutt and Carhart-Harris. In the first, an open study, patients with resistant depression were given two doses of psilocybin (a 10 mg “test” dose and a 25 mg therapeutic dose) 1 week apart with psychological support before and after the experience. In practice, participants were usually multiply-treatment resistant (mean number of failed medications was 4.6 +/− 2.6), and the illness was very long-standing (mean duration of illness was 17.7 years +/− 8.4 years). The primary outcome measure was the mean change in the participant-rated quick inventory of depressive symptoms (QIDS-SR) rating scale with follow-up for 6 months. Highly significant improvements in depression ratings were seen at all time points, with the maximal effect at 5 weeks (Cohen’s *d* = 2.3). The trial established the feasibility and initial evidence of safety, but efficacy interpretations are limited by the open-label design.

Subsequently, they conducted a comparative trial of two 25 mg doses of psilocybin 3 weeks apart versus the SSRI escitalopram (10 mg for 3 weeks, then 20 mg for a further 3 weeks). The escitalopram group was also given two 1 mg (placebo equivalent) treatments of psilocybin with psychological support, so both groups had the same level of psychotherapy. The primary outcomes were mood and well-being changes from baseline at 6 weeks. Well-being was significantly improved by both treatments but more with the high-dose psilocybin. Depression scores also improved with both treatments, and though the primary measure—change in QIDS SR—did not differentiate the groups, all other mood measures favored psilocybin, as did remission rates.

fMRI imaging of both groups revealed fundamental differences in the brain effects of psilocybin compared with escitalopram (Daws et al., 2022).

Several further studies have been conducted—see Table 33.14b–1. Of particular importance is the Goodwin et al.'s 2022 study as it was the first by a pharmaceutical company. This was a large multicenter, multicountry RCT in patients with treatment-resistant depression in which three doses (1, 10, 25 mg) of psilocybin were used. The 25-mg dose produced remission rates of 25% at 3 months—so replicating the Carhart-Harris studies. The lower (nontrip) doses had very little therapeutic impact. Based on this, a phase 3 study of 25 mg in treatment-resistant depression has been started. In 2023, Raison et al. reported a major U.S. multicenter study in which a single 25-mg psilocybin dose produced profound and enduring reductions in depression.

An important consequence of these positive trials is that in July 2023 the Australian regulators approved the use of psilocybin on a compassionate basis for patients with treatment-resistant depression.

Finally, three separate controlled studies have been published on the use of psilocybin for anxiety and depression associated with life-threatening illnesses. Griffiths and his Johns Hopkins team treated 51 patients with anxiety and depressive symptoms occasioned by a life-threatening cancer diagnosis. Placebo was a very low (ineffective) dose of psilocybin (1 mg or 3 mg/70 kg) compared with the much higher active treatment dose (22 mg or 30 mg/70 kg). The administration was counterbalanced with 5 weeks between sessions and a 6-month follow-up. The Hamilton Depression and Anxiety scales were the primary outcome measures and showed superiority for the high dose versus the low dose at 5 weeks. The placebo group was then crossed over to a high dose, and these experienced significant improvements also.

In a similarly designed study, Ross and colleagues at NYU gave 29 patients a single dose of 0.3 mg/kg psilocybin or 250 mg niacin as an active placebo with crossover at 7 weeks. The treatment was delivered safely, with no reports of serious adverse events. The group receiving psilocybin showed clinical benefits as measured by both clinician and participant-rated scales that lasted for 7 weeks prior to crossover and were also sustained approximately 8 months after dosing. The group that received niacin showed transient reductions that were not sustained at 7 weeks. After they crossed over to psilocybin, they also showed immediate and sustained reductions in anxiety and depression scores that were sustained at 6 months.

Additionally, Gasser et al. in Switzerland performed a trial with LSD, either a low (20 ug) or a high (200 ug) dose in depression/trauma patients, and these data led to this drug being made available for compassionate use by a few psychiatrists in that country.

Other controlled trials of psilocybin in OCD anorexia and addictions are underway.

DMT AND AYAHUASCA

A number of countries in South and Latin America allow the use of ayahuasca drink for religious and therapeutic purposes. This drink contains a mixture of plant products, one of which contains the psychedelic dimethyl tryptamine (DMT) and the other a monoamine oxidase inhibitor harmaline. The harmaline blocks the activity of MAO in the gut and liver and so allows the DMT in the drink to get to the brain. Human neuroimaging studies of ayahuasca have shown it to have similar effects to psilocybin and LSD, and several open clinical trials have been conducted in depressed patients. The first RCT was conducted by Palhano-Fontes, who found rapid and highly significant reductions in depressive symptoms. However, moving ayahuasca into Western medicine is challenging because it is a plant mixture of two active ingredients, so concentrations of these are hard to control, plus the need for coadministration of an MAOI is problematic for some patients. To overcome these issues, several pharmaceutical companies are now developing infusions of synthetic DMT as a potential antidepressant and antiaddiction treatment. Also, the related compound 5-MEO-DMT, a very potent short-acting psychedelic, is being developed for clinical testing.

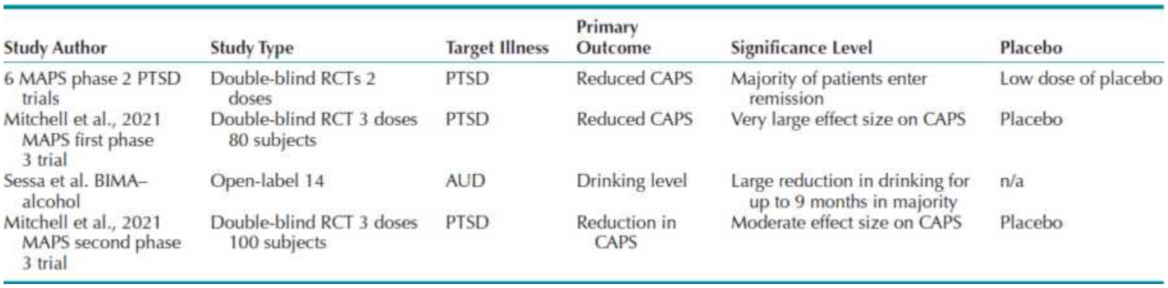
IBOGAINE

Ibogaine has developed in a number of countries as an off-license treatment for addictions, especially heroin though there are no high-quality studies. Some deaths have been reported probably due to QTc prolongation. This cardiac effect has limited research, and its effects on the brain are not yet characterized. An active metabolite noribogaine is being developed as a possibly safer alternative.

METHYLENEDIOXYMETHAMPHETAMINE

Though MDMA isn't a psychedelic in the true sense of the word, it does have profound effects that allow people insights into their psychiatric problems and has proved especially helpful in the treatment of PTSD. Several studies run by the Mithoefers for MAPS (Multidisciplinary Association for Psychedelic Studies) have demonstrated that a couple of sessions of exposure therapy under MDMA (usually 125 mg + a 62.5 mg booster after 2 hours) can have powerful therapeutic effects (Table 33.14b–2). Based on these positive findings, both the FDA and EMA gave their approval for multicenter studies in the United States and Europe and the first one of these was reported in 2021 by Mitchell et al. and the second in a broader patient group including some less severely ill patients by Mitchell et al. (2023). Both reported very positive clinical outcomes and good safety so it seems likely that MDMA will also become an approved medicine sometime in the 2020s. As already mentioned with psilocybin, these positive trials with MDMA led to the Australian regulators in July 2023 approving the use of MDMA on a compassionate basis for patients with treatment-resistant PTSD.

Table 33.14b–2.
MDMA Trials



Study Author	Study Type	Target Illness	Primary Outcome	Significance Level	Placebo
6 MAPS phase 2 PTSD trials	Double-blind RCTs 2 doses	PTSD	Reduced CAPS	Majority of patients enter remission	Low dose of placebo
Mitchell et al., 2021 MAPS first phase 3 trial	Double-blind RCT 3 doses 80 subjects	PTSD	Reduced CAPS	Very large effect size on CAPS	Placebo
Sessa et al. BIMA–alcohol	Open-label 14	AUD	Drinking level	Large reduction in drinking for up to 9 months in majority	n/a

Key Differences Between Psychedelic/MDMA Therapy and Conventional Treatments in Psychiatry

Treatment with psychedelics and MDMA is more complex than conventional antidepressant therapies as it requires psychotherapy as well as drug administration. It is, therefore, best considered a new form of psychiatric treatment—drug-assisted psychotherapy (or psychotherapy-assisted drug treatment). Patients have to be properly prepared for the powerful psychological impact of the psychedelic/MDMA session, and this involves at least one dedicated prep session with a trained therapist (often called a guide) before the drug session. In this prep session, the patient is educated about the rationale, purpose, and procedure of the drug administration session and is reassured that they will be looked after throughout it.

The drug session itself is usually given in an environment that optimizes patient comfort and security—often a pleasantly decorated room (rather than a traditional medical clinic) with soft ambient lighting and a comforting soundtrack (as music may contribute to the therapeutic value as well). Ideally, two, though at least one, therapists (often called guides) are present in the room (optimally one male and one female) who are there to provide reassurance, medical cover, and care. They only talk with the patient if the patient wants to, which they generally do not. It is important to note that there is no expectation of conversation during the “trip” and no direction by either therapist of the patient’s speech or thought. It is the next day in the “integration” session that the contents and experiences of the trip are discussed with the same guides(s), and psychotherapeutic insights are developed and promoted. Often additional integrations visits (typically 2 to 4 in total) are part of the study design, and in addition, different psychotherapeutic methods, namely Acceptance and

Commitment Therapy (ACT), are being tested as an integrated part of the psychedelic-assisted therapy program. An important difference between psychedelic- and MDMA-assisted therapy is that therapists/guides are more actively engaged during a therapeutic session with MDMA than with psychedelics. Whereas therapeutic material, such as trauma, is discussed actively during the presence of MDMA, the approach with psychedelics is more “hands off” during the exposure period to the drug (i.e., during the trip). In psychedelic therapy sessions, patients typically spend most of the time wearing eyeshades with music in their ears and with the guide(s) providing support to ensure that the patients feel safe during the experience rather than engaging in or exploring therapeutic content. With psychedelics, the active involvement of the therapist occurs before and after the actual experience in the preparation and integration of the sessions.

For some patients, the impact of just one or two dosing sessions can be very long-lasting—allowing the concept of a “cure” to be considered. For others, the beneficial effects though powerful, wane over time probably as the underlying disorder has become so deeply entrenched in the brain. Top-up treatments are now being explored for patients who relapse, but the still-illegal status of these drugs in most countries makes their use outside of clinical trials impossible.

What about safety? Although the banning of psychedelics and MDMA was based on largely fictitious claims of harm, there is no doubt that psychedelics, in particular, are powerful mind-altering drugs that can leave deep negative as well as positive memories. There is also the risk of precipitating or worsening psychosis, and so they are to be avoided in patients with a history of psychosis in themselves (or in first-degree family members) and most studies excluded patients with bipolar depression in case mania might be precipitated. With these precautions, modern psychedelic research has confirmed the data from the 1950 and 1960s, which found adverse effects to be rare. Note that a bad trip can be terminated with a benzodiazepine given either IM or IV or with a serotonin 5-HT2A receptor blocker (e.g., risperidone or olanzapine).

One common clinical challenge is the fact that so many patients are already on antidepressants and other drugs that block the effects of psychedelics. 5-HT2A receptor-blocking antipsychotic drugs such as quetiapine and olanzapine, as well as some antidepressants such as mirtazapine, block the access of the psilocybin to the 5-HT2A receptor, so it cannot work; the effects of MDMA are also attenuated. Also, SSRIs desensitize these receptors and so reduce the psychedelic effects. To optimize therapeutic effects, it’s best to stop these, but this has to be done with care to avoid the risk of worsening the underlying depression and producing withdrawal or discontinuation reactions.

HOW DO THESE DRUGS WORK?

The current thinking about psychedelics and depression is that they disrupt the dysregulated brain circuits that underpin depression, PTSD, and addictions. In the introduction, we already mentioned the switching down of activity in the SGC by psilocybin, in common with other treatments for depression. Another interesting idea is that psilocybin reduces brain activity—and communication between cortical mid-line regions—within the DMN. Several neuroimaging studies have demonstrated that a much greater amount of the brain is engaged in the DMN in depressed people than in healthy controls, likely a manifestation of the intense self-deprecatory rumination that these patients experience. Psychedelics are thought to completely disrupt this DMN overactivity, so for the duration of the trip, these thinking processes stop. Recent data also suggest some of these brain effects are lasting beyond the presence of the drug. This in itself may give the patients a view of a depression-free world, but more than that, the increase in brain flexibility produced by 5-HT2A receptor stimulation may allow the brain to reset itself into a different, depression-free state. Another possibility shown by fMRI connectivity analysis is that psilocybin may alter the pattern of dominant connections between the frontal cortex and subcortical regions.

There is now good conceptual evidence that the antidepressant effects of psychedelics are mediated in quite a different way to those of serotonin-acting antidepressant drugs such as SSRIs. The latter seems to provide a buffer against stress by enhancing serotonin function at the 5-HT1A receptor and so making the person more resilient. In contrast, we believe that psychedelics, via stimulation of the 5-HT2A receptor, work to reset the brain processes that underpin depressive thinking and so allow the patient to work through their issues and so overcome their depression.

MDMA works differently; it is a serotonin-releasing agent. fMRI studies have revealed its main activity being in the limbic system, where it suppresses activity, especially in the amygdala and hippocampus. This damping down of the emotional memory circuits helps patients relive their traumas and, at the same time, overcome and eventually extinguish the intense emotions that go with these memories.

MICRODOSING

In recent years the use of subpsychedelic and even subdetectable doses of psychedelics, typically 5% to 10% of full psychedelic doses, has become popular, especially among people working in the creative industries who believe it improves creativity. Some claim it helps keep depression and/or anxiety at bay. These doses are taken regularly, usually a couple of times a week over longer periods (weeks/months). However, since these drugs are illegal, there is no way of knowing for sure what they are and what exact doses are being taken. The best-controlled trial, using a novel citizen science "self-blinding" approach conducted by Szigeti et al. found that the effect of LSD and psilocybin microdosing was likely mostly due to expectation.

33.15 Hormone Receptor Enhancers

33.15a Melatonin Receptor Agonists

TAWNY L. SMITH, PHARM.D., B.C.P.P., AND D. JEFFREY NEWPORT, M.D., M.S., M.DIV.

Neuroscience-Based Nomenclature (NbN)	
Melatonin, Rameleton, Tasimelteon	
Pharmacologic Domain	Melatonin
Mechanism of Action	Receptor agonists (MT1, MT2)
Agomelatine	
Pharmacologic Domain	Melatonin, Serotonin
Mechanism of Action	Receptor agonist (M1, M2), receptor antagonist (5-HT2B, 5-HT2C)

Insomnia is the most common sleep disorder, affecting approximately one-third of U.S. adults (NHLBI 1999), with as many as one in five regularly experiencing insomnia. *DSM-5-TR* characterizes Insomnia Disorder as difficulty initiating or maintaining sleep, or early morning awakening with an inability to return to sleep, occurring 3 or more nights per week for at least 3 months that results in significant psychosocial impairment, affecting physical and mental health, productivity, and quality of life. While therapeutic guidelines recommend cognitive behavioral therapy as a first-line intervention for insomnia, pharmacotherapies are commonly employed. Historically, many classes of pharmacologic agents have been used to treat insomnia, including classic benzodiazepines, other benzodiazepine receptor agonists (i.e., “z-drugs”), antihistamines, naturopathic agents, and even sedating antidepressants and antipsychotics. Potential side effects of such drugs include residual daytime sedation, gait instability, memory impairment, weight gain and metabolic complications, and abuse and withdrawal potential. Consequently, the availability of safe, well-tolerated medications with low side-effect profiles for insomnia is imperative.

The pineal hormone melatonin (N-acetyl-5-methoxytryptamine; 5-methoxy-N-acetyltryptamine) was first isolated in the 1950s. Nearly 40 years would elapse before human melatonin receptors were characterized. Melatonin is released from the pineal gland in accordance with a circadian rhythm producing high nocturnal levels (400 pM) peaking around 2 AM and low daytime levels (40 pM). In most vertebrates, nocturnal melatonin secretion varies inversely with the length of the day, thereby regulating not only sleep but also seasonal variation in reproductive behavior in some species. Interestingly, the circadian clock in humans is slightly longer than 24 hours, but the suprachiasmatic nucleus (SCN) of the hypothalamus synchronizes melatonin synthesis to the light/dark cycle, transmitting neural signals from retinal neurons to the pineal gland. In the absence of environmental light–dark cues, circadian desynchronization can occur. In fact, 50% to 70% of totally blind individuals experience non–24-hour sleep–wake phase disorders.

Melatonergic dysfunction has garnered heightened attention as a putative pathophysiologic mechanism underlying circadian disruptions associated with insomnia, depression, and other disorders. Accordingly, the medicinal use of melatonin, categorized in the United States as a nutritional supplement, has rapidly expanded and has been accompanied by the development and introduction of several melatonin receptor agonists. Agents currently approved for use in the United States, Europe, or Australia include melatonin, agomelatine, ramelteon, and tasimelteon.

CHEMISTRY

Melatonin is derived from serotonin within the pineal gland and other sites. As a result, the molecular structure of melatonin (Fig. 33.15a–1) closely resembles that of serotonin. Both molecules are comprised of an indole aromatic ring (i.e., a 6-member benzene ring fused with a 5-member nitrogen-containing pyrrole ring) with a side chain at position 3. To form melatonin, the terminal amine group on serotonin’s side chain is acetylated, producing an acylaminoethyl side chain, and serotonin’s hydroxyl group is methylated, producing a methoxy group at position 5. These changes render melatonin a more lipophilic molecule that, unlike serotonin, readily crosses the blood–brain barrier.

All currently available melatonin receptor agonists are structurally similar to melatonin. Most similar is agomelatine, the only structural difference being the replacement of melatonin’s indole (fused benzene and pyrrole rings) aromatic ring with a naphthalene (two fused benzene rings) aromatic ring (Fig. 33.15a–2). Ramelteon and tasimelteon preserve melatonin’s acylaminoethyl side chain but replace the indole with a benzofuran aromatic ring in which a 6-member benzene ring is fused with a 5-member oxygen-containing furan ring (Figs. 33.15a–3 and 33.15a–4).

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Pharmacokinetic profiles for melatonin and the three commercially available melatonin receptor agonists are remarkably similar (Table 33.15a–1). Each is readily and rapidly absorbed when administered orally, reaching peak plasma concentrations within an hour of administration. Concomitant intake of a high-fat meal lowers the absorption of tasimelteon (44%), ramelteon (22%), and melatonin (13%), delaying the time to maximum concentration, but does not affect agomelatine absorption.

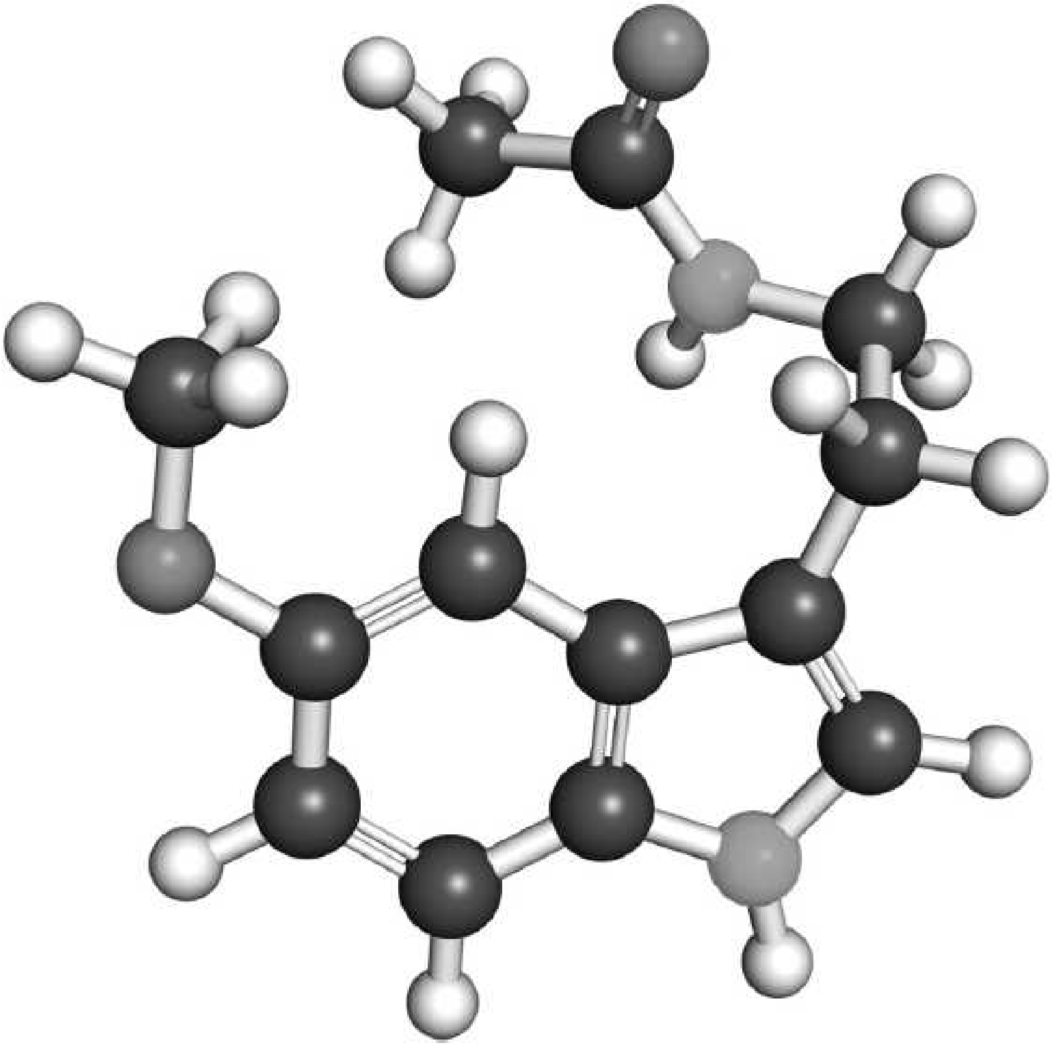

FIGURE 33.15a–1. Molecular structure of melatonin. Light gray, nitrogen; gray, carbon; medium gray, oxygen; white, hydrogen.

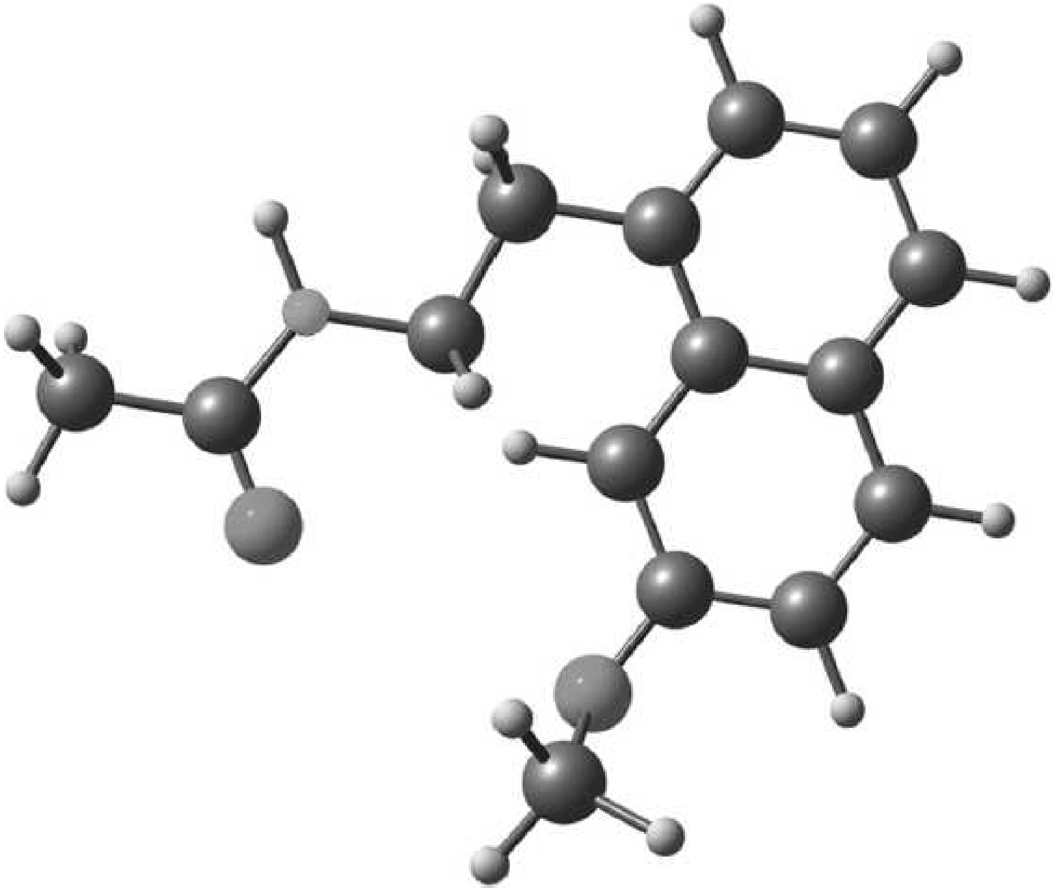

FIGURE 33.15a–2. Molecular structure of agomelatine. Light gray, nitrogen; gray, carbon; medium gray, oxygen; white, hydrogen.

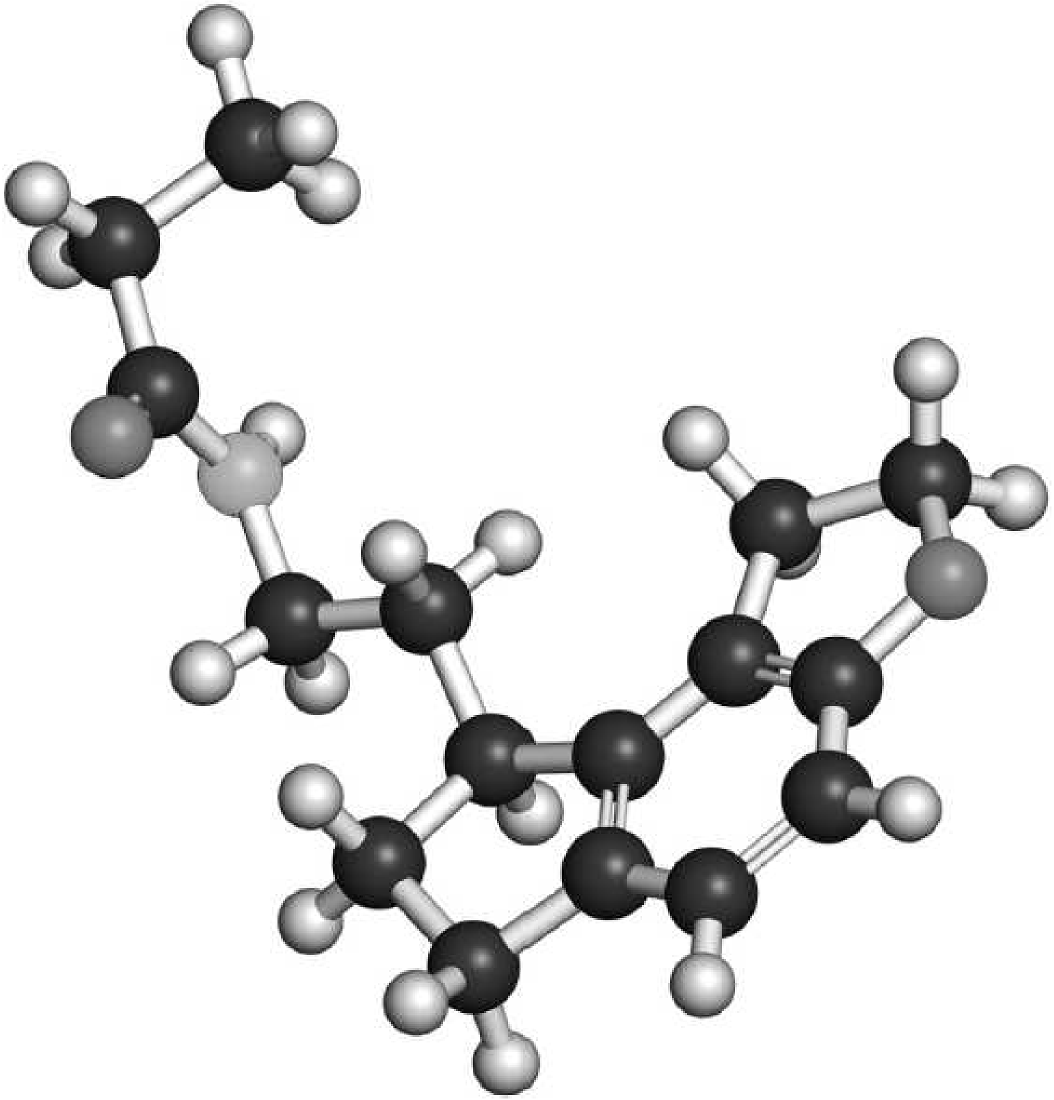

FIGURE 33.15a–3. Molecular structure of ramelteon. Light gray, nitrogen; gray, carbon; medium gray, oxygen; white, hydrogen.

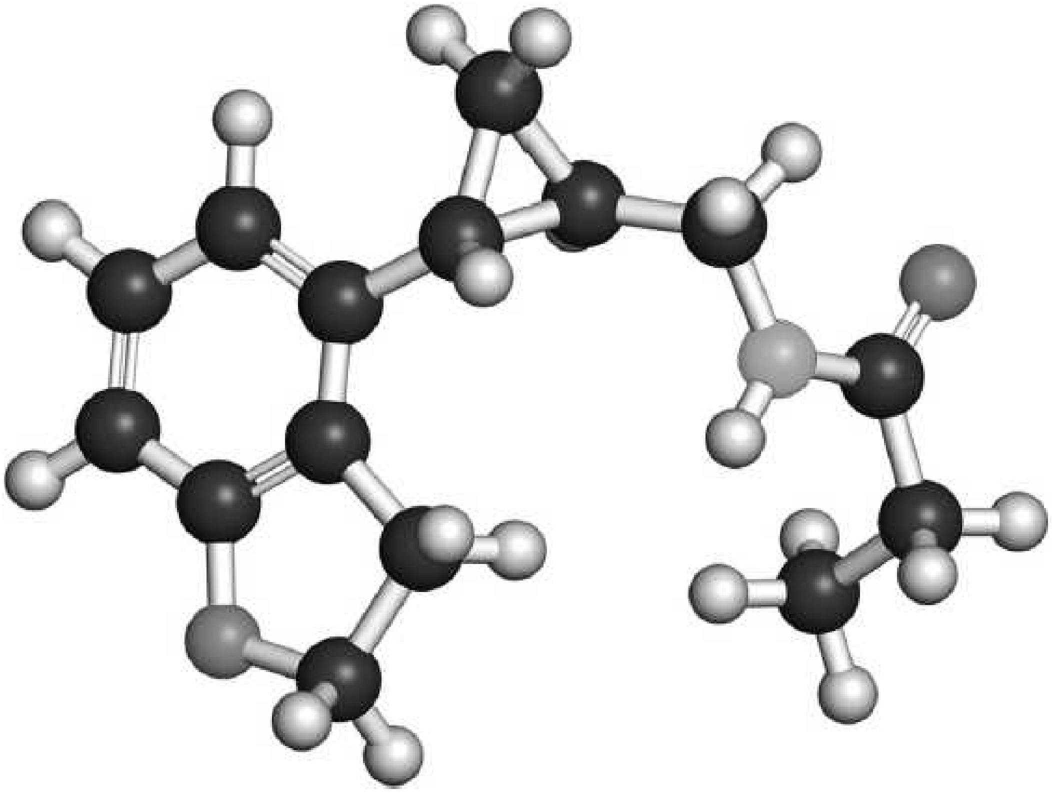

FIGURE 33.15a–4. Molecular structure of tasimelteon. Light gray, nitrogen; gray, carbon; medium gray, oxygen; white, hydrogen.

Despite uniformly high absorption rates (≥80%), absolute oral bioavailability is only 38% for tasimelteon, 15% for melatonin, and <5% for the others due to extensive hepatic first-pass metabolism and probable tissue uptake. All four are rapidly and extensively metabolized with elimination half-lives less than 2 hours and no more than 2% of the parent compound excreted unchanged in the urine.

All four agents undergo extensive oxidative metabolism primarily by the cytochrome P450 (CYP) 1A2 isoenzyme. Ramelteon and tasimelteon are also minor substrates for CYP3A4, whereas melatonin, agomelatine, and ramelteon are minor substrates for the CYP2C9 and CYP2C19 isoenzymes.

Renal impairment does not change the rate of drug clearance for any of the four melatonin receptor agonists. Conversely, mild and moderate hepatic impairment, respectively, produce 70-fold and 140-fold increases in agomelatine exposure and 4-fold and 10-fold increases in ramelteon exposure. Alterations in tasimelteon clearance have not been observed in mild to moderate hepatic impairment. Although the effect of hepatic impairment upon the clearance of exogenous melatonin has not been formally evaluated, it has been reported that clearance of endogenous melatonin is reduced by hepatic impairment.

The pharmacokinetic profiles for melatonin, ramelteon, and tasimelteon are significantly affected by age, with older adult patients exhibiting higher peak concentrations, diminished clearance rates, and longer elimination half-lives. However, these differences are not thought to be clinically relevant. Age-associated pharmacokinetic changes have not been observed with agomelatine.

Table 33.15a–1.
Pharmacokinetic Profiles of Melatonin Receptor Agonists

Generic Name	Oral Absorption (%)	Time to Peak Concentration (Hours)	Absolute Oral Bioavailability (%)	Protein Binding (%)	Elimination Half-Life (Hours)	Renal Excretion of Parent Compound (%)	Metabolism (Cytochrome P450 Substrate)		
							1A2	2C9/19	3A4
Agomelatine	≥80%	1–2	<5%	95%	1.0–2.0	<1%	+++	+	
Melatonin	100%	0.75	15%	60%	0.8	2%	+++	+	
Ramelteon	84%	0.75	1.8%	82%	1.3	<1%	+++	+	+
Tasimelteon	≥90%	0.5-3	38%	90%	1.3	<1%	+++		+

There is a distinct gender difference in pharmacokinetic profile, with higher peak concentrations and/or longer elimination half-lives reported among women for all four agents, arguably a consequence of CYP1A2 inhibition by estradiol. If so, gender differences may be most pronounced among premenopausal women.

Finally, all four agents are highly lipophilic compounds that readily traverse the blood–brain barrier. Of note, melatonin is less tightly protein-bound (60%) than the other melatonin receptor agonists.

Pharmacodynamics

Melatonin's physiologic activity is primarily mediated by two membrane-bound G protein–coupled receptors, melatonin receptor 1 (MT_1) and melatonin receptor 2 (MT_2), which are located in numerous brain regions and peripheral tissues. Both MT_1 and MT_2 receptors are expressed in the SCN of the hypothalamus, a region adjacent to the optic chiasm that is well recognized for its role in regulating circadian rhythms. Additional MT_1 receptors are located in the *pars tuberalis* of the pituitary and retina. MT_2 receptors are also found in the hippocampus, cerebellum, and retina. Although their respective roles are not clearly delineated, MT_1 receptors in the SCN are thought to be involved in sleep promotion, whereas MT_2

receptors are believed to play a major role in melatonin's phase-shifting activity.

Melatonin receptor 3 (MT_3), a quinone reductase 2 enzyme present in multiple peripheral tissues, may explain the antioxidant properties of melatonin but has a negligible impact on the sleep–wake cycle. Other physiologic roles ascribed to melatonin include regulation of metabolic, cardiovascular, and immune systems with reported antioxidant, antinociceptive, and anticancer effects. These may be mediated, at least in part, by activation of MT_1 and MT_2 receptors, which like MT_3, are present in various peripheral tissues.

Melatonin and the other commercially available agents (i.e., agomelatine, ramelteon, tasimelteon) are all considered nonselective MT_1/MT_2 receptor agonists, albeit with distinct affinity profiles (Table 33.15a–2). None has a pharmacologically meaningful affinity for benzodiazepine, histaminic, or cholinergic receptors. The affinities of agomelatine, ramelteon, and tasimelteon for the MT_3 receptor are obscure. Among the current agents, ramelteon has the greatest MT_1 selectivity, with six times melatonin's affinity for the MT_1 receptor. Alternatively, tasimelteon has a two to fourfold higher affinity for the MT_2 than the MT_1 receptor, which would theoretically explain its particular utility in remedying circadian rhythm disturbances.

Agomelatine, approved in Europe and Australia for the treatment of depression, is not only an MT_1 and MT_2 agonist but also a serotonin-2C ($5HT_{2C}$) receptor antagonist. It remains debated whether the antidepressant efficacy of agomelatine is a consequence solely of its action on $5HT_{2C}$ receptors or of synergy between its effects on MT_1, MT_2, and $5HT_{2C}$ receptors.

Table 33.15a–2.
Receptor Affinities of Melatonin Receptor Agonists

Generic Name	**Receptor Affinity (K_i)**		
	MT_1	**MT_2**	**MT_1/MT_2 K_i Ratio**
Agomelatine	62 pM	268 pM	0.231
Melatonin	81 pM	383 pM	0.211
Ramelteon	14 pM	112 pM	0.125
Tasimelteon	350 pM	170 pM	2.059

MT_1, Melatonin 1 Receptor; MT_2, Melatonin 2 Receptor.

CLINICAL DRUG STUDIES

Numerous randomized clinical trials have demonstrated the beneficial effects of melatonin and other melatonin receptor agonists for sleep disturbances. For example, a recent umbrella review encompassing 18 meta-analyses and systematic reviews concluded that short-term use for insomnia improved sleep quality and sleep latency.

Ramelteon is approved in the United States for the treatment of insomnia characterized by difficulty with sleep onset. A meta-analysis encompassing 13 trials and 5,812 participants concluded, ramelteon improves sleep quality and reduces sleep latency by 4.30 minutes in a nondose-dependent manner, with somnolence as the only significant side effect. A similar meta-analysis including eight trials reported improvements in subjective and polysomnographic sleep latency, total sleep time, and latency to REM with ramelteon. Moreover, improvements in sleep latency produced by ramelteon may be enduring, with one study demonstrating reduced sleep latency for up to 6 months.

Tasimelteon is approved in the United States for the treatment of Non–24-Hour Sleep–Wake Disorder (Non-24) in blind adults. In a controlled trial of 84 Non-24 patients, tasimelteon significantly outperformed placebo in circadian rhythm entrainment to a 24-hour day (20% vs. 3%) with longer nighttime sleep duration and less daytime nap time. Moreover, a subsequent Non-24 withdrawal study by the same group reported greater maintenance of 24-hour synchronization among those maintained on tasimelteon than those who transitioned to placebo (90% vs. 20%). Two reports drawn from three randomized trials collectively encompassing 769 participants experiencing insomnia subsequent to a sleep-time shift, for example, jet lag, reported greater sleep efficiency among those receiving tasimelteon than placebo. Finally, a clinical trial (NCT00548340) for primary insomnia (*n* = 321) demonstrated significantly greater reductions in sleep latency for tasimelteon at both 20 mg and 50 mg doses than placebo.

Melatonin receptor agonists have consistently outperformed placebo in clinical trials of insomnia and other circadian sleep disturbances. Unfortunately, tolerance to these agents has not been systematically assessed, nor have they been scrutinized in head-to-head comparisons against other classes of hypnotic agents. Nevertheless, one meta-analysis reported that polysomnographically determined reductions in sleep latency and wakefulness after sleep onset for extended-release melatonin (2 mg) and ramelteon (16 mg) were less than that of benzodiazepines but comparable to changes produced by other benzodiazepine receptor agonists.

Because of the negative consequences associated with long-term benzodiazepine use, there has been considerable interest in the use of melatonin to aid in reducing the frequency of prescribing benzodiazepines as hypnotics. Unfortunately, in a meta-analysis and systematic review of six trials, melatonin did not outperform placebo in enabling benzodiazepine discontinuation. In 2020, a retrospective observational study (*n* = 170) by An and colleagues reported a successful switch from chronic zolpidem or benzodiazepine use to control-release melatonin in nearly half of the study participants.

The utility of melatonin receptor agonists in the management of mood disorders has also been a focus of inquiry, albeit with mixed results. A controlled trial (NCT00705003) evaluating melatonin (3 mg) augmentation of buspirone for depression demonstrated no evidence of therapeutic efficacy. Similarly, a controlled trial of ramelteon (8 mg) augmentation of escitalopram for depression (NCT00642694) was terminated due to lack of efficacy. Finally, in an 8-week depression trial (NCT01428661) including 507 subjects, 20 mg tasimelteon failed to separate from placebo in reducing depressive symptom severity.

Among melatonin receptor agonists, the strongest evidence for efficacy in the treatment of depression is found with agomelatine, which, in Europe and Australia, is indicated for the treatment of depression. It is suggested that the antidepressant efficacy of agomelatine stems both from its effects on mood and on circadian resynchronization. A meta-analysis conducted by Taylor and colleagues, incorporating 20 placebo-controlled agomelatine trials and 7,460 subjects, demonstrated a significant odds ratio for the antidepressant therapeutic response of 1.25 (95% CI: 1.11–1.40). Interestingly, in a meta-analysis of 21 antidepressants, which included 522 double-blind trials and 116,477 subjects, agomelatine had a therapeutic response rate comparable to other antidepressants and the highest acceptability rate.

The foundation for the role of chronobiotic therapies for mood disorders has largely emerged from the study of seasonal affective disorder (SAD). Most patients with SAD experience a phase delay, or later secretion of dim light melatonin, due to the absence of early morning light during the winter months in the northern hemisphere. Both the dose and timing of chronobiotic administration are arguably key to successful treatment. Proper treatment results in phase advancement with improvements in mood symptoms, while incorrect dosing or timing may actually worsen insomnia and mood disturbances. Unfortunately, a recent Cochrane Review, limited to only one trial, reported inconclusive evidence with wide confidence intervals encompassing both prevention and worsening of SAD symptoms with agomelatine. No SAD studies of other melatonin agonists were identified.

Controlled trials of melatonin receptor agonists for bipolar disorder have produced mixed results. A trial of ramelteon (8 mg) as a maintenance therapy augmentation agent for euthymic bipolar patients reported a significantly longer time to relapse among those receiving ramelteon than placebo (188 vs. 84 days, respectively). For bipolar mania, two augmentation trials reported that neither melatonin nor ramelteon outperformed placebo; however, a third study ($n = 60$) in manic patients treated with lithium and risperidone demonstrated a modest but statistically significant greater reduction in manic symptoms for those receiving melatonin 6 mg than those receiving placebo.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Cardiovascular System

Endogenous melatonin is likely involved in the circadian regulation of the cardiovascular with decreases in cardiac output, blood pressure, and heart rate when melatonin levels peak during the evening hours. Rodent studies indicate similar effects of exogenous administration of melatonin.

Clinical trial data have not indicated any adverse effects on cardiovascular function among the four commercially available melatonin receptor agonists. In fact, it has been speculated that melatonin receptor agonists may have beneficial cardiovascular effects.

Central Nervous System

As a group, the melatonin receptor agonists compare favorably to benzodiazepines and other hypnotics with respect to adverse effects on the central nervous system. Indeed, melatonin receptor agonists may promote sleep and aid in the prevention of delirium in the intensive care setting, though their benefit for preventing delirium has been questioned. Moreover, the risk of abuse liability for this class of medications has not been found in small cross-over trials.

Endocrine System

Preclinical studies indicate that supraphysiologic administration of exogenous melatonin may disrupt secretory profiles for numerous hormones, including corticosteroids, gonadal steroids, luteinizing hormone, insulin, prolactin, and thyroid hormone.

In a controlled trial of adults with chronic insomnia, ramelteon 16 mg nightly for 6 months was not associated with alterations in indices of adrenal or thyroid function; however, prolactin concentrations increased 34% in female participants, although no clinical effects of elevated prolactin were noted. Endocrine function has not been specifically examined in clinical trials of the other commercially available melatonin receptor agonists.

Hepatic and Renal Systems

There is no evidence that clearance of any of the four available melatonin receptor agonists is altered by preexisting renal impairment. Nor is there evidence that these agents impair renal function. In fact, some preclinical studies suggest that melatonin may protect the kidneys from renal ischemia and reperfusion injury, exposure to carcinogens, hemorrhagic shock, or other injuries.

Agomelatine, unfortunately, has been associated with hepatic dysfunction. During clinical trials, 1.4% of patients receiving agomelatine 25 mg and 2.5% of those receiving agomelatine 50 mg experienced elevations in serum transaminase concentrations greater than three times the upper limit of normal. Rare occurrences of hepatitis, γ-glutamyltransferase concentrations three times the upper limit of normal, jaundice, and hepatic failure have been reported in association with agomelatine therapy. Hepatic injury has not been reported in association with any of the other three approved melatonin receptor agonists.

Respiratory System

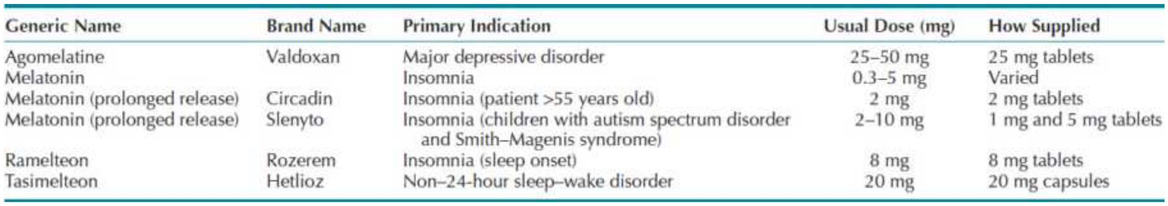
In contrast to benzodiazepines and other hypnotics, melatonin receptor agonists appear to be devoid of respiratory depressant effects. For example, in studies of patients with obstructive sleep apnea and chronic obstructive pulmonary disease, ramelteon did not adversely affect apnea-hypopnea indexes or arterial oxygen saturation levels.

THERAPEUTIC INDICATIONS

As shown, melatonin agonists provide a novel approach to the treatment of insomnia and other circadian sleep disturbances (Table 33.15a–3). In addition to its effect on the circadian rhythm, melatonin has also been reported to possess anti-inflammatory, antitumor, vascular, retinal, antioxidant, neuroprotective, and pain-modulatory effects, perhaps providing other avenues for which to explore its therapeutic potential. For example, because of its potential anti-inflammatory and antioxidant properties, the use of adjuvant ramelteon is being studied in individuals with SARS-CoV-2 infection to evaluate whether it can modulate protective effects against acute lung injury (NCT04470297).

Melatonin receptor agonists also hold potential utility in the treatment of depression and other mental disorders associated with disturbances of circadian rhythmicity. Indeed, agomelatine is indicated for the treatment of major depression in Europe. It is speculated that agomelatine's antidepressant properties may be due to a synergism between its effects on melatonin receptors and $5HT_{2c}$. Although studies of other melatonin receptor agonists for depression have produced disappointing results, one study of tasimelteon, which overall produced negative results, suggested tasimelteon might offer benefit to African Americans experiencing depression. Further study is required before melatonin receptor agonists can be recommended for bipolar disorder and the prevention of delirium.

Table 33.15a–3.
Formulations of Commercially Available Melatonin Receptor Agonists



Generic Name	Brand Name	Primary Indication	Usual Dose (mg)	How Supplied
Agomelatine	Valdoxan	Major depressive disorder	25–50 mg	25 mg tablets
Melatonin		Insomnia	0.3–5 mg	Varied
Melatonin (prolonged release)	Circadin	Insomnia (patient >55 years old)	2 mg	2 mg tablets
Melatonin (prolonged release)	Slenyto	Insomnia (children with autism spectrum disorder and Smith–Magenis syndrome)	2–10 mg	1 mg and 5 mg tablets
Ramelteon	Rozerem	Insomnia (sleep onset)	8 mg	8 mg tablets
Tasimelteon	Hetlioz	Non–24-hour sleep–wake disorder	20 mg	20 mg capsules

PRECAUTIONS AND ADVERSE REACTIONS

In many respects, the side effect profile of the melatonin receptor agonists compares favorably to other sleep agents. Unlike benzodiazepine hypnotics, melatonin agonists have not been associated with prominent cognitive impairment, fall risk, discontinuation-associated withdrawal syndromes, or rebound insomnia. The melatonin agonists are also devoid of prominent anticholinergic (e.g., dry mouth, constipation, blurred vision) or antihistaminic (e.g., carbohydrate craving, weight gain) side effects associated with other hypnotic agents.

Pregnancy

Endogenous maternal melatonin plays an important role during pregnancy. Although the fetal pineal gland does not yet produce melatonin (infant melatonin production does not begin until 2 to 3 months after delivery), there are more melatonin binding sites in both the fetal pituitary and fetal hypothalamus than in the adult. It is speculated that maternal melatonin, known to cross the placenta, establishes periodicity and entrains the circadian pacemaker. For example, in evening deliveries, significantly elevated melatonin levels are detected via sampling of the umbilical artery or vein at birth. One hypothesis is that maternal melatonin might communicate important information about maternal sleep–wake cycles and entrain the fetal pineal gland so that fetal circadian rhythms may be found as early as 3 months. Preclinical evidence suggests other roles for endogenous melatonin during fetal life, including influencing the development of reproductive organs, regulating gonadal hormone activity, and protecting the fetal brain from oxidative damage during episodes of fetal hypoxia.

Despite the growing evidence that endogenous melatonin benefits the fetus, exogenous melatonin administration, which likely produces markedly higher fetal circulating concentrations, should not carry a presumption of safety. For example, in a series of rodent studies, administering exogenous melatonin during pregnancy at doses as low as 2 to 10 times recommended human doses have demonstrated decreased luteinizing hormone levels, decreased ovarian and uterine size, and delayed vaginal opening in the offspring. Following delivery, offspring exposed to exogenous melatonin exhibit disruption in estrous cycles and blunted responses to testosterone, suggesting impairment in the maturation of the hypothalamic–pituitary–gonadal and prolactin axes.

There are no controlled data addressing the reproductive safety of exogenous administration of melatonin or other melatonin receptor agonists in humans.

In summary, there is no clear evidence of teratogenicity, though there is preclinical evidence that increased levels of melatonin may interfere with the regulation of sex hormone levels and cycles, as well as delay sexual maturation. Pending further data, exogenous administration of melatonin and other melatonin receptor agonists should be avoided during pregnancy.

Lactation

Existing studies have examined levels of endogenous, but not exogenous, melatonin in breast milk. Cyclic levels of melatonin in breast milk replicate maternal patterns, including elevations in the evening and decreases during daylight, with endogenous melatonin breast milk levels ranging from 35% to 80% of maternal serum levels. Circadian fluctuations in breast milk melatonin concentrations may dictate nursing schedules for the infant.

In one case report, agomelatine was detectable in breast milk, with peak concentrations occurring 2 hours after the drug was administered with undetectable levels 4 hours after administration. The milk:plasma ratio was 0.19. Clinical breast milk excretion data have not been published for other melatonin receptor agonists.

In a recent edition of Hale's standard lactation reference, both melatonin and ramelteon are assigned an LE (no data-probably compatible) rating.

DRUG INTERACTIONS

All currently available melatonin receptor agonists, including melatonin itself, are predominantly metabolized by the CYP1A2 isoenzyme and, to a lesser extent, the CYP2C9/2C19 and/or CYP3A4 isoenzymes. Thus, there are potential interactions with drugs that inhibit or induce the activity of these P450 isoenzymes (Table 33.15a–4).

Of greatest concern are drug interactions mediated by CYP1A2. For example, coadministration with fluvoxamine, a potent CYP1A2 inhibitor, produces a 6.5-fold increase in total tasimelteon exposure, a 17-fold increase in melatonin exposure, a 60-fold increase in agomelatine exposure, and a whopping 160-fold increase in ramelteon exposure. By comparison, coadministration with ketoconazole, a potent CYP3A4 inhibitor, produces a 0.84-fold increase in ramelteon exposure and a 0.54-fold increase in tasimelteon exposure, although the clinical significance of this is unknown. Fluconazole, a potent CYP2C9 inhibitor, produced a 1.5-fold increase in ramelteon exposure and was not observed to alter agomelatine exposure.

The magnitude of the drug interaction observed between fluvoxamine and the four melatonin receptor agonists raise concern for interactions with other agents that alter 1A2 activity. For example, coadministration with estrogen-containing compounds (e.g., oral contraceptives, hormone replacement therapies) may produce similar increases in levels of exposure to these agents. Unfortunately, no data are available to clarify the magnitude of this potential interaction. Tobacco, a known inducer of CYP1A2, may produce the opposite effect, which is lowering exposure and thus the efficacy of melatonergic agents. Indeed, smoking has been associated with a 40% reduction in exposure to tasimelteon and a 3.7-fold lowering of cumulative exposure to agomelatine.

Table 33.15a–4.
Potential Drug interactions for Melatonin Receptor Agonists

Pharmacokinetic Activity	Cytochrome P450 Isoenzyme		
	1A2	2C9/2C19	3A4
Substrates[a]	Agomelatine	Agomelatine	
	Melatonin	Melatonin	
	Ramelteon	Ramelteon	Ramelteon
	Tasimelteon		Tasimelteon
Inhibitors[b]	Estrogen[c] Fluvoxamine Quinolones[d]	Amiodarone Azole antifungals[e] Fluoxetine Fluvoxamine Omeprazole, Esomeprazole	Antiretrovirals[f] Azole antifungals[e] Conivaptan Diltiazem Fluvoxamine Macrolides[g] Nefazodone Verapamil
Inducers[b]	Carbamazepine Montelukast Phenobarbital Phenytoin Tobacco (Smoking)	Carbamazepine Phenytoin Rifampin	Carbamazepine Efavirenz Etravirine Modafinil Nafcillin Oxcarbazepine Phenobarbital Phenytoin Rifampin St. John's Wort Topiramate

[a] Substrate status for melatonin receptor agonists.

[b] Representative lists of strong and moderate potency inhibitors and inducers.

[c] Estrogen-containing agents include oral contraceptives and hormone replacement therapies.

[d] Quinolone antibiotics include ciprofloxacin and ofloxacin.

[e] Azole antifungals include fluconazole, itraconazole, ketoconazole, miconazole, and voriconazole.

[f] Antiretroviral agents include atazanavir, boceprevir, darunavir, fosamprenavir, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir, and telaprevir.

[g] Macrolide antibiotics include clarithromycin, erythromycin, and telithromycin.

None of the four melatonergic agents, at therapeutic concentrations, has been observed to alter CYP enzyme activity; therefore, they are unlikely to alter the clearance of other medications. However, *in vitro* research indicates that melatonin, at supratherapeutic concentrations, induces the activity of CYP3A4. The clinical relevance of melatonin's impact on CYP3A4 activity, if any, is unknown. An additive impact upon psychomotor performance when taken with alcohol has been reported for the melatonin receptor agonists.

LABORATORY INTERFERENCE

None of the four approved agents (i.e., agomelatine, melatonin, ramelteon, tasimelteon) have been shown to have significant laboratory interferences. They also have not been shown to interfere with drug urine toxicology screens or to produce false-positive results.

DOSAGE AND ADMINISTRATION

Extended-release melatonin is administered using a 2 mg bedtime dose. Exogenous melatonin should not be administered to patients with moderate or severe hepatic impairment.

Ramelteon is usually administered at an 8 mg dose 30 minutes prior to bedtime, but there have been reports of efficacy between 4 mg and 64 mg. No dosing adjustment is needed for renal impairment. Ramelteon should be used cautiously in those with moderate hepatic impairment, and use is not recommended in severe hepatic impairment.

Tasimelteon is administered at a 20 mg dose 1 hour prior to bedtime. It may take several weeks or months before the full benefit is achieved. There is no dosing adjustment necessary for renal impairment or mild-to-moderate hepatic impairment; however, it is not recommended for those with severe hepatic impairment.

Agomelatine is administered for depression using a 25 mg bedtime dose. No dose adjustment is needed for renal impairment. Agomelatine should not be administered to patients with even mild hepatic impairment.

INVESTIGATIONAL DRUGS

Other novel melatonin receptor agonists are in various phases of development. TIK-301, formerly known as LY-156735 and PD-6735, was initially developed by Eli Lilly and is currently licensed to Tikvah Therapeutics, where Phase 3 trials were planned. Unfortunately, further testing and development of this product appear to have been abandoned. The pharmacodynamic profile of TIK-301 is similar to agomelatine, a nonselective MT_1/MT_2 agonist (Table 33.15a–3), as well as a $5HT_{2B}$ and $5HT_{2C}$ antagonist. It would theoretically have utility for insomnia, circadian rhythm disorders, and depression.

Piromelatine, also known as Neu-P11, is a nonselective MT_1/MT_2 agonist and $5HT_{1A}/5HT_{1D}$ agonist under development by Neurim Pharmaceuticals for sleep and cognitive function in association with insomnia and Alzheimer Disease. Piromelatine outperformed placebo in a 4-week phase II trial (NCT01489969) for insomnia released in 2013. A subsequent Phase II study specifically in individuals with Alzheimer disease (NCT02615002) was completed in 2019; however, the results of that trial are not yet available. Preclinical research indicates that piromelatine may improve cognitive function in animal models of Alzheimer Disease and prevent insulin resistance and metabolic derangements associated with sleep deprivation.

A number of other melatonin receptor ligands are in various stages of development and/or preclinical testing. Melatonin agonists in development exhibit one of four pharmacodynamic profiles: (1) nonselective MT_1/MT_2 agonists; (2) nonselective MT_1/MT_2 agonists with agonist or antagonist activity at one or more serotonin receptor subtypes; (3) MT_1 selective agonists, and (4) MT_2 selective agonists. By convention, a selective agonist must display at least 50 times greater affinity for one receptor subtype.

Two MT_2 selective partial agonists, UCM765 and UCM924, have demonstrated antinociceptive properties in animal models of neuropathic pain. In other preclinical studies, UCM765 showed anxiolytic effects and promoted non-REM sleep. Production of MT_1 selective ligands has proven more challenging. Thus, progress toward the development of MT_1 selective agonists is lagging.

33.15b Thyroid Hormones

RENA COOPER-KAZAZ, M.D., AND BERNARD LERER, M.D.

Neuroscience-Based Nomenclature (NbN)	
Levothyroxine, liothyronine	
Pharmacologic Domain	Thyroid hormones
Mechanism of Action	Thyroid hormone receptor agonists (multiorgan systems)

Various hormonal systems have been implicated in the biology of the stress response and in the pathophysiology of affective disorders. The hypothalamic–pituitary–adrenal (HPA) axis has been the focus of most attention, but the thyroid axis has also been established as an important endocrine system, particularly in depression.

Thyroid hormones have long been of interest to those who study and treat mood disorders, mainly unipolar major depression and bipolar disorder. There have been two major areas of research. The first is whether thyroid hormones are implicated in the etiology of mood disorders and whether there is a specific abnormality of the thyroid axis in primary mood disorders. The second, following the first, is whether thyroid hormones may be useful in the treatment of unipolar or bipolar affective disorders.

For more than a century, depressive symptoms have been known to be one of the most prominent features of clinical thyroid disease, particularly hypothyroidism. However, a recent meta-analysis suggested that the association of hypothyroidism with depression may be less definitive than previously thought, especially for subclinical hypothyroidism, and may be more prominent in females than in males. Clinical hyperthyroidism has a much more heterogeneous psychiatric presentation with a wider variety of symptoms reported. Earlier studies and clinical observations noted that when the thyroid deficiency or excess was corrected, depressive or other psychiatric symptoms frequently, but not invariably, resolved. As a result of the inverse relationship between thyroid function and depression observed in endocrine patients, it was suggested that thyroid hormones—particularly thyroid hormone deficiency—might be a factor in the etiology of unipolar and bipolar mood disorders.

Although thyroid hormone deficiency has been excluded as a major contributor to the biologic basis of primary mood disorders, particularly depression, its potential role in the cascade of biologic events that leads to depressive and bipolar disorders remains to be clarified. Thyroid hormones have extensive effects on various cellular mechanisms and may still be implicated in the biology of these disorders.

USE OF THYROID HORMONES IN TREATMENT

The early link established between abnormal mood symptomatology and thyroid deficiency in endocrine patients prompted an investigation into the use of thyroid hormones to treat depression. Earlier studies yielded ambiguous findings, which may have been contributed to methodologic limitations, especially a lack of controlled designs and heterogeneous groups of patients. In the 1960s, synthetic forms of thyroxine (levothyroxine, T_4) and triiodothyronine (liothyronine, the synthetic levorotatory isomer of triiodothyronine, T_3), were developed and replaced desiccated thyroid as a primary replacement therapy for thyroid disease. This allowed a more refined approach to examining the efficacy of thyroid hormones in the treatment of mood disorders, and the therapeutic use of thyroid hormones in the treatment of depression became the subject of study. Although thyroid hormones have been used to treat a range of psychiatric illnesses, systematic research data have been collected primarily on unipolar mood disorders and, to a lesser extent, bipolar mood disorders.

THYROID HORMONE BIOCHEMISTRY

The source of thyroid hormones in the body is the thyroid gland. The self-regulated hypothalamic–pituitary–thyroid axis (HPT) is responsible for the homeostasis of thyroid function. The two main active hormones, T_4 and T_3 are tyrosine-based molecules produced by the thyroid gland and conjugated to iodide, an essential dietary element. T_4 and T_3 are stored in the follicular lumen of the thyroid gland bound to the iodinated protein, thyroglobulin, and are released into the circulation upon stimulation (T_4—80%, T_3—20%). The circulating lipophilic hormones are bound to transport proteins leaving approximately 0.03% T_4 and 0.3% T_3 unbound and active (free T_4/T_3). T_4 is derived almost entirely from the thyroid gland, whereas the main source of T_3 is the monodeiodination of T_4 in extrathyroidal tissue by deiodinase enzymes.

FIGURE 33.15b–1. Metabolism of thyroid hormones by deiodinase enzymes. (Reprinted from Guo T-W, St. Clair D, He L. The deiodinase type 2 (DIO2) gene and mental retardation in iodine deficiency. In: Preedy VR, Burrow GN, Watson R. *Comprehensive Handbook of Iodine: Nutritional, Biochemical, Pathological and Therapeutic Aspects*. Academic Press; 2009:635–641, with permission from Elsevier.)

There are three types of deiodinases: type I, II, and III (Fig. 33.15b–1). Types I (DIO1) and II (DIO2), located in the liver, kidneys, muscles, and thyroid gland, convert T_4 to the active form, T_3, via deiodination of T_4's outer ring. Type III (DIO3) deiodinase is located in the CNS, skin, and placenta. Deiodinase 1 (*DIO1*) and *DIO3* inactivate both T_4 and T_3 and terminate thyroid hormone action via deiodination of T_4's inner molecular ring.

Polymorphisms in the three deiodinase genes exist, and several were found to be associated with (1) autoimmune thyroid diseases, (2) symptoms of anxiety and depression after ischemic stroke, (3) executive function and personality traits, and (4) cardiac-related mortality after acute myocardial infarction.

Other thyroid hormone products include reverse T_3, 3-diiodothyronine, 3-monoiodothyronines, and the acetate metabolites of T_4 and T_3—tetrac and triac, respectively. These other thyroid hormone products appear in very small amounts, and their physiologic significance is limited.

The secretion of thyroid hormones by the thyroid gland is regulated by the HPT axis. This involves the classic negative-feedback regulatory mechanism, which applies to most of the major endocrine systems. The cells of the hypothalamus secrete thyrotropin-releasing hormone (TRH), which stimulates the secretion of thyrotropin (thyroid-stimulating hormone [TSH]) from the cells of the anterior pituitary via the portal venous blood system, which connects the hypothalamus and the pituitary gland. The TSH released from the pituitary then acts on the thyroid gland to stimulate the production of thyroid hormones, including T_4 and T_3. A negative feedback system operates at the levels of both the pituitary and the hypothalamus to modulate circulating levels of T_4 and T_3 and thereby regulate the activity of the thyroid axis.

The physiologic action of T_4 is largely dependent on its extrathyroidal conversion to T_3, which then acts at T_3 receptors in various tissues to initiate the physiologic actions of thyroid hormones. T_4 thus fulfills the definition of a prohormone. In the brain to a greater extent and pituitary to a lesser extent, the main source of thyroid hormone for action at the receptor is T_4, which is converted locally within the neuron or cell to T_3 before exerting its hormonal action. T_3 receptors are located within the nucleus and are members of the nuclear receptor superfamily. T_3 receptors (TR) are encoded by two different genes and exist in a number of different isoforms, predominantly TRα1 and TRβ, that vary among tissues. Nuclear receptors such as T_3 influence gene expression by binding to specific DNA elements, which, in the case of T_3, are called thyroid response elements (TREs) and are located in the promoter region of T_3-responsive genes. Thus, the physiologic effects of thyroid hormone are brought about by the changes it causes in the expression of T_3-responsive genes in target tissues.

PHARMACOLOGIC ACTION

Pharmacokinetics

T4 and T3 are both relatively small molecules that are easily absorbed across the gastrointestinal (GI) tract. Both hormones are strongly protein-bound and are widely distributed in tissues. There is an active mechanism for the transportation of thyroid hormones across the blood–brain barrier. There is also a transport mechanism at the choroid plexus to ensure the wide distribution of thyroid hormones within the CNS. The deiodinase enzymes, particularly DIO3, convert T_3 to smaller molecules, including reverse T_3, which are then excreted in both urine and feces. T4 has a long half-life of approximately 7 days, whereas T3 has a half-life of approximately 8 to 12 hours.

Pharmacodynamics

Thyroid hormones have widespread metabolic effects in virtually every organ or system in the body, including the CNS, heart, lungs, bones, muscles, GI, reproductive system, and more. They activate genes that increase metabolic rate and thermogenesis. They are also critically important in pre- and postnatal brain development and influence key neurodevelopmental processes such as neurogenesis and neural migration. Thyroid hormones continue to play an active role in the mature brain in processes such as adult neurogenesis; therefore, their levels remain highly regulated within narrow limits to ensure optimal neuronal functioning. Indeed, hypothyroidism is a known cause of reversible cognitive impairment and even dementia syndrome.

THYROID FUNCTION IN PRIMARY AFFECTIVE DISORDERS

The vast majority of patients with primary major depression are euthyroid. A large number of studies evaluating baseline thyroid function tests have produced inconsistent findings. The most consistent findings to emerge are higher measures of T_4 or free T_4 in the depressed state as compared with recovery or healthy controls, with much more inconsistent findings for measures of circulating T_3 or free T_3. Up to one-third of depressed patients may have a blunted TSH response to TRH, which often normalizes with treatment. However, due to low sensitivity and moderate specificity for major depression, the TRH test is not diagnostic for depression.

In a recent Mendelian randomization study, no associations were found between genetically predicted TSH and fT_4 levels and major depressive disorder (MDD) risk, nor MDD subtypes and minor depressive symptoms. A slight increase in free T_4 levels was nominally associated with a decrease in the overall bipolar disorder risk.

Suicide attempters with MDD had more pathologic psychiatric rating scale scores (depression, anxiety, and psychosis) along with higher serum levels of TSH, antithyroglobulin antibodies (TgAb), and thyroid peroxidase antibodies (TPOAb) compared to nonsuicide attempters. This suggests the importance of regular assessment of thyroid function parameters for suicide prevention and possible biomarkers of suicide risk in MDD.

Indeed, evidence points to a shared pathophysiology of immune dysfunction and mood disorders. High rates of thyroid dysfunction have been found in patients with bipolar disorder compared to the general population. Thyroid autoimmunity may, in fact, be an independent risk factor for bipolar disorder with no clear association with lithium treatment.

Neither hypothyroidism nor hyperthyroidism was significantly associated with rapid-cycling bipolar disorder; however, TPOAb were significantly related to rapid-cycling bipolar disorder. This finding warrants further investigation into a possible biomarker, an underlying mechanism, and even treatment for rapid-cycling bipolar disorder.

There is limited data on baseline thyroid function and the relationship to antidepressant response. In some studies, higher mean T_4 levels and in other studies, higher mean TSH levels have been associated with an antidepressant response. A reduced TSH response to TRH has also been associated with treatment response. There are preliminary data that polymorphisms of the deiodinase enzymes, which are responsible for the extrathyroidal conversion of T_4 to T_3 (type I and type II deiodinase) and for the inactivation of T_3 by conversion to reverse T_3 (type III deiodinase), may be associated with antidepressant response in euthyroid-depressed patients.

AFFECTIVE DISORDERS IN PRIMARY THYROID DISORDERS

Approximately 15% of patients taking T4 (LT_4) for hypothyroidism report impaired quality of life and depressive symptoms compared to controls and are dissatisfied with their treatment. Although T4 is a good treatment for hypothyroidism, the prevalence of anxiety and depression among T4-

treated hypothyroid women was higher compared to women without hypothyroidism. Thus, psychiatric symptoms can remain despite adequate hormone replacement and should be a focus of interest for treating physicians. Indeed, when T4 doses were increased in older adults undergoing thyroid hormone replacement, their depressive symptoms improved without significant hyperthyroid symptoms or signs. These findings suggest the potential for varying the treatment target for primary hypothyroidism to include mood status. The setting of TSH cutoff values for hypothyroid patients should, therefore, also include associated symptoms such as mood. Some suggest a TSH cutoff value of 2.5 mIU/L to be optimal.

Recent studies showed promising advantages for the combined treatment of hypothyroidism with T4 (T_4) and T3 (T_3) in symptomatic patients. Further investigation is needed to assess the benefits and safety of this combination. Finally, adherence to T4 among hypothyroidism patients was associated with significantly lower rates of comorbid diagnoses, including depression and bipolar disease.

Subclinical hypothyroidism (SCH), defined as elevated TSH levels with normal circulating T_4 and T_3 levels, occurs in a minority of patients, at most 10% to 15%, with primary mood disorders. SCH is more common with advanced age and in women. SCH is associated with a lower response rate to antidepressants, and there is recent evidence that even the presence of thyroid autoimmunity as measured by positive anti-TPOAb with normal TSH may be associated with lower rates of antidepressant response. There are no data to guide clinical decision-making about whether thyroid replacement would enhance antidepressant response, so the decision on thyroid replacement should be consistent with current guidelines for the treatment of SCH. Several clinical guidelines recommend treatment of SCH with thyroid hormones for adults with TSH levels >10 mIU/L and for people with lower TSH values who are young, symptomatic, or have specific indications for treatment. However, most recent studies and guidelines raise doubts as to the benefits and risks associated with treatment. This controversy remains unresolved.

CLINICAL HORMONE STUDIES

All peptides and hormones of the HPT axis have been studied for the treatment of mood disorders. These include TRH and TSH, as well as the peripheral hormones T_4 and T_3. The best evidence for therapeutic efficacy is for the use of T3 in unipolar major depression; there are fewer data on the role of T4 in the treatment of depression. Preliminary data suggest that T4 may have a role as a mood stabilizer in bipolar disorder.

FIGURE 33.15b–2. Thyroid hormone supplementation strategies in major depression.

In major depression, thyroid hormones have been used in several ways (Fig. 33.15b–2). In very early studies, they were used as *monotherapy* for the treatment of depression with uncertain benefits. More recent work has focused on the *supplementation* of antidepressants (tricyclics or selective serotonin reuptake inhibitors [SSRIs]) with thyroid hormone. The first type of supplementation is *acceleration,* in which thyroid hormones have been used at the outset of an antidepressant trial, primarily with tricyclic antidepressants, to accelerate the response to antidepressant treatment. A second type of supplementation is the addition of thyroid hormones to antidepressants in patients who have failed to have a satisfactory response to an antidepressant trial, termed *augmentation*. A third supplementation approach is to initiate thyroid hormone from the start of an antidepressant trial to achieve both *acceleration* and *enhancement* of antidepressant response in depressed patients starting antidepressant therapy. Finally, thyroid hormones, particularly thyroxine, have been used as mood stabilizers in bipolar disorder, especially in rapid-cycling forms.

Thyrotropin-Releasing Hormone

TRH is a peptide released from the hypothalamus that regulates thyroid hormone secretion by the thyroid gland through its effects on pituitary TSH release. In addition, TRH has direct behavioral effects on the brain. TRH also has effects on cardiorespiratory, GI, and neurologic functions. Due to its widespread effects, TRH was tested as an antidepressant both as monotherapy and together with electroconvulsive therapy (ECT). TRH was administered both intravenously (single dose or repeated) and orally, but only a transient antidepressant effect was demonstrated. In conclusion, the administration of TRH in its various forms had little if any antidepressant effect, and in any case, this may be a nonspecific activating effect of the peptide rather than a direct effect on the HPT axis. When TRH was administered intravenously to eight patients before ECT, this yielded greater arousal and improved cognitive functioning compared with placebo.

Thyrotropin

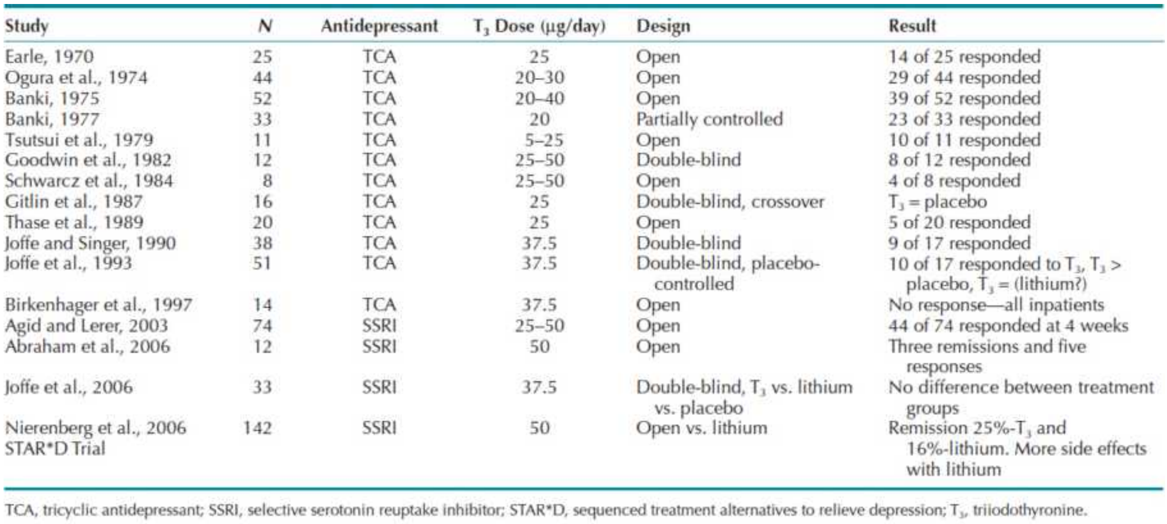
TSH has also received limited attention as an antidepressant. The rationale for its use is based on its stimulation of the thyroid gland and, thus, would achieve an effect similar to the administration of peripheral thyroid hormones for the treatment of depression. One study has examined the antidepressant effect of TSH by administering 10 IU of TSH intravenously to 20 depressed women 1 day before beginning an antidepressant trial with the tricyclic imipramine. When compared to a placebo control group, the TSH-treated patients had a rapid antidepressant response. These data, while of interest, require replication with larger samples, a more current methodology for clinical trials, and the use of SSRIs. Such study designs would allow a more appropriate evaluation of the efficacy of TSH in accelerating the response to antidepressants.

T3

T3 is the most widely studied thyroid hormone for the treatment of depression. In early studies, it was used as *monotherapy* for the treatment of depressed patients. The data from these studies were largely inconclusive, as they involved small patient samples, inadequate clinical trial designs by current standards, and the use of heterogeneous patient groups who, by today's diagnostic criteria, would not necessarily be diagnosed with major depression. There have been no well-designed studies of T3 monotherapy to date; therefore, its use as a single treatment for depression has not gained any clinical ground.

T3 was used in earlier studies to *accelerate* the response to tricyclic antidepressants. T3 was administered at the outset of a tricyclic antidepressant trial, and a shorter lag in onset of therapeutic effect as compared with placebo was noted in some but not all studies. This acceleration effect was observed particularly in women as compared to men. All these studies had major methodologic flaws, including small numbers of patients, poorly defined patient groups, and relatively brief duration of treatment. These earlier studies involved tricyclic antidepressants only, usually at suboptimal doses by current standards, as SSRIs were not available. Nonetheless, a meta-analysis of these earlier studies showed a significant acceleration of antidepressant response during the initial 4 weeks of tricyclic treatment for T3 over placebo.

Table 33.15b–1.
T3 Augmentation of Antidepressants



Study	N	Antidepressant	T_3 Dose (μg/day)	Design	Result
Earle, 1970	25	TCA	25	Open	14 of 25 responded
Ogura et al., 1974	44	TCA	20–30	Open	29 of 44 responded
Banki, 1975	52	TCA	20–40	Open	39 of 52 responded
Banki, 1977	33	TCA	20	Partially controlled	23 of 33 responded
Tsutsui et al., 1979	11	TCA	5–25	Open	10 of 11 responded
Goodwin et al., 1982	12	TCA	25–50	Double-blind	8 of 12 responded
Schwarcz et al., 1984	8	TCA	25–50	Open	4 of 8 responded
Gitlin et al., 1987	16	TCA	25	Double-blind, crossover	T_3 = placebo
Thase et al., 1989	20	TCA	25	Open	5 of 20 responded
Joffe and Singer, 1990	38	TCA	37.5	Double-blind	9 of 17 responded
Joffe et al., 1993	51	TCA	37.5	Double-blind, placebo-controlled	10 of 17 responded to T_3, T_3 > placebo, T_3 = (lithium?)
Birkenhager et al., 1997	14	TCA	37.5	Open	No response—all inpatients
Agid and Lerer, 2003	74	SSRI	25–50	Open	44 of 74 responded at 4 weeks
Abraham et al., 2006	12	SSRI	50	Open	Three remissions and five responses
Joffe et al., 2006	33	SSRI	37.5	Double-blind, T_3 vs. lithium vs. placebo	No difference between treatment groups
Nierenberg et al., 2006 STAR*D Trial	142	SSRI	50	Open vs. lithium	Remission 25%-T_3 and 16%-lithium. More side effects with lithium

TCA, tricyclic antidepressant; SSRI, selective serotonin reuptake inhibitor; STAR*D, sequenced treatment alternatives to relieve depression; T_3, triiodothyronine.

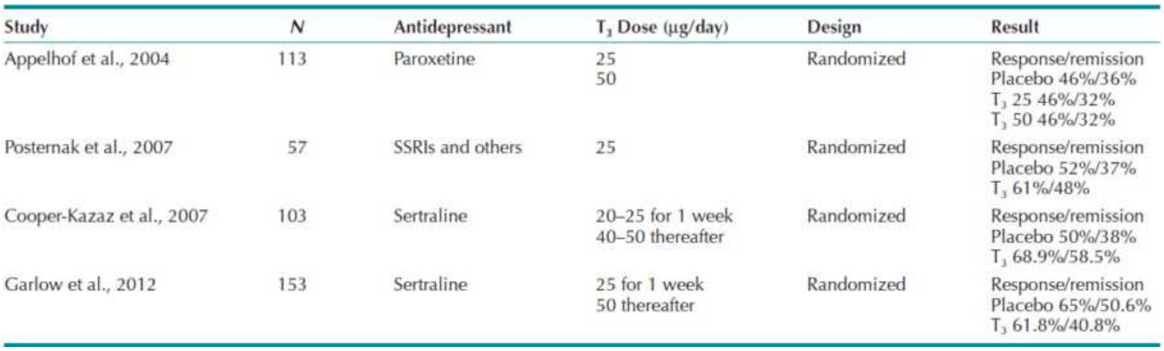
A third approach to the use of T3 in depressive disorders has been to *augment* response to antidepressants in those who failed to respond to an antidepressant trial. These studies are summarized in Table 33.15b–1. Open and controlled studies show that approximately 50% to 60% of patients who do not respond to an antidepressant trial with tricyclics will respond within 2 to 3 weeks after the addition of T3. Notwithstanding the limitations of the studies of T3 augmentation to date, a meta-analysis of these studies concluded that T3 may increase response rates and decrease the severity of depression scores in patients who are refractory to tricyclic antidepressant treatment. Patients with T3 augmentation were approximately twice as likely to respond as were controls.

In the past few years, there has been emerging data on the use of T3 to augment SSRIs in antidepressant nonresponders. The findings with the SSRIs are consistent with those for the tricyclics and are included in Table 33.15b–1. Both open and controlled studies have generally been positive and indicate that T3 may be an effective augmentation agent for SSRI nonresponders. In data from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial, T3 augmentation had comparable remission rates to other augmentation options and a more favorable adverse event profile and dropout rate.

There are also preliminary data that if T3 is administered at the outset of a course of ECT, a reduced number of treatments are required to achieve a therapeutic response, and there may be a greater sparing of cognitive difficulties.

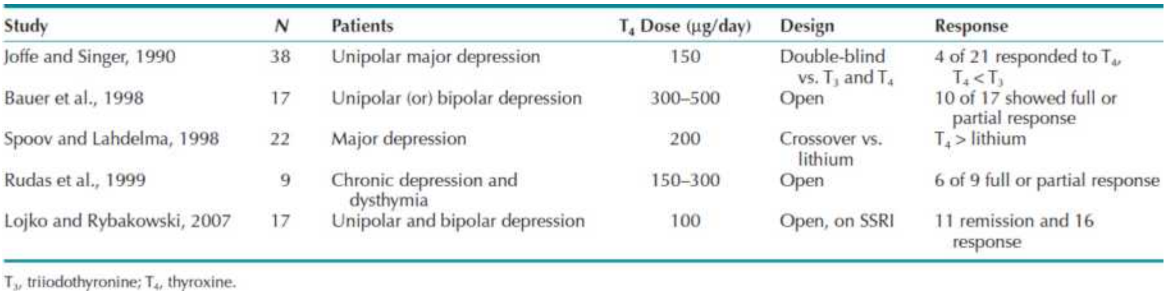
In recent studies, there has been another use of T3; administration from the outset of an SSRI trial to determine whether this will reduce delay in therapeutic onset (*acceleration*) and increase rates of treatment response (*enhancement*) in patients not necessarily refractory to antidepressant treatment. There have been four randomized controlled trials which are summarized in Table 33.15b–2. One study showed clearly significant results for enhancement of sertraline treatment by T_3 (Cooper), and one showed moderately positive results for enhancement of several different SSRIs (Posternak). Two trials showed no difference in the effect of T_3 to enhance paroxetine (Appelhof) and sertraline (Garlow), respectively. A meta-analysis of these four trials did not show a significant effect of T3 administered from the outset of treatment to enhance the antidepressant effect of SSRIs. However, the response may be specific to subgroups of patients and may also be influenced by genetic polymorphism of the *DIO1* receptor gene. The dose of SSRI may also be a factor, with patients receiving a lower SSRI dose more likely to show enhancement of response with T3 supplementation from the onset of treatment.

Table 33.15b–2.
T3 Enhancement of SSRI



Study	N	Antidepressant	T_3 Dose (µg/day)	Design	Result
Appelhof et al., 2004	113	Paroxetine	25 50	Randomized	Response/remission Placebo 46%/36% T_3 25 46%/32% T_3 50 46%/32%
Posternak et al., 2007	57	SSRIs and others	25	Randomized	Response/remission Placebo 52%/37% T_3 61%/48%
Cooper-Kazaz et al., 2007	103	Sertraline	20–25 for 1 week 40–50 thereafter	Randomized	Response/remission Placebo 50%/38% T_3 68.9%/58.5%
Garlow et al., 2012	153	Sertraline	25 for 1 week 50 thereafter	Randomized	Response/remission Placebo 65%/50.6% T_3 61.8%/40.8%

Table 33.15b–3.
Antidepressant Augmentation With T4



Study	N	Patients	T_4 Dose (µg/day)	Design	Response
Joffe and Singer, 1990	38	Unipolar major depression	150	Double-blind vs. T_3 and T_4	4 of 21 responded to T_4, $T_4 < T_3$
Bauer et al., 1998	17	Unipolar (or) bipolar depression	300–500	Open	10 of 17 showed full or partial response
Spoov and Lahdelma, 1998	22	Major depression	200	Crossover vs. lithium	T_4 > lithium
Rudas et al., 1999	9	Chronic depression and dysthymia	150–300	Open	6 of 9 full or partial response
Lojko and Rybakowski, 2007	17	Unipolar and bipolar depression	100	Open, on SSRI	11 remission and 16 response

T_3, triiodothyronine; T_4, thyroxine.

In summary, there is evidence suggesting that T3 augmentation may be effective in treatment-resistant patients. Larger studies are required to address several issues. First, further studies of T3 augmentation of SSRIs with large-scale, well-controlled designs are needed. Second, issues such as dosing and duration of treatment need to be addressed to provide solid data to guide the use of T3 in a broad-based safe clinical approach to treatment-resistant depression.

T4

This thyroid hormone has been used in two ways in the treatment of mood disorders. First, it has been used as an augmentation agent for the treatment of tricyclic-refractory depression and, second, as a mood stabilizer for rapid-cycling bipolar disorder.

Data on the use of T4 in refractory depression are summarized in Table 33.15b–3. These studies have generally involved open designs and various diagnoses, including both unipolar and bipolar subjects in one study and chronic depression or dysthymic patients in another study. All involve small sample designs. In each of these studies, T4 showed an augmentation effect in antidepressant nonresponders.

T4 has also been used in high doses as a mood stabilizer. There are now five case studies or case series, four involving rapid-cycling bipolar patients and one involving nonrapid-cycling bipolar patients. The total patient sample in the 5 studies consists of 30 patients. These studies are summarized in Table 33.15b–4. Doses of T4 ranged from 150 to 500 µg/day. Of the 30 patients, 27 were reported to respond to T4 or augmentation of mood stabilizers. Clearly, these data are of considerable interest, especially because rapid-cycling bipolar patients represent a substantial therapeutic challenge. A large-scale systematic controlled trial would clarify the efficacy of T4 in bipolar disorder and its role relative to other mood-stabilizing interventions.

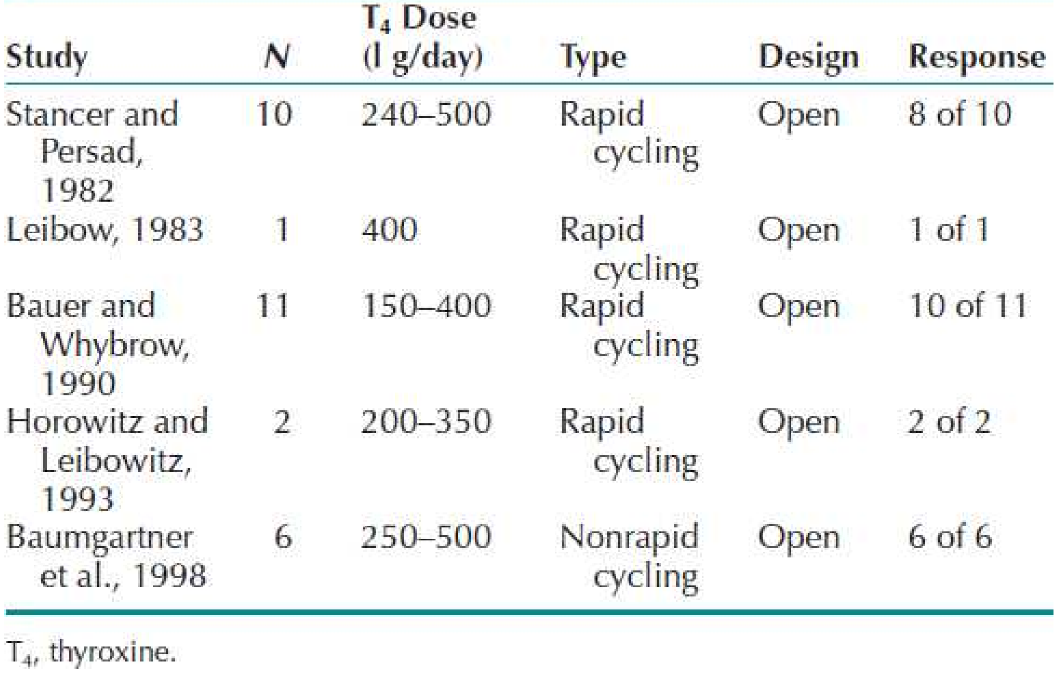
Therapeutic Indications

None of the peptides or hormones of the HPT axis have received formal approval by regulatory authorities in North America or worldwide for use in the treatment of depression. Evidence suggests that these hormones may have clinical use in the treatment of different types of mood disorders. Indeed, the use of thyroid hormones (mainly T_3) appears in various clinical practice guidelines for the treatment of major depressive depression. T3 may be useful as an augmentation agent in refractory depression and may also have some use in accelerating antidepressant response. The use of T4 in refractory depression requires further study, and T4 may be an adjunct to mood-stabilizer treatment, particularly in rapid-cycling patients. For thyroid hormones to have a broad clinical application, empirical data are required to clarify their efficacy and to determine their role relative to other options for these various types of mood disorders. Until such data are obtained, T3 remains one of many possibilities to consider for use in patients who do not respond to their first or subsequent antidepressant trial. Moreover, T4 may be considered an option for the refractory bipolar patient, especially when conventional mood stabilizers have proven to be ineffective or only partially effective. Finally, the presence of depressive symptoms in SCH patients could warrant the initiation of T4.

Precautions and Adverse Reactions

T3 administered in the usual doses for augmentation treatment should not lead to symptoms of hyperthyroidism or thyrotoxicosis. A dosage of 25 µg/day is below the replacement dosage for this hormone; thus, symptoms of thyroid toxicity are extremely rare. A dose of 50 µg/day is closer to the daily T_3 production range; thus, symptoms of thyroid excess could occur. We recommend continuous clinical monitoring and TSH assessment while administering T3. It should be noted that there are no well-demonstrated dose–response studies for T3; therefore, doses in excess of 25 µg/day should be used with caution. Long-term administration of T3 to euthyroid individuals is not advisable; in depressed patients who have responded, the treatment should be tapered and stopped by 12 weeks. T3 is generally well tolerated when administered to depressed patients. A transient headache is the most commonly reported adverse effect, and it usually subsides after 1 or 2 days, either spontaneously or with the administration of mild analgesics. Allergic reactions are extremely uncommon. T3 should be used with great caution in older adults and in patients with various medical disorders, including endocrine and cardiovascular disease, and should be avoided in pregnancy.

Table 33.15b–4.
T4 as Adjunctive Mood Stabilizer in Bipolar Disorder



Study	N	T_4 Dose (l g/day)	Type	Design	Response
Stancer and Persad, 1982	10	240–500	Rapid cycling	Open	8 of 10
Leibow, 1983	1	400	Rapid cycling	Open	1 of 1
Bauer and Whybrow, 1990	11	150–400	Rapid cycling	Open	10 of 11
Horowitz and Leibowitz, 1993	2	200–350	Rapid cycling	Open	2 of 2
Baumgartner et al., 1998	6	250–500	Nonrapid cycling	Open	6 of 6

T_4, thyroxine.

The same precautions as noted for T3 apply to T4, especially since this compound is commonly used in supraphysiologic doses. A recent study has demonstrated that depressed patients are able to tolerate supraphysiologic doses of T4 much better than healthy controls. Long-term thyroid hormone treatment may be associated with bone demineralization, resulting in osteoporosis in women. Although this association is still controversial, one should approach the long-term use of thyroid hormones with caution.

Dosage and Administration

T3 is generally administered as a single dose of 25 to 50 mcg in the morning to avoid insomnia. There is a good rationale for divided administration of T3 because of its short half-life, but a single daily dose is commonly used to improve compliance. T4 has been administered in dosages that produce a circulating T4 concentration, which exceeds or is at the upper range of normal for patients with bipolar mood disorder. These dosage recommendations apply to healthy adults and should be modified for older patients or those with significant medical illnesses.

There are no data to support the efficacy of thyroid hormone treatment for depression in children.

33.16 Combination Pharmacotherapy

CHARLES DEBATTISTA, D.M.H., M.D., AND ALAN F. SCHATZBERG, M.D.

Historically, the combination of multiple psychotropic medications for the treatment of psychiatric disorders has been frowned upon. The practice of “polypharmacy” was often seen as evidence of poor clinical judgment. A patient who was on three or four psychotropics was one whom many clinicians and impartial observers would characterize as overmedicated and perhaps improperly diagnosed and cared for.

However, the significant limitations of monotherapy with antidepressant, antipsychotic, and mood-stabilizing agents have become increasingly apparent. For many patients, monotherapy results in insufficient benefit.

There are three primary reasons for combining medications in psychiatric practice. Perhaps the most common reason for polypharmacy is that many patients do not respond adequately to a single agent. For example, in acute trials with antidepressants, most unipolar depressed patients are either partial or nonresponders to monotherapy. Medications are thus frequently combined to enhance antidepressant response. A second related reason for combining therapy is that not all aspects of a given illness may respond to a single agent. This may be particularly true in bipolar disorder, where monotherapy with a single mood stabilizer has become “the exception rather than the rule.” Treating the manic phase or the depressed phase may require different combinations of medications. Finally, medications are sometimes added to counteract the side effects of the original medication. Thus, patients on first-generation antipsychotics are usually given an anticholinergic agent to mitigate extrapyramidal side effects.

In addition to the advantages of combination treatment, there can be important downsides to combining psychotropic agents. The most important of these are the risks of pharmacodynamic and pharmacokinetic drug interactions. Cytochrome P450 interactions can result in either substantially higher or lower serum levels which might increase side effects or render one or more agents less effective. For example, the combination of paroxetine and imipramine can substantially raise the serum levels of imipramine and potentially increase antimuscarinic, hypotensive, cardiac conduction, or sedating effects of the imipramine. Likewise, pharmacodynamic interactions can be equally serious. For example, the combination of an monoamine oxidase inhibitor (MAOI) and a serotonergic agent may result in a potentially lethal serotonin syndrome. Thus, clinicians must carefully weigh the risks and benefits of all combination treatments.

COMBINATION STRATEGIES IN THE TREATMENT OF MAJOR DEPRESSION

Antidepressant–Antipsychotic Combinations

Given the limited efficacy of antidepressant monotherapy in the treatment of major depression, augmenting agents or combination strategies are frequently employed in clinical practice to enhance response. Conventionally, *augmentation* is used to describe the addition of an agent that is not viewed as a primary antidepressant by itself (i.e., thyroid hormone). *Combination* has been used when a known antidepressant is added to another (i.e., bupropion [Wellbutrin] and fluoxetine [Prozac] combination).

Although antipsychotics have been used in combination with antidepressants for many years in the treatment of psychotic depression, the second-generation antipsychotics were the first group of agents food and drug administration (FDA) approved in the adjunctive treatment of depression that had not responded to monotherapies. The pharmacology of the second-generation drugs, including their 5-hydroxytryptamine type 2 (5-HT2) antagonism, has long been thought to imbue them with antidepressant properties. In addition, they clearly help a number of symptom domains in depressed patients, including sleep, appetite, and agitation. As of this writing, several second-generation antipsychotics have FDA approval in the adjunctive treatment of resistant depression, and several more are in late-stage clinical trials.

Olanzapine (Zyprexa) was the first of the second-generation antipsychotics to seek approval in the adjunctive treatment of depression. The combination of 10 to 20 mg/day of olanzapine with fluoxetine in the treatment of various types of depression, including resistant depression. In 2007, the olanzapine–fluoxetine combination (Symbyax) was approved for the treatment of resistant depression. Combination pills, however, tend not to be popular with clinicians. Many clinicians prefer the more flexible dosing options of combining two different agents. Since both olanzapine and fluoxetine are generically available, there is also a cost advantage of using two generic agents over one branded drug.

Aripiprazole (Abilify) has long been of interest in the treatment of depression because it is a partial agonist of dopamine and a 5-HT1A agonist in addition to its 5-HT2 effects. Randomized controlled trials have demonstrated that the addition of aripiprazole to an selective serotonin reuptake inhibitor (SSRI) or venlafaxine (Effexor) is more effective than the addition of a placebo in relieving depressive symptoms. As a result, aripiprazole was FDA approved in the adjunctive treatment of major depression. In addition to the FDA registration trials demonstrating the efficacy of aripiprazole in major depressive disorder (MDD), a 1,500-patient multicenter trial (VAST-D) found that aripiprazole augmentation was somewhat more effective in achieving remission in MDD patients than either switching to bupropion or augmentation with bupropion. The relative lack of weight gain, sedation, or metabolic effects in aripiprazole compared to other second-generation agents such as olanzapine has made it among the most frequently prescribed antidepressant-augmenting agents. However, akathisia and some weight gain were noted in the aripiprazole augmentation trials.

Quetiapine (Seroquel), the first monotherapy approved for bipolar depression, also appears to be useful in many unipolar patients. Several registration trials demonstrated that the addition of 150 to 300 mg/day of quetiapine to standard antidepressants improved antidepressant response. Thus, quetiapine was approved as an adjunctive treatment for major depression in 2009. In 2015, brexpiprazole, which is chemically related to aripiprazole, was also FDA approved for the adjunctive treatment of depression. Other second-generation antipsychotics, including lurasidone (Latuda), ziprasidone (Geodon), cariprazine (Vraylar), and risperidone (Risperdal), also appear effective in some open-label and controlled studies as adjunctive agents in unipolar depression. While lurasidone is approved as a treatment for bipolar depression and schizophrenia, it also has demonstrated efficacy in at least four registration trials for the treatment of depressive symptoms associated with schizophrenia. As with other combination strategies, the potential benefits of augmenting with a second-generation antipsychotic must be weighed against the possible side effects of weight gain, extrapyramidal symptoms (EPS), and metabolic effects.

Lithium–Antidepressant Combinations

After antipsychotics, lithium has been among the best-studied augmenters to standard antidepressants in MDD. However, lithium augmentation has become less popular with clinicians in the past 25 years, secondary to the potential toxicity of lithium, the requirement for laboratory monitoring, and the availability of other augmenters. Nonetheless, lithium is still used by many clinicians to boost antidepressant response in partial and nonresponders to monotherapy with an antidepressant.

The early reports of lithium augmentation indicated that the addition of lithium to a tricyclic antidepressants (TCA) often resulted in clinical improvement within 72 hours in patients who had failed to respond to a TCA alone. Since then, at least 80 studies have been completed on lithium augmentation, and the vast majority have suggested some acute benefits of the addition of lithium to an antidepressant. However, many of these reports suggest maximum benefits may not be seen for weeks. Furthermore, the addition of lithium also appears to prevent relapses in unipolar patients more effectively than an antidepressant alone. The response often occurs at low doses (600 to 1,200 mg/day) and at relatively low serum levels. Current data would suggest that serum levels in the range of 0.5 to 0.8 mEq/L are effective in lithium augmentation of antidepressant effects.

Although most studies of lithium augmentation have employed TCAs, a number of studies have evaluated the efficacy of lithium augmentation of SSRIs. The National Institute of Mental Health (NIMH)-funded Sequenced Treatment Alternatives for Resistant Depression (STAR*D) trial is among the most frequently cited study that included augmentation strategies. In patients who had failed monotherapy with citalopram (Celexa) and an augmentation trial with either buspirone (BuSpar) or bupropion, only 15.9% of patients achieved a remission level response with the addition of lithium. This was a numerically but not statistically lower level of response than those patients who were augmented with thyroid hormone at that point in treatment. Since most lithium augmentation trials do not indicate the degree of treatment resistance in the study population, the STAR*D data may be the most relevant to date on the limitations of lithium augmentation in resistant–depressed patients. There are likely certain characteristics in depressed patients that may predict response to the addition of lithium to their antidepressant regimen. For example, there is some suggestion that lithium augmentation may be more successful in MDD patients who exhibit psychomotor retardation, have significant anorexia and weight loss, have suicidal thoughts, or have a low serum cortisol level.

Thyroid Supplement–Antidepressant Combinations

The addition of thyroid hormone to augment antidepressant response has been employed since the 1960s. As with lithium, it has also faded in popularity with the advent of new augmentation options.

Trials that have compared thyroid to lithium augmentation directly have generally suggested that thyroid augmentation is at least as effective as lithium augmentation. The few head-to-head trials of thyroid to lithium augmentation have tended to favor thyroid augmentation.

Although most trials employing thyroid augmentation have involved the use of TCAs, a number of trials also suggest efficacy when thyroid supplements are added to SSRIs. Multiple case reports and small studies have suggested that 25 to 50 mcg of liothyronine (Cytomel) (triiodothyronine or T3), added to various SSRIs, potentiate their antidepressant effects. Among the largest and most systematic thyroid augmentation of an SSRI trial to date was the STAR*D trial. In this trial, patients who had failed two other trials (monotherapy with citalopram and augmentation with bupropion or buspirone) were treated with triiodothyronine or lithium augmentation. About 25% of patients on T3 augmentation of citalopram achieved a remission level response compared to about 15% of the lithium-augmented patients. Among the limitations of the STAR*D trial was that it was an open-label trial, and patients had the option of not participating in randomization. Not all placebo-controlled studies have shown the benefit of thyroid augmentation.

The question of whether T3 is more effective than supplementation with levorotatory thyroxine (T4) has not been adequately addressed in the literature. Most studies have employed T3, and the only head-to-head study favored T3 over T4. Since the half-life of T4 is relatively long and the study was short (2 weeks), it cannot be conclusively interpreted for the superiority of T3. Indeed, there are positive studies employing T4 in thyroid augmentation. Although side effects were not common in this trial, the use of supraphysiological doses of thyroxine for an extended period might be problematic for some patients.

Patient characteristics of responders to thyroid augmentation include females and those with a history of thyroid abnormalities. There is growing evidence that patients with mild thyroid abnormalities (slightly elevated thyroid stimulating hormone (TSH), normal T3 and T4) are less likely to respond to antidepressants alone but may respond to the addition of a thyroid supplement. Women over the age of 50, perhaps because they are most susceptible to hypothyroidism, also appear to have higher levels of response to thyroid augmentation. One study has reported that responders to T3 could be identified by their having lower T3 levels and by being carriers for a specific allele on an single nucleotide polymorphism (SNP) for the deiodinase-converting enzyme for T3 to T4. This finding is in need of replication but could explain why some patients appear to derive great benefit from thyroid augmentation.

Stimulants/Dopamine Agonist–Antidepressant Combinations

There are a variety of stimulants and stimulant-like agents that have been useful augmenters in depression. Amphetamines have been used since the early 1930s for the treatment of depression. In addition, dopamine agonists such as pramipexole (Mirapex), dopamine reuptake blockers including bupropion, nondopamine and wake-promoting agents such as modafinil (Provigil) have shown some promise as augmenters in the treatment of depression.

The use of stimulants as augmenting agents in the treatment of depression has been applied to special populations, including medical and geriatric patients. Amphetamines tend to be used to target fatigue, hypersomnia, and cognitive difficulties in depressed patients. When combined with TCAs, methylphenidate and amphetamines inhibit the cytochrome P450 CYP isoenzyme 2D6 and artificially increase TCA serum levels.

Although most amphetamine augmentation studies have involved TCAs, a few have shown benefits in combination with MAOIs and SSRIs. Pharmacodynamic interactions between the stimulants and MAOIs can be problematic. Most controlled trials with amphetamine in the treatment of major depression have not shown benefits as a monotherapy. By far, the largest and most comprehensive studies to evaluate a stimulant to augment standard antidepressants involved lisdexamfetamine combined with an SSRI or serotonin norepinephrine reuptake inhibitor (SNRI). Subjects who failed to respond to 8 weeks of antidepressant monotherapy were randomized to an additional 8 weeks of lisdexamfetamine or placebo combined with the antidepressant. The two phase III trials involving over 800 patients failed to show an advantage of adding the lisdexamfetamine over adding a placebo to the antidepressant monotherapy.

There are now several dopamine agonists approved for the treatment of Parkinson disease, including pramipexole. Preliminary work with pramipexole as an adjunctive agent to SSRIs has suggested that it may have a role in treatment-resistant patients in doses of 1 mg/day (starting doses are lower). Ropinirole (Requip) is also actively being investigated as an adjunctive treatment in resistant depression. In addition, pramipexole and ropinirole clearly treat restless legs, including restless legs exacerbated by the use of SSRIs.

Modafinil and armodafinil are nonstimulants that are approved by the FDA for the treatment of excessive sleepiness associated with narcolepsy, obstructive sleep apnea, and shift work sleep disorder. The lack of a more significant abuse potential for modafinil and armodafinil has led to their application as adjunctive agents in the treatment of depression with the same symptom targets as the stimulants: fatigue and hypersomnia. Several studies have indicated that modafinil is well tolerated and appears to be useful in depressed partial responders to SSRIs. While meta-analyses of completed randomized trials with combination treatment with modafinil and armodafinil have generally suggested the efficacy of these drugs in bipolar and unipolar patients, registration trials of armodafinil for the treatment of bipolar depression failed to demonstrate adequate efficacy.

Bupropion has weak dopamine reuptake–blocking properties but may act primarily as a noradrenergic agent. It is among the most common augmenting agents used today in resistant depression. The combination of bupropion with SSRIs is simple and usually well tolerated. Studies completed to date have been retrospective or open. The largest of these open trials, the STAR*D trial, reported a remission rate of about 30% in patients who had failed to achieve remission on citalopram alone. As with many augmentation trials, it is not clear whether longer treatment with citalopram alone may have resulted in the improvement. In fact, the CO-MED trial demonstrated that starting with the combination of escitalopram and bupropion was no more effective than treating with escitalopram alone in achieving antidepressant remission or response. Nonetheless, the experience of U.S. clinicians supports the use of bupropion augmentation.

Sex Steroid–Antidepressant Combinations

It is known that estrogen-deficiency states, such as the postpartum period, may increase the risk of depressive symptoms in some women. In addition, estrogen possesses some antidepressant properties, including

MAO inhibition and serotonin agonist properties that are dose and duration specific. However, estrogen supplementation has been inconsistently useful in the treatment of depressed women. Some studies found that estrogen had no significant antidepressant effect when used alone for perimenopausal depression. In addition, other studies have found estrogen to be an effective prophylaxis against recurrent affective illness in the postpartum period. However, there are few adequately controlled studies, and a number of studies have not shown substantial benefit.

The combination of estrogens with antidepressants has sometimes been useful. For example, there have been case reports of oral contraceptives augmenting the effects of antidepressants in patients with refractory depression. In addition, postmenopausal women may respond better to fluoxetine if they are on hormone replacement therapy than if they are not. Recent studies of estrogen augmentation of SSRIs in both pre- and postmenopausal women have not shown a consistent benefit. However, 0.1 mg of transdermal estradiol (Alora) was suggested to accelerate SSRI response in some perimenopausal women. The potential benefits of estrogen augmentation must be balanced against the defined risks to long-term treatment with unopposed estrogen, and the benefits have not been clearly established in the treatment of depression. Overall, the data suggest maximal benefit during the perimenopausal phase.

Dehydroepiandrosterone (DHEA), a corticosteroid precursor of both androgens and estrogens, is used over the counter in many older patients with claims of enhanced mood, energy, and sexual vigor. There are a few controlled trials that indicate that DHEA may be efficacious in the treatment of major depression, minor depressive symptoms, and dysthymia. The safety of DHEA has been called into question because of its potential to enhance the growth of sex-steroid tumors and possible virilizing effects in women.

Esketamine/Ketamine–Oral Antidepressant Combination

Racemic ketamine and its S-enantiomer, esketamine (Spravato), are increasingly used in the treatment of resistant depression. In addition to second-generation antipsychotics, esketamine is the only other drug currently FDA approved as an adjunctive treatment with oral antidepressants in resistant depression. Esketamine was approved as a rapidly acting adjunctive agent in 2019 and, in 2020, received another indication for treating depressive symptoms in patients with suicidal ideation or actions. Racemic etamine has demonstrated utility as a treatment for resistant depression in smaller controlled trials since 2006 and is used off-label for this indication. Intranasal esketamine was shown to be effective in one-third of registration trials in patients who had failed two or more antidepressants and was near positive in the other two trials. In addition, adjunctive esketamine was shown to effectively reduce the relapse rate of patients who had responded to or remitted with acute, adjunctive treatment of esketamine in combination with an oral antidepressant. The antidepressant effect of ketamine and esketamine is often seen in 2 to 24 hours after administration and tends to last about 1 week. Thus, repeated, intermittent dosing is generally required to sustain a response. Between 30% to 60% of patients unresponsive to monotherapies for MDD may respond to an acute trial of ketamine or esketamine.

Ketamine and esketamine are Schedule 3 drugs administered in the clinic and, as such, are different than other antidepressant combinations. As controlled substances, they require a drug enforcement administration (DEA) registration and protocols for administration, inventory, security, disposal, etc. Ketamine is a common drug of abuse in many parts of the world, particularly in Asia. Thus, patients with a significant history of abuse may not be ideal candidates. In addition, disassociation is a common side effect of ketamine, and some patients with dissociative symptoms, including some post traumatic stress disorder (PTSD) patients, may be sensitive to these drugs. Patients with a history of psychosis may also be sensitive to the psychotomimetic effects of ketamine and esketamine.

Other Antidepressant Combinations

A variety of other antidepressant combinations are used in the treatment of resistant depression with varying degrees of scientific support. Given the poor response to antidepressant monotherapy, the question of whether combining antidepressants from the onset of treatment would improve remission or response rates was evaluated in a large multicenter trial. The CO-MED trial (2011) evaluated whether the combination of escitalopram and bupropion or the combination of venlafaxine and mirtazapine from the onset of treatment was superior to monotherapy treatment with escitalopram or venlafaxine alone in achieving remission or response. There appeared to be no benefit from starting treatment with combination treatment versus monotherapy.

Trazodone (Desyrel) has been used primarily as a hypnotic to treat depression or emergent insomnia. Although some small open studies have suggested an augmenting role for the use of trazodone combined with SSRIs, there is little evidence of benefit beyond the hypnotic effects of the drug. Likewise, buspirone, a generically available anxiolytic, has been applied as an augmenter to SSRIs with inconsistent benefits. Double-blind trials for buspirone augmentation of SSRIs in the treatment of obsessive compulsive disorder (OCD) have been negative, and only open studies in depression suggest some benefit of adding buspirone to an SSRI. The STAR*D study found that among patients who had failed to achieve remission to citalopram alone, about 30% of patients achieved remission with the addition of buspirone. This is the same rate found to remit with bupropion augmentation in the trial.

The beta-blocker pindolol (Visken) has some support in the literature as an augmenter to SSRIs but little support among clinicians.

There have been multiple controlled trials of pindolol augmentation, with most being positive. The relative lack of use among clinicians may be related to the perception that pindolol is not efficacious, or to concerns about the implication of beta-blockers in inducing depression, and some wariness of possible pharmacokinetic interactions between beta-blockers and CYP 2D6 inhibiting SSRIs such as fluoxetine and paroxetine (Paxil). Mirtazapine, like trazodone, can treat depression-associated insomnia and may help stimulate appetite in depressed older adult patients. The combination of venlafaxine and mirtazapine in patients who had failed three other trials in the STAR*D trial and the combination of venlafaxine and mirtazapine showed more of an improvement in depressive symptoms and was far better tolerated than the MAOI tranylcypromine (Parnate). However, the overall response rates in the mirtazapine SNRI combination and tranylcypromine groups were not statistically different. Only about 10% of patients achieved remission.

The combination of bupropion and dextromethorphan was approved for the treatment of MDD in 2022. Dextromethorphan has been available as an over-the-counter antitussive agent since the 1950s but studied in the treatment of mood disorders since at least 2014. For example, an open-label study of quinidine/dextromethorphan for the treatment of major depression showed had 45% response rate over 10 weeks of treatment.

While subsequent studies with quinidine in combination with dextromethorphan for major depression did not demonstrate efficacy, the combination of bupropion with dextromethorphan has proven effective. Like quinidine, bupropion is also a CYP2D6 inhibitor which inhibits the normally rapid metabolism of dextromethorphan allowing for adequate and consistent blood levels. In an early comparison study, the combination of bupropion 105 mg/dextromethorphan 45 mg twice daily was compared to bupropion alone 105 mg twice daily in 80 patients with MDD. The combination showed rapid response by week 2 and by week 6, was 46% for the combination and 17% for bupropion monotherapy. The phase III program has also shown consistent efficacy of the combination tablet compared to placebo. The combination appeared to be well tolerated with anxiety being the only side effect that leads to discontinuation of the combination tablet at higher rates than placebo and was seen in 2% of patients.

COMBINATION PHARMACOTHERAPY IN BIPOLAR DISORDER

Combination of Two Mood Stabilizers

Mood stabilizers typically refer to agents that are used to treat one or more poles of bipolar illness and might also have utility in the maintenance treatment of bipolar disorder. Mood stabilizers have historically included agents such as lithium, divalproex (Depakote), carbamazepine (Tegretol), and perhaps other anticonvulsants. Although agents such as second-generation antipsychotics might also be appropriately referred to as mood stabilizers, in this section, mood stabilizers will refer to lithium and anticonvulsant agents that have demonstrated utility in bipolar disorder. Approximately two-thirds of patients with bipolar affective disorder are treated with two more medications as maintenance therapy. In addition, second-generation antipsychotics are now frequently added during acute manic and depressive episodes, and sedative/anxiolytics are used to manage sleep, anxiety, and agitation. Thus, monotherapy is the exception in the treatment of bipolar disorder rather than the standard of care.

Lithium is commonly combined with anticonvulsants such as valproate, carbamazepine, and lamotrigine in the treatment of patients with refractory mania, in maintenance treatment, and in the treatment of bipolar depression. In most, although not all, studies, the combination of two mood stabilizers or a mood stabilizer and an antipsychotic is somewhat more effective than monotherapy with a single mood stabilizer. A number of reports have indicated that lithium–carbamazepine combinations are effective in patients who have failed to respond to these two agents given separately. Retrospective reviews have generally found the combination of lithium and carbamazepine to be useful and synergistic. There is also evidence that this combination may be particularly useful in rapid-cycling bipolar disorder. The combination of lithium and carbamazepine appears to be well tolerated. There is no evidence of increased neurotoxicity or blood dyscrasias with the combination. Dosing schedules of the lithium and carbamazepine should parallel regimens used for prescribing each drug alone. Therapeutic serum levels of both drugs should be monitored and maintained.

Perhaps the most common mood stabilizer combination in recent years has been the addition of valproate (Depakote) to lithium in patients who have manic breakthroughs or are unresponsive to lithium monotherapy. There are still relatively few prospective studies that have examined the efficacy of this combination. One naturalistic study indicated that the addition of valproate to lithium is more likely to be effective if the lithium level is above 0.6 mEq/L. Open-label studies have suggested that the combination of valproate and lithium may be more effective than either agent alone in the treatment of rapid-cycling bipolar disorder. For example, one study reported that eight of nine rapid-cycling patients with bipolar disorder, most of whom failed to respond to the combination of lithium and carbamazepine, responded when lithium was combined with valproate. However, other studies have not necessarily supported the advantage of adding valproate to lithium in the treatment of rapid-cycling bipolar disorder. Likewise, while the combination of valproate and lithium is commonly thought to be more effective in preventing cycles of mania and depression than monotherapy, there is little data to support this idea. The largest trial to date to evaluate the efficacy of the valproate/lithium combination in the maintenance treatment of bipolar 1 disorder, the BALANCE study (2010), failed to show an advantage of the combination treatment over lithium alone. However, the combination was more effective than valproate monotherapy. The combination of lithium and valproate seems to be well tolerated, and the dosing should aim to achieve adequate serum levels for both drugs.

The combination of valproate with carbamazepine has fallen out of favor in the past decade. Unfortunately, only anecdotal data support the combination of valproate and carbamazepine in the treatment of resistant bipolar disorder. In addition, a CYP450-based interaction increases the risk of carbamazepine toxicity. Also, the two taken together may result in even greater leucopenia than either alone.

A variety of other anticonvulsants such as gabapentin (Neurontin), topiramate (Topamax), lamotrigine (Lamictal), and tiagabine (Gabitril Filmtabs), levetiracetam (Keppra), and oxcarbazepine (Trileptal) have been combined with lithium and divalproex in the treatment of resistant bipolar patients. With the exception of lamotrigine, most of the reports detailing the benefits of combining standard mood stabilizers with these other anticonvulsants in the treatment of bipolar disorder have been anecdotal. For example, many open-label studies have supported the role of gabapentin in the treatment of bipolar disorder. At this time, no controlled trials have demonstrated a clear benefit of gabapentin in any phase of bipolar disorder as either an adjunct or a monotherapy. In one large-scale, double-blind study, gabapentin was no more effective than placebo when added to lithium. In that study, the lithium dosage could be adjusted during the trial, and this may have limited the likelihood of finding statistically significant differences. However, gabapentin may still benefit some symptoms in bipolar patients. For example, one small controlled trial has suggested that while gabapentin does not show acute benefits, it may augment the effect of standard mood stabilizers in preventing relapse in bipolar patients. Gabapentin is well tolerated in combination with most mood stabilizers and appears to benefit anxiety and agitation associated with a variety of conditions. A chemically related compound, pregabalin (Lyrica), has shown utility in the treatment of generalized anxiety but has not been extensively evaluated in the treatment of bipolar disorder.

Lamotrigine has shown efficacy in the maintenance treatment of bipolar disorder and in some studies in the treatment of acute bipolar depression, but its efficacy in the treatment of acute mania has not been demonstrated. Open-label augmentation with lamotrigine for bipolar depression in the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) did not show significant benefits on the primary outcome measures when compared to either risperidone or inositol. However, the patients treated with adjunctive lamotrigine had lower depression ratings than patients treated either with adjunctive lamotrigine or inositol. The benefits of lamotrigine make it likely that it will be increasingly employed as an adjunctive treatment to lithium, an atypical antipsychotic, or valproate in the treatment of the depressed phase of the illness. There do not appear to be significant pharmacokinetic interactions between lamotrigine and lithium. However, the risk for interactions does exist in the combination of lamotrigine with either valproate or carbamazepine. Valproate doubles the serum level of lamotrigine, thus increasing the risk of rash, while carbamazepine, on the other hand, cuts the lamotrigine serum levels in half.

The addition of oxcarbazepine, tiagabine, levetiracetam, and topiramate to lithium or valproate has not been extensively studied in the treatment of bipolar disorder. Oxcarbazepine is thought to carry fewer risks of pharmacokinetic interactions than does its chemical cousin carbamazepine. Thus, oxcarbazepine may be easier to combine with standard mood stabilizers than carbamazepine. However, some enzyme induction still occurs with the drug, and at least one controlled study did not find any benefit of adding oxcarbazepine to lithium. Earlier studies have supported the efficacy of oxcarbazepine in the treatment of mania and hypomania.

Topiramate has been studied primarily as an adjunctive agent in the treatment of bipolar disorder. Open trials suggest that the addition of topiramate to a standard mood stabilizer may help the depressed phase of the illness and improve symptoms in refractory patients. However, most controlled trials have failed to show a benefit of topiramate in bipolar disorder. The most common current rationale for combining topiramate with a mood stabilizer is to mitigate the weight gain associated with standard therapy. Topiramate has been associated with weight loss averaging up to 5 kg in 8 weeks as adjunctive treatment in bipolar disorder.

Tiagabine has not been proven effective or practical in the treatment of acute mania. The drug requires a slow titration secondary to potential side effects, including sedation and risk of seizure, with loading doses. However, open trials of tiagabine as an add-on to a standard mood stabilizer in refractory bipolar disorder have reported benefits at low doses (1 to 8 mg/day).

Levetiracetam was approved as an adjunctive treatment for partial seizures in 2000. A number of small case series have suggested some benefits of adding 1,000 to 4,000 mg/day of levetiracetam to standard mood stabilizers in the treatment of resistant mania. Likewise, adjunctive treatment with zonisamide (Zonegran) may have benefits for both the manic and depressed phase of bipolar disorder in open-label studies. Like topiramate, zonisamide has been associated with weight loss.

Mood Stabilizer–Antipsychotic Combinations

Antipsychotics have long been used as adjunctive treatments in bipolar disorder and are now used as monotherapies as well. Historically, an antipsychotic was used to treat acute mania or the psychotic symptoms and agitation associated with mania. Most of the second-generation antipsychotics are now approved for the treatment of acute mania, and a number are now approved in the depressed and maintenance phase of bipolar disorder. Many patients who are hospitalized with a manic episode will be treated with an antipsychotic soon after admission because of their more rapid onset of action relative to mood stabilizers. Multiple controlled studies have demonstrated that the addition of an antipsychotic to a mood stabilizer, particularly lithium and valproate, may be more effective in treating both manic and depressive symptoms than a mood stabilizer alone. For example, controlled trials employing risperidone, quetiapine, lurasidone, ziprasidone, and olanzapine have shown benefits in augmenting the antimanic effects of mood stabilizers. In a pooled analysis of five large controlled trials of second-generation antipsychotics combined with lithium in the treatment of acute mania, there appeared to be about a 20% advantage of the combination treatment over monotherapy with lithium or the antipsychotic.

Given that the second-generation antipsychotics appear effective in preventing mania, antipsychotics are commonly added to lithium or valproate when there are breakthrough symptoms during monotherapy. However, to date, there is very little controlled data to evaluate the efficacy of the antipsychotic/mood stabilizer combination in the prevention of bipolar cycling. Likewise, while several second-generation antipsychotics are now approved in the treatment of acute bipolar depression, relatively few studies have been completed to demonstrate that lurasidone, cariprazine, quetiapine, or olanzapine added to a mood stabilizer increases antidepressant efficacy. Still, the combination of one of the approved antipsychotics with either lithium or lamotrigine makes intuitive sense.

The combination of lithium clozapine (Clozaril) is occasionally used in the most treatment-resistant bipolar patients. A potential disadvantage of lithium combined with clozapine is the risk of neuroleptic malignant syndrome (NMS) as well as other side effects.

Carbamazepine–antipsychotic combinations may result in a pharmacokinetic interaction that reduces the serum levels of concurrent antipsychotics. A higher dose of the antipsychotic may be required.

Mood Stabilizer–Antidepressant Combinations

The treatment of bipolar depression remains a vexing problem. The mood stabilizers and antipsychotics, even in combination, are often inadequate to prevent or treat the depressed phase of the illness alone. On the other hand, the addition of an antidepressant may increase the risk of a switch into mania or rapid cycling. It is even unclear whether the addition of an antidepressant has any benefit in most patients. The few controlled studies to date have not necessarily supported the benefit of adding an antidepressant to a mood stabilizer. For example, the STEP-BD did not find that the addition of an antidepressant to lithium or valproate was more effective than an adjunctive placebo in the treatment of bipolar depression. In fact, there was a nonsignificant trend favoring the placebo group in a number of secondary measures. However, the rates of switching were also not different between the groups.

TCAs may be more problematic than other classes in exacerbating the illness, but all effective antidepressants, including electroconvulsive therapy, have the potential to switch a bipolar patient into a manic episode. Other SNRIs, including venlafaxine, may share a greater proclivity for inducing switches than bupropion. Bupropion may be less likely to induce rapid cycling or mixed states than either TCAs or venlafaxine, but there have been reported cases of bupropion-induced mixed states and manic episodes. In addition, the data on switch rates with bupropion is limited, although some studies, including the Stanley Foundation study on antidepressant treatment in bipolar disorder, have suggested that the switch rate into hypomania may be lower with bupropion than with some agents, including SNRIs. The addition of antidepressants, including TCAs, to lithium, does not appear to increase the risk of switching any more than lithium alone. Thus, most antidepressants can probably be added to lithium without substantially increasing the risk of a switch. By extrapolation, it would be expected that the addition of an antidepressant to valproate or carbamazepine might also mitigate the risk of a switch to mania. However, prospective trials are lacking on antidepressant–anticonvulsant combinations in the treatment of bipolar depression.

An important question is whether the addition of a second mood stabilizer is more efficacious for the treatment of bipolar depression than the addition of an antidepressant. Although antidepressants may destabilize bipolar cycling in the long run, at least one acute study has suggested that adding an SSRI may be as useful as adding a second mood stabilizer. This finding may be more a reflection of the lack of efficacy of adding a second agent to a mood stabilizer rather than an indication that both antidepressants and a second mood stabilizer are equally effective.

The Combination of Thyroid Hormone and Mood Stabilizers

Abnormalities in the thyroid axis have long been known to destabilize bipolar disorder. Thyroid dysfunction has been associated with rapid cycling, mixed states, depression, and refractory mania in bipolar patients.

The use of thyroid supplements in the treatment of bipolar has primarily been in bipolar disorder in two states: rapid cycling and bipolar depression. In the 1990s, small studies of supraphysiologic doses of levothyroxine (100 to 300 mcg/day) were effective in treating rapid cycling disorder. Most of the studies supporting this approach have been open-label or small case series. However, there is one more recent (2018) randomized controlled trial (RCT) that has evaluated high-dose levothyroxine (T4), triiodothyronine (T3), or placebo added to lithium. That study dosed the thyroid supplements to the point of suppressing TSH levels (<0.1) and found the T4 but not T3 or placebo-treated patients spent less time depressed or in a mixed state and great time feeling euthymic.

As with rapid cycling, most studies of thyroid hormone combined with mood stabilizers for bipolar depression have been small, uncontrolled, and difficult to draw conclusions from. The largest study to date is a retrospective of 159 patients with insufficient response to previous medications. This analysis included bipolar 1, bipolar II, and bipolar not otherwise specified (NOS) patients who had failed an average of 14 previous medication trials. T3 was added to the existing regimen to an average dose of 90.4 mcg. Eighty-four percent of patients were reported to have had significant improvement on a Clinical Global Impression (CGI) scale, and 33% were reported to be in remission.

While the existing data on thyroid augmentation in bipolar disorder does suggest benefits when combined with mood stabilizers or antipsychotics, the data remain sparse. Potential side effects of high-dose thyroid supplements include osteoporosis, tachycardia, palpitations, and tremor. However, thyroid supplementation has generally been well tolerated in most of the studies to date.

COMBINATION STRATEGIES IN THE TREATMENT OF SCHIZOPHRENIA

Combining Two Antipsychotics

The combination of two or more antipsychotics in a schizophrenic patient who has inadequately responded to one agent is commonly attempted but has been rarely studied. Earlier onset of illness, a longer duration of illness, more frequent hospitalizations, and the presence of violence as a symptom of schizophrenia are more likely to be associated with treatment with a combination of antipsychotics. The augmentation strategy that has been perhaps most investigated in resistant schizophrenia has been the combination of clozapine with another antipsychotic. Since 40% to 70% of patients fail to achieve an adequate response to clozapine, clinicians have typically added a second antipsychotic. For example, a number of small studies have suggested a modest benefit of adding risperidone to clozapine-nonresponsive patients. Case reports and small open studies have also suggested a potential role for amisulpride (Solian) and aripiprazole in patients who do not respond to clozapine alone. A meta-analysis of 19 studies examining the combination of antipsychotics in the treatment of resistant schizophrenia concluded that there may be an advantage of combining antipsychotics in some resistant patients. However, the combination of antipsychotics has also been associated with more side effects, including an increased risk of parkinsonism and elevated prolactin levels.

Risperidone has been combined with typical antipsychotics to produce some improvement in chronic schizophrenic patients studied prospectively. In addition, risperidone has been added to clozapine with a benefit for refractory schizophrenic patients. The primary risks of combining antipsychotics may be the increased risk of EPS or the risk of hypotension with low-potency and atypical antipsychotics.

Antidepressant–Antipsychotic Combinations in Schizophrenia

Antidepressants are frequently combined with antipsychotics in the treatment of schizoaffective disorder and psychotic depression. In addition, antidepressants have shown benefits in the treatment of negative symptoms. Trazodone produces significant but modest improvements in negative symptoms compared to placebo when added to a standard antipsychotic. Likewise, the addition of a low-dose MAOI or moderate doses of nefazodone (Serzone) to a typical antipsychotic has been found to benefit negative symptoms. Controlled trials of adding SSRIs and mirtazapine to antipsychotics have been reported to benefit negative symptoms. Furthermore, the addition of mirtazapine has also been suggested to help antipsychotic-associated akathisia.

Mood Stabilizer–Antipsychotic Combinations in Schizophrenia

Some reports have suggested that lithium can augment standard antipsychotics in the treatment of schizophrenia. However, most controlled studies have not shown many benefits. In addition, the combination of lithium with standard antipsychotics may increase the risk of EPS. Lamotrigine has been effective in some studies as an augmenter to clozapine in treatment-resistant schizophrenia. For example, in a double-blind study, 200 mg of lamotrigine was more effective than placebo in improving negative symptoms as well as general psychopathology in treatment-resistant schizophrenia patients who had not responded to clozapine alone. However, a more recent study of the addition of lamotrigine to other second-generation antipsychotics did not show an advantage of adding lamotrigine in the treatment of positive or negative symptoms of schizophrenia. In addition, lamotrigine has been observed to reduce alcohol cravings in at least one study when added to standard antipsychotics in the treatment of schizophrenics with alcohol dependence.

The addition of carbamazepine to standard antipsychotics has not been clearly beneficial. On the other hand, a clear disadvantage of adding carbamazepine to many antipsychotics is that carbamazepine can induce the metabolism of the concurrent antipsychotic and reduce serum levels. Oxcarbazepine is less likely than carbamazepine to have a pronounced effect on the CYP450 system.

Valproate has been added to typical and atypical antipsychotics in resistant schizophrenia and catatonia. The data suggest that there may be a role for the addition of valproate in controlling agitation and perhaps impacting some positive and negative symptoms in schizophrenia. In addition, valproate augmentation of risperidone and olanzapine has been associated with more rapid improvement in schizophrenia. However, most studies have not shown a significant advantage of adding valproate to an antipsychotic in the treatment of schizophrenia.

The use of newer anticonvulsants in combination with antipsychotics is largely untested in schizophrenic patients. The use of gabapentin has anecdotally been beneficial in treating anxiety and agitation in some schizophrenic patients. Likewise, there are anecdotal reports of tiagabine being used for agitation in combination with both typical and atypical antipsychotics in some patients. Depressed schizoaffective patients have sometimes benefited from the addition of lamotrigine. Valproate has been applied for the treatment of agitation in schizophrenia.

Other Augmentation Strategies in Schizophrenia

Abnormalities in glutamate transmission have been proposed to play a role in the pathophysiology of deficit symptoms in schizophrenia. As a result, studies have examined the role of glycine and D-cycloserine as augmenters to antipsychotics. Glycine is an amino acid that is an agonist of the N-methyl-D-aspartate (NMDA) receptor. Early open trials have suggested that glycine helps some schizophrenic patients but worsens symptoms in others. D-cycloserine, another agonist of the NMDA receptor, may improve negative symptoms and neuropsychological functioning in patients on standard antipsychotics but not clozapine.

Cyproheptadine (Periactin) is a general serotonin antagonist used primarily to treat migraines and allergies. Its serotonin antagonist properties have made it of interest to clinicians treating negative symptoms since all atypical antipsychotics are also 5-HT2 antagonists. Cyproheptadine also has the advantage of being anticholinergic and can help with EPS. The problem with cyproheptadine is that most patients find it quite sedating, and 24 mg/day is a large dose for many patients. It is unclear whether smaller doses might work just as well.

FUTURE DIRECTIONS

The monotherapy of major depression, bipolar disorder, and schizophrenia is often insufficient to achieve an adequate therapeutic response. Thus the combination of psychotropic agents is often attempted in order to improve outcome. Although augmentation strategies have been best demonstrated in the treatment of resistant depression, combination treatment is common in the treatment of bipolar disorder and increasingly common in the treatment of resistant schizophrenia. Studies such as STAR*D and STEP-BD have provided additional insights into the utility and limitations of combination pharmacotherapy. However, much remains to be learned about optimal strategies for combining agents in the treatment of resistant psychiatric disorders.

33.17 Sex and Psychopharmacology

33.17a Sex Differences in Psychopharmacology

Anna E. Bauer, Ph.D., M.P.H., and Samantha Meltzer-Brody, M.D., M.P.H.

There are well-known sex-related differences in the incidence and prevalence of psychiatric conditions. The prevalence of anxiety and mood disorders is greater in women, while schizophrenic psychoses and substance use disorders (SUDs) are more prevalent in men. The difference in depression is particularly profound; the ratio of women to men with major depressive disorder (MDD) is 2:1. Because of the greater burden of psychiatric illness, women use psychotropic agents more frequently than men, particularly antidepressants and anxiolytics. Women are also more susceptible to misuse and adverse effects of psychotropic drugs than men. Differences in the pathogenesis of psychiatric illness are affected by both physiologic and social factors, and sex is an important variable that is often neglected.

Although the precise mechanisms of psychiatric illness are still under investigation, it is well accepted that the underlying pathogenesis of psychiatric illness is associated to some extent with deficiency and dysregulation of neurotransmitter systems (i.e., norepinephrine, dopamine, serotonin, glutamate, and gamma-aminobutyric acid [GABA]) and changes in synaptic strength. These systems may be modulated by sex-specific factors such as fluctuations of neurosteroid hormones or dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis due to gender-based violence and other stressors. There is evidence in both preclinical and clinical studies of sex differences in the functioning of monoaminergic systems that are implicated in the pathogenesis of mental illness. For example, women have more dopamine in the striatum than men and also greater availability of serotonin transporter. Estrogen also enhances presynaptic function and increases neurotransmitter release.

There is considerable evidence for sex-specific physiologic differences that affect drug metabolism, efficacy, and safety. Approximately 7% of new drug applications to the U.S. Food and Drug Administration (FDA) include evidence of robust pharmacokinetic sex differences. Factors that differ between sexes and might affect the pharmacokinetics of psychiatric medications are numerous and include body fat and weight distribution, liver metabolism rates, changes in physiology and hormone levels during times of reproductive change (i.e., puberty, menstruation, pregnancy, menopause), gastric emptying, gastric acid production, splanchnic blood flow, plasma volume, protein levels, enzyme activity, drug transport and clearance rates, medication adherence, side-effect profile differences, interactions between reproductive hormones and neurotransmitters, and brain monoamine functioning.

Despite the potential of physiologic sex differences to influence the efficacy, safety, and acceptability of psychopharmacologic agents, prior to the early 1990s, women were underrepresented in clinical trials. Researchers worried including women in clinical trials would increase interindividual variability due to menstrual cycles and other factors and would require larger sample sizes to detect significant effects. In 1993, the FDA issued its Guideline for the Study and Evaluation of Gender Differences in the Clinical Evaluation of Drugs and now recommends separate analyses of men’s and women’s responses to pharmaceutical agents.

Although data regarding sex differences in pharmacodynamics and pharmacokinetics of psychopharmacologic agents are still sparse, and current prescribing guidelines and recommendations do not generally differentiate sex, the current evidence provides cause to consider sex as an important factor when prescribing and dosing psychotropic medications. This chapter will describe the modulation of synaptic pathways by gonadal steroid hormones, sex differences in pharmacokinetic processes, sex differences in the pharmacokinetics of specific psychotropic drug classes, sex differences in efficacy and safety of psychotropic drugs, and periods of reproductive and hormonal change that may affect psychopharmacology.

SEX DIFFERENCES IN PHARMACOKINETICS AND PHARMACODYNAMICS

The efficacy and safety of a pharmacologic agent are primarily dependent on pharmacokinetics, which describes how a drug is absorbed, distributed, metabolized, and excreted in the body. Each of these pharmacokinetic phases is potentially affected by biologic sex differences. Sources of sex differences in pharmacokinetics include differences in body weight, plasma volume, gastric acid production, gastrointestinal (GI) motility, regional blood flow, transport protein levels, enzyme activity, basal metabolic rate, and drug clearance rate.

Anatomical differences alone account for higher average body weight, height, body surface area, total body water, and intra- and extracellular water volume in men compared with women. In contrast, women have a greater proportion of fat mass relative to body size compared to men. Women are also characterized by lower gastric acidity, lower levels of plasma binding proteins, differential gastric enzyme levels, and more efficient renal function than men. In combination with the specific pH, lipophilicity, and binding capacity of a drug, these factors change absorption, distribution, metabolism, and excretion, which subsequently alter the effective dose and tolerability of a drug.

Pharmacokinetic sex differences exist broadly for many pharmaceutical agents due to physiologic differences. These physiologic differences and the specific drug profiles of many psychotropic medications lead to the potential for divergent efficacy and safety profiles in men and women.

Absorption

Absorption of a drug is dependent on its physical and chemical properties, formulation, and route of administration. If given orally, absorption is highly dependent on the GI environment, including pH within the lumen of the GI tract, surface area per luminal volume, blood perfusion, presence of bile and other secretions, and epithelial membrane structure. Similarly, if given dermally, intravenously, or via aerosol, absorption is dependent on surface area and regional blood and fluid flow. Although sample sizes were small and differences were attenuated when correcting for body weight, a 20-year review of sex differences in pharmacokinetics demonstrated that women broadly have greater drug absorption and higher area under the concentration (AUC) time curve than men. GI motility, bile and gastric acid production, gastric enzymes, and transporter proteins, all affect drug absorption and differ between males and females.

On average, men have greater basal and maximal gastric fluid flow, faster gut motility, and faster gastric emptying. Mean transit times are shorter in men (44.8 hours) compared to women (91.7 hours). This leads to increased absorption and gastric hydrolysis in males. Bile acid composition and gastric acid secretion affect ionization and drug solubility, depending on the pH of the drug. Men have higher concentrations of cholic acid, while women have a higher concentration of chenodeoxycholic acid. Gastric fluids are generally more acidic in males than females (pH 1.92 vs. 2.59, respectively). A lower and more acidic pH increases the absorption of basic compounds, resulting in higher drug concentrations. Differential levels of gastric enzymes and transporter proteins by sex also affect absorption. Increased gastric enzyme activity can increase plasma drug concentrations. For example, alcohol dehydrogenase and aldehyde dehydrogenase are more active in men than women. These enzymes are involved in oxidative degradation, which subsequently makes ethanol more bioavailable in women and leads to greater effects of alcohol on women than men. Differential intestinal expression of proteins that modulate gut transport of drugs can also lead to differential plasma drug concentrations by sex. Transporter proteins like H^+ di- and tripeptide enhance drug absorption, while others, such as P-glycoprotein, inhibit drug absorption.

Distribution

The volume of distribution of a drug is determined by factors such as body composition, regional blood flow, and protein-binding capacity. Water and adipose tissue content affect drug concentration and distribution. On average, total body water, intra- and extracellular water, total blood volume, plasma volume, and red blood cell volume are greater in men than women. Therefore, a water-soluble drug will have an increased volume of distribution in a man, decreasing the overall drug concentration. Conversely, although women have lower body weight and lower blood volume on average, they have a higher percentage of adipose tissue. Thus, a lipid-soluble drug will have an increased volume of distribution in a woman, resulting in lower overall plasma concentrations.

Cardiac output and regional blood flow can impact drug distribution. When adjusted for body surface area, the cardiac index is similar between males and females. Regional blood flow is similar between sexes for some organs (adrenal, bone, brain, lung, skin, thyroid) but quite different for others (adipose, heart, kidney, liver, muscle). Differences in body fat and organ blood flow have been implicated in the speed of onset and duration of action.

Once absorbed, drugs typically bind to plasma proteins that are structurally specific to the drug, such as albumin, alpha-1-acid glycoprotein (AGP), and alpha-globulins. The concentration of the drug is dependent on the amount of protein-bound compound, and generally only the free quantity is active and can pass through the blood–brain barrier. AGP and alpha-globulins are lower in women and influenced by estradiol, which theoretically increases proportion of free drug in women.

Metabolism

Metabolism is one of the strongest sources of sex-dependent variability in pharmacokinetics. Men typically have a higher basal metabolic rate than women, which is partially attributed to differences in the body composition of adipose and muscle tissue. Metabolism of most psychotropic drugs is catalyzed by enzymatic systems in the liver, and hepatic metabolism is divided into two sequential reactions: drug modification (phase I) and conjugation (phase II). Lipophilic compounds are most susceptible to phase I types of metabolism.

Much of the hepatic metabolism of psychotropic drugs is regulated by the phase I cytochrome P450 (CYP) family of isozymes, particularly CYP2D6, CYP2A4, CYP1A1/2, and CYP2C19. Hydroxylation is slower in women than men, increasing drug plasma concentrations in women. Some of the CYP enzymes demonstrate clear sex-related differences. The most important and well established of these sex differences is with CYP3A4. CYP3A4 is responsible for the metabolism of benzodiazepines, painkillers, calcium channel blockers, and steroids. CYP3A4 is known to be up to 50% more active in young adult women than men and declines with age, resulting in lower plasma levels of these drugs in women of reproductive age.

Tricyclic antidepressants (TCAs), fluvoxamine, and clozapine are all metabolized by CYP1A2. CYP1A2 activity is slower in women than men, which can increase drug concentrations and the possibility of adverse events in women.

CYP2C19 contributes to the metabolism of diazepam and mephenytoin. Women show greater enzymatic activity in CYP2C19 than men. and activity is quite variable by ethnicity and contraceptive use.

CYP2D6 is responsible for the metabolism of most antidepressants, haloperidol, and some analgesics. Inhibition of CYP2D6 leads to increased plasma drug concentrations. CYP2C9 contributes to the metabolism of diazepam, imipramine, amitriptyline, and phenytoin. However, there have not been any significant sex differences found in CYP2D6 or CYP2C9 metabolism.

Enterocytes also express significant levels of phase II isoenzymes such as uridine diphosphate glucuronosyltransferase, and as with hydroxylation, glucuronidation is slower in women than men, making conjugation reactions less efficient in women than men.

Elimination

Elimination is responsible for drug inactivation, and drugs are eliminated primarily by hepatic, renal, and pulmonary routes. They can also be eliminated through sweat, tears, and breast milk. Some elimination occurs through hepatic elimination, in conjunction with metabolism, and is a function of liver blood flow and enzyme activity. Hepatic blood flow is lower in women than in men, and some hepatic enzymes differ by sex. Expression of p-glycoprotein regulates biliary excretion and is twofold lower in women than men. Most elimination occurs via the kidneys, and renal function, including glomerular filtration rate (GFR), tubular secretion, and tubular reabsorption, is typically more efficient in men than women, even when adjusted for body weight and surface area. Thus, on average, the overall elimination of compounds is typically lower and slower in women than men.

GONADAL STEROID MODULATION

Reproductive steroid hormones are regulated by the hypothalamic–pituitary–gonadal (HPG) axis. The hypothalamus releases gonadotropin-releasing hormone, which stimulates the pituitary to produce and release gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). LH then stimulates the release of steroid hormones from the gonads. These hormones include estrogen and progesterone, which both regulate reproductive and cognitive function. Estrogen and progesterone both increase cerebral blood flow, and both can have neuroprotective effects. Within the brain, the prefrontal cortex, amygdala, hippocampus, and thalamus, all contain estrogen receptors, and estrogen can act both as a neurotransmitter and as a modulator of other neurotransmitters in synaptic pathways. Progesterone reduces the expression of proapoptotic proteins and apoptotic DNA fragmentation, which leads to reduced cell death and gliosis. Estrogen influences neurotrophic factors and facilitates the formation of dendritic spines.

Gonadal steroid receptors bind to enhancer elements to regulate genes and modify the expression of neurotransmitters and neuropeptides (e.g., serotonin by affecting tryptophan hydroxylase; GABA by affecting glutamic acid decarboxylase; acetylcholine by affecting choline acetyltransferase), their receptors (e.g., 5-HT1A, 5-HT2A), receptor conformation (e.g., GABA_A receptor), and neurotransmitter reuptake (e.g., serotonin transporter and postreceptor signal transduction). Within the cell, gonadal steroids can also modulate ion channels and activate signal transduction cascades.

Estrogen’s specific mechanism of action is unclear, but it is thought to be involved in both the pathogenesis of depression and the effectiveness of antidepressant medications. Estrogen also specifically interacts with the serotonergic system. Estrogen may separately play a role as both a mood enhancer and an antidepressant enhancer. Numerous studies have evaluated the association between absolute estrogen concentration and depression, but none have found a direct correlation. However, in perimenopausal women who have had recurrent episodes of depression, withdrawal of estrogen replacement therapy rapidly induced a new depressive episode. Further, in women at high risk for postpartum depression (PPD), treatment with conjugated estrogen prevented depression symptoms. Similarly, transdermal estradiol prevented depression symptoms in one study of perimenopausal women, and in another, treatment with estradiol resolved symptoms of depression, even in the absence of antidepressant use. In a study of postmenopausal women, those receiving estrogen replacement therapy and a selective serotonin reuptake inhibitor (SSRI) had a better response compared to those only treated with an SSRI. Several other studies of serotonergic agents showed a poorer response in postmenopausal women compared to premenopausal women, supporting the role of estrogen in enhancing serotonergic response.

LH may also interact with the serotonergic system. Serotonin levels tend to vary inversely with LH. Therefore, lower LH levels suggest higher baseline serotonin level for antidepressants to work upon, and low LH levels may predict an improved response to antidepressant therapy.

Gonadal steroid hormones, particularly LH, also influence HPA axis activity, which is disrupted in depression and other psychopathology. A hyperexcitable HPA axis is a common feature of depression, and antidepressants act to reduce HPA axis activity. Low LH levels are associated with HPA axis hyperactivity, and, thus, may identify those with hyperactive HPA axes who may be good responders to antidepressant treatment.

The GABA system is important in inhibiting the HPA axis, and GABA acts as the dominant inhibitory neurotransmitter at the level of the paraventricular nucleus of the hypothalamus. Gonadal steroid hormones are allosteric modulators of the $GABA_A$ receptor, and in particular, the progesterone metabolite, allopregnanolone, is a positive allosteric modulator of the $GABA_A$ receptor and has strong anxiolytic and tranquilizing effects. When administered in rats, allopregnanolone reduces the release of stress hormones and attenuates HPA axis activity.

In addition to modulating neurotransmitters, gonadal steroid hormones also alter protein binding and enzymatic activity, which affect the metabolism and excretion of substrates. Estrogen increases levels of serum-binding globulins: sex hormone–binding globulin, corticosteroid-binding globulin, and thyroxine-binding globulin. Increased levels of estrogen and progesterone alter hepatic enzyme activity. Reproductive hormones may lower the expression of p-glycoprotein in women.

All of the CYP family enzymes are coded for by autosomal (i.e., nonsex) chromosomes, but differences in regulation of expression and enzyme activity may be affected by endogenous hormones. Gonadotropin hormone secretion profiles are different in males and females and are preprogrammed during development by estrogens. Gonadotropin hormone secretion profile strongly controls expression and activity of CYP enzymes in rats and moderately in humans. Several CYP family enzymes are inhibited (e.g., CYP1A2) or increased (e.g., CYP2D6) by gonadal steroid hormones.

Hormonal variations due to the menstrual cycle and periods of hormonal variability can affect GI physiology and function. Estrogens inhibit gastric acid and reduce GI mobility, and progesterone decreases gastric emptying. Absorption time of antidepressants and other agents is increased by exogenous estrogens and progesterone.

Nearly all psychotropic drugs act via modulation of neurotransmitter-gated ion channels or signal transduction systems, which are affected by gonadal steroid levels. Thus, the same psychotropic agents would be expected to produce differential responses by sex. For most pharmacologic agents, absorption, distribution, metabolism, and excretion are all influenced to some extent by hormones. Thus, prescribing must take into account menstrual cycle phase, reproductive stage, and concomitant use of oral contraceptives or hormone replacement therapy.

REPRODUCTIVE PERIODS THAT AFFECT PHARMACOKINETICS AND PHARMACODYNAMICS

Gonadal steroid hormones change throughout the life course, and those changes may result in differences in the pharmacokinetics of psychotropic drugs. In particular, periods of reproductive transition, most notably pregnancy and menopause, can significantly alter hormone levels to increase susceptibility to psychiatric illness and alter pharmacokinetics. Gonadal steroid hormones also change throughout the menstrual cycle and with the use of oral contraceptives or hormone replacement therapy. Each of these stages may result in changes in baseline psychiatric symptoms and the efficacy, safety, and tolerability of psychotropic medications.

Menstrual Cycle

Levels of FSH, LH, estrogen, and progesterone fluctuate throughout the menstrual cycle which can affect all of the pharmacokinetic phases. Gut motility and esophageal emptying are slower during the luteal phase, and gastric emptying is slower during the follicular phase. Both may lead to decreased drug concentration during the luteal and follicular phases. Absorption rates may vary widely throughout the menstrual cycle and are perhaps highest premenstrually when progesterone levels are highest. However, results are conflicting. Heart rate and systolic blood pressure also increase during the luteal phase and may lead to greater absorption. The volume of distribution may be affected by weight gain that typically occurs during the early menstrual phase and after ovulation. AGP has a peak concentration during menses, which affects the amount of unbound compound and overall plasma concentration. Estrogen, which is highest in the late luteal phase, is a substrate for some of the CYP isozymes, particularly CYP3A4, which affects drug metabolism. Finally, there is some evidence of changes in renal function during the luteal phase. Creatinine clearance increases as does vasopressin, aldosterone, and renin activity, which may either increase or reduce elimination during the luteal phase.

Use of Oral Contraceptives and Hormone Replacement Therapy

Oral contraceptives contain a combination of synthetic estrogen and progesterone to suppress ovulation and LH secretion. Similarly, hormone replacement therapy uses similar hormones to increase and normalize fluctuating hormone levels. These exogenous hormones change metabolic enzyme activity, particularly for the CYP family of isozymes involved in the metabolism of psychotropic medications. Oral contraceptives are moderate inhibitors of CYP1A2 and CYP2C19 and weak inhibitors of CYP2B6 and CYP3A4. Lower metabolism and clearance rates subsequently increase drug plasma concentration. Oral contraceptive-induced changes in metabolism and drug concentration have been observed for bupropion, imipramine, and escitalopram.

Progesterone-containing oral contraceptives also increase the receptor binding of benzodiazepines. Metabolism of oxidized benzodiazepines (triazolam, alprazolam) is inhibited by oral contraceptives, and metabolism of conjugated benzodiazepines (lorazepam, temazepam) is enhanced.

Pregnancy and Postpartum

Estrogen and progesterone increase substantially during pregnancy, particularly during the last trimester, where they increase to 10 and 50 times prepregnancy levels, respectively. The HPA axis is activated, cortisol levels increase substantially, and high levels of reproductive steroids create an immunosuppressive response. Similar to the synthetic estrogens and progestins in oral contraceptives, endogenous increases in steroid hormones during pregnancy induce or inhibit enzyme activity and can increase or decrease the metabolism of psychotropic compounds. In addition to direct induction or inhibition of CYP enzymes and UDP-glucuronosyltransferase (UGT) isoenzyme changes, numerous other changes occur during pregnancy that affect the pharmacokinetics, including increases in plasma volume, total body water, cardiac output, heart rate, body fat proportion, and regional blood flow to uterine, renal, skin, and mammary tissue. Renal plasma flow and GFR increase about 1.5-fold during pregnancy, increasing elimination. Thus, faster metabolism during pregnancy may result in lower drug plasma concentration and potentially lower efficacy, requiring an increase in dose. Conversely, however, lower CYP1A2 activity has been observed during pregnancy, resulting in decreased metabolism and clearance. Combined with higher body fat mass in pregnancy that can increase the accumulation of lipid-soluble drugs, other drugs may require a reduction in dose.

Following labor and delivery, there is a precipitous and sudden drop in estrogen and progesterone levels. Reproductive steroids are involved in the regulation of both the HPA axis and nearly every neurotransmitter, including GABA, dopamine, glutamate, serotonin, and norepinephrine. Some women are particularly sensitive to the rapid change in hormone withdrawal, as has been demonstrated in experimental studies in which euthymic women became depressed after blinded exposure and subsequent withdrawal of high doses of progesterone and estradiol. Thus, these rapid hormonal changes may affect psychopharmacology through the regulation of neurotransmitters and changes in metabolism and clearance.

Perimenopause and Menopause

Evidence of estrogen’s effect on CYP enzymatic activity supports an important role in the menopausal transition in psychopharmacologic sex differences. However, data on the pharmacokinetic differences in menopausal women are less consistent. Although some studies have found no difference in pharmacologic response, most have found that response to psychotropic medication is poorer in postmenopausal women than premenopausal women and that elevated FSH is possibly associated with poorer response. As fat mass also increases with age, concentrations of lipophilic drugs accumulate more in older adult women.

In addition, there are also important racial and ethnic differences in treatment response and metabolism of antidepressant medications. Clinical trials of antidepressant treatments have historically included few Black and Hispanic women, and as such, the optimal treatment for non-White women represents a major gap in the literature.

SEX DIFFERENCES IN THE PHARMACOKINETICS OF SPECIFIC DRUG CLASSES

Numerous studies examine pharmacokinetic sex differences of specific psychotropic drugs. Antidepressants are the most widely studied, but there is also evidence for antipsychotics, benzodiazepines, anticonvulsants, and others. Details of each of these drug classes are described below. Drugs that show sex differences in pharmacokinetics include alcohol, beta-blockers, benzodiazepines, clorazepate, clozapine, diazepam, ketamine, lithium, metoprolol, midazolam, naratriptan, olanzapine, phenobarbital, phenytoin, propranolol, rizatriptan, SSRIs, and valproic acid. Table 33.17a–1 describes metabolic routes, sex-specific enzyme activity, modulation by steroid hormones, and potential drugs affected.

Antidepressants

Most antidepressants present some extent of pharmacokinetic sex differences. Women generally have higher exposure to equal doses of antidepressants than men, indicated by higher maximal or AUC concentration, metabolism and formation of active metabolites, elimination half-life, and other pharmacokinetic indices. There are substantial and consistent differences in pharmacokinetics, but data on how much they affect clinical outcomes is limited. Clinical findings indicate that women might respond better to newer antidepressants than men, particularly to SSRIs. However, drug serum levels do not correlate well with the therapeutic effect, and evidence of clinical differences is still quite limited.

Physiologic differences in males and females lead to differences in all pharmacokinetic phases. As discussed, women have lower secretion of gastric acid, slower gut transit times, and a higher proportion of adipose tissue. There are also differences in transport proteins and metabolic enzymes between men and women, all resulting in differences in the absorption, distribution, metabolism, and excretion of antidepressants.

Most antidepressants are weak bases and more effectively absorbed under basic conditions. Because women secrete less gastric acid, antidepressants are absorbed more quickly and reach higher concentrations in women than men. This is particularly true for TCAs that have a more basic pH. Higher plasma levels and lower clearance of TCAs have been found in females compared to males.

Most antidepressants are lipophilic and have an affinity for adipose tissue. Because women have a higher percentage of body fat than men, lipophilic antidepressants may have a larger volume of distribution and lower clearance. Bupropion and trazodone are particularly lipophilic antidepressants and have a longer half-life and lower plasma concentrations in women than men.

Protein binding affects how much free drug is available and therapeutically active. AGP and alpha-globulins are lower in women, increasing the proportion of active drug in women. Many antidepressants are bound by AGP and include triazolam, amitriptyline, desipramine, imipramine, dioxepine, nortriptyline, reboxetine, chlorpromazine, thioridazine, and olanzapine. SSRIs are typically highly bound (>95%), TCAs are moderately bound (75%, 77%), and citalopram and venlafaxine have low levels of binding (<50%).

As mentioned, most psychotropic drugs are metabolized through the CYP enzyme superfamily, and expression of these CYP isoenzymes differs by sex. CYP3A4 helps metabolize SSRIs and TCAs, and CYP2C19 helps metabolize clomipramine, imipramine, and citalopram. Both CYP3A4 and CYP2C19 are more active in females than males, leading to faster clearance and lower plasma concentrations in women. Conversely, substrates of CYP1A2 and CYP2D6 clear faster in males than in females. CYP1A2 metabolizes escitalopram, TCAs, and fluvoxamine, and CYP2D6 metabolizes desipramine and mirtazapine. CYP2C9 metabolizes imipramine and amitriptyline but does not seem to vary by sex.

Table 33.17a–1.
Sex Differences in the Pharmacokinetics of Psychotropic Drugs

Pharmacokinetic Factor	Sex-Specific Activity	Modulated by Sex Hormones or Reproductive Stage	Potential Drugs Affected
Absorption			
Gastric acidity	More acidic in M than F; increases absorption of basic compounds in F	Yes, reduced acidity during pregnancy	Compounds with alkaline pH; benzodiazepines, tricyclic antidepressants
Gastric fluid flow	Greater in M than F, increases absorption in M		Any oral compound
Gastric emptying	Faster in M than F; increases plasma levels in M	Yes, gastric emptying is slower during pregnancy and slower during follicular phase	Any oral compound
Intestinal transit time	Faster in F than M, increases absorption in M and reduces plasma levels in F	Yes, transit time is slower during pregnancy and during luteal phase	Any oral compound
Distribution			
Plasma, blood, and water volume	M > F, so greater volume of distribution of water-soluble compounds in men	Yes, fluid volume increases during pregnancy, early menstrual phase, and after ovulation	Water-soluble compounds
Proportion adipose tissue	F > M, so greater volume of distribution of	Yes, increases during pregnancy	Lipophilic compounds

	lipophilic compounds in women; may increase half-life from bioaccumulation		
Cardiac output	M = F	Yes, cardiac output increases during pregnancy and during luteal phase	Any compound
Regional blood flow	M = F for adrenal, bone, brain, lung, skin, thyroid; M > F for renal, muscle; F > M for adipose, liver, heart	Yes, uterine, renal, skin, mammary blood flow increase during pregnancy	Any tissue-specific compound
Plasma Binding Proteins			
Albumin[14]	M = F	Yes, decreases during pregnancy	
Alpha-1-acid glycoprotein	M > F, thus more free (active) drug in women	Yes, decreases during pregnancy and is greatest during menses, modulated by estradiol	Highly protein-bound compounds; amitriptyline, benzodiazepines, chlorpromazine, desipramine, doxepin, fluoxetine, imipramine, nefazodone, nortriptyline, olanzapine, paroxetine, reboxetine, sertraline, thioridazine, triazolam, tricyclic antidepressants
Metabolism			

Basal metabolic rate	M > F	Yes, hepatic metabolism increases during pregnancy	Any compound
Phase I enzymes			
CYP1A2	M > F	Yes, decreased in pregnancy and with oral contraceptives (OCs)	Clomipramine, clozapine, duloxetine, fluvoxamine, olanzapine, tacrine
CYP2A6	F > M	Yes, increased with OCs	Ketamine
CYP2B6	F > M		Bupropion, ketamine
CYP2C9	M = F	Yes, increased in pregnancy	Fluoxetine, imipramine, phenytoin
CYP2C19	M = F	Yes, decreased in pregnancy and with OCs	Diazepam, citalopram, fluoxetine, fluvoxamine, hexobarbital, imipramine, methylphenobarbital, propranolol, topiramate
CYP2D6	F > = M	Yes, increased in pregnancy	Clomipramine, desipramine, fluoxetine, haloperidol, hydrocodone, imipramine, metoprolol, mirtazapine, paroxetine, propranolol, sertraline, testosterone, venlafaxine
CYP3A4	F > M	Yes; stimulated by testosterone	Alfentanil, alprazolam, carbamazepine, cortisol, diazepam, estradiol, fentanyl,

			midazolam, zolpidem
Phase II enzymes			
UDP-glucuronosyltransferases (UGTs)	M > F; M = F		Oxazepam, lemotrigine
N-acetyltransferases	F > M; M = F		Catecholamine derivatives
Methyltransferases	F > M; M > F		Dopamine, epinephrine, levodopa, norepinephrine
Elimination			
Renal blood flow and glomerular filtration rate	M > F	Yes, higher in pregnant women, increased clearance in luteal phase	Any compound

F, females; M, males.

Although antidepressants in the same drug class may be similarly metabolized, each substance has its own pharmacokinetic profile and may exhibit different sex-dependent effects depending on the specific affinity for various CYP isozymes. Pharmacokinetic sex differences for each drug are described below and in Table 33.17a–1.

Selective Serotonin Reuptake Inhibitors

CITALOPRAM. Marketing data suggests AUC concentrations of citalopram are generally higher in females compared to males. Although some studies failed to replicate, most subsequent studies have demonstrated that concentrations of citalopram and its metabolite, desmethylcitalopram, are higher in women than men. Results for ***S***-citalopram/escitalopram have been more variable.

FLUOXETINE. According to the manufacturer, sex differences have not been observed for fluoxetine. Although experimental studies show female rats metabolize fluoxetine faster than males and have higher levels of its active metabolite, giving support for the possibility of sex differences in pharmacokinetics, only one human study has shown any evidence of higher concentrations of fluoxetine in women compared to men. Although strong evidence for sex differences has not been reported, the manufacturer's dosing guidance suggests a lower starting dose if used in combination with olanzapine for those who may have factors that slow metabolism, including female sex.

FLUVOXAMINE. In phase 1 trials of fluvoxamine, maximal and AUC concentrations were robustly increased in women compared with men. At lower doses, fluvoxamine levels are significantly higher in females than males; however, this sex difference is attenuated at higher doses. This relationship suggests CYP1A2 saturation or autoinhibition by fluvoxamine at higher doses.

PAROXETINE. Higher plasma concentrations of paroxetine in women have been demonstrated in some populations, but other populations show no sex differences in concentration. Men have been shown to have a larger volume of distribution and greater dose–concentration correlation.

SERTRALINE. Few sex differences in plasma concentrations of sertraline have been demonstrated, particularly for adolescents and young adults. Women do have a better dose–concentration correlation than men for sertraline and its metabolite, desmethylsertraline, as well as longer half-lives and decreased clearance.

Serotonin and Norepinephrine Reuptake Inhibitors

DULOXETINE. Research on the sex differences of duloxetine is very sparse. According to the manufacturer, the elimination half-life of duloxetine is similar for males and females, but a meta-analysis of five studies (***n*** = 2,000 participants) found that oral clearance was lower in females, which is consistent with lower CYP1A2 activity in females. In older adult females, AUC was about 25% higher, and half-life was 4 hours longer compared to reproductive-aged females.

VENLAFAXINE. Aside from one larger study (***n*** = 1,780), which showed higher serum venlafaxine concentrations in women than men, there have not been demonstrated sex differences in plasma levels of venlafaxine. However, women do tend to have slightly higher concentrations of venlafaxine's metabolites, ***O***-desmethylvenlafaxine and ***N***-desmethylvenlafaxine, consistent with known associations of CYP3A4- and CYP2D6-mediated metabolism.

Noradrenaline and Dopamine Reuptake Inhibitors

BUPROPION. Pooled marketing data of bupropion generally found higher systemic concentration in males (***n*** = 90 females, 90 males); however, later studies have generally demonstrated slightly higher plasma concentrations, a larger volume of distribution, and longer elimination half-life in females compared to males. Bupropion is primarily metabolized by CYP2B6, and this relationship is consistent with higher CYP2B6 activity in women compared to men.

Tricyclic Antidepressants

AMITRIPTYLINE AND NORTRIPTYLINE. No pharmacokinetic sex differences were found in early studies of amitriptyline and nortriptyline, but later studies have been consistent in finding higher plasma levels and lower clearance rates of amitriptyline and nortriptyline in women compared to men. This sex difference becomes more pronounced with increasing age. Sex differences in amitriptyline and nortriptyline are primarily attributed to CYP2D6 activity.

CLOMIPRAMINE. Several studies in both humans and animals have found no pharmacokinetic sex differences in clomipramine. A few studies have found higher clomipramine plasma levels in women compared to men. However, most consistent are the studies of clomipramine metabolites. Desmethylclomipramine concentrations are higher in women, and studies of metabolic ratios support greater demethylation for women and greater hydroxylation for men.

IMIPRAMINE. Both animal and human studies of imipramine have demonstrated higher imipramine plasma levels and lower and slower clearance in females compared to males. Female rats treated with imipramine also have higher brain levels of its metabolite desipramine than male rats.

Tetracyclic Antidepressants

MIRTAZAPINE. Studies of mirtazapine consistently show that concentrations of mirtazapine and its metabolite, desmethyl mirtazapine, are higher in women than men. Women also have longer elimination half-life (37 hours in females vs. 26 hours for males), and all results have been replicated in large studies.

Serotonin-2 Antagonists and Reuptake Inhibitors

NEFAZODONE. An early study of nefazodone found no evidence for sex differences, but later studies found support for sex variation when age was taken into account. Older adult women consistently have higher concentrations of nefazodone and its metabolite, hydroxynefazodone. Nefazodone has been largely discontinued due to declining use.

TRAZODONE. Evidence for sex differences in trazodone is conflicting and may be dependent on age and menopausal status. An underpowered observational study found no sex differences in plasma levels of trazodone or its metabolites, but several additional studies have found some evidence for higher plasma concentrations and higher distribution of volume in women than men. Trazodone clearance seems to be affected by age, and elimination half-life is longer in young women than young men but shorter in older adult women than older adult men.

MONOAMINE OXIDASE INHIBITORS. Very few sex differences in monoamine oxidase inhibitors (MAOI) pharmacokinetics have been reported. Sex differences have not been reported for any of the nonselective irreversible hydrazines, isocarboxazid, and phenelzine. Manufacturing data for selegiline, a highly selective reversible MAOI indicated for Parkinson disease, showed no differences in overall AUC concentration, time to maximum exposure, or elimination half-life, but did find that female subjects have approximately a 25% decrease in maximum concentration compared to male subjects.

GABA_A Receptor–Positive Allosteric Modulators. Brexanolone was the first ever FDA-approved treatment with specific indications for PPD. It has only been studied in women for the indication of PPD but is notable as it is a novel and innovative treatment that has had a powerful response in clinical trials. Brexanolone has also been investigated for essential tremor and treatment-refractory status epilepticus. Brexanolone is a proprietary formulation of the GABA allosteric modulator and progesterone metabolite, allopregnanolone, administered intravenously over the course of 60 hours to women with PPD. Three double-blind, randomized, placebo-controlled trials displayed a swift remission of symptoms (by hour 60) that was sustained (they remained in remission at 1-month follow-up). The effect was strong even among those being treated with other antidepressant therapy, supporting consideration of brexanolone for monotherapy or adjunct treatment with other pharmacotherapies. Zulranolone, a structurally different compound from brexanolone of the same drug class, is an oral treatment for PPD approved by the FDA in August 2023. Zulranolone also has a rapid onset of action, with clinical improvement observed by day 3 of a 15 day outpatient treatment trial, and demonstrated efficacy and safety compared with placebo in phase 3 trials.

Rapid-Acting Antidepressants. Ketamine (administered intranasally as esketamine) is another novel therapeutic with rapid-acting antidepressant efficacy, which is indicated specifically for treatment-resistant depression and depressive symptoms with acute suicidal ideation or behavior. Ketamine is a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist, and preliminary data indicate sex differences in ketamine metabolism and clearance may be dose dependent. Female rodents had greater concentrations of ketamine and norketamine in both brain and plasma and exhibited a more sensitive response to lower doses. Ketamine is moderated by estrogen via induction of CYP2A6 and CYPB6.

Antipsychotics

As with antidepressants, antipsychotics tend to be lipophilic, so the volume of distribution is greater in women than in men. Adipose tissue proportion, in conjunction with the lipophilicity of antipsychotics, may also prolong the half-life of antipsychotics and accumulate over time. Sex differences in pharmacokinetics have been observed for haloperidol and for atypical antipsychotics (clozapine, olanzapine, and sertindole). Data for pharmacokinetic sex differences of aripriprazole and quetiapine are lacking, however, limited data showing greater increases in prolactin levels in females compared to males after administration of these drugs suggest there may be differential effects.

Haloperidol. CYP2D6 is responsible for the metabolism of haloperidol. Inhibition of CYP2D6 leads to increased plasma concentrations in women compared to men.

Clozapine and Olanzapine. Clozapine is metabolized by CYP1A2. CYP1A2 activity is higher in men than women, which affects the metabolism of clozapine and olanzapine. Plasma levels of clozapine and its major metabolite, norclozapine, are higher in women than men, particularly at the beginning of treatment. Similarly, plasma levels of olanzapine are higher for women than men at the beginning of treatment. In addition, manufacturer dosing guidance for olanzapine suggests a lower starting dose if used in combination with fluoxetine for those who may have factors that slow metabolism, such as female sex.

Benzodiazepines

Benzodiazepines are highly lipophilic and, as with other psychotropic drugs, accumulate in adipose tissue, which may decrease in half-life. Benzodiazepines are highly bound to plasma proteins, with a percentage of 99%. Differences in body fat content and protein binding cause larger volumes of distribution in females than in males. CYP3A4 is highly sex dependent and responsible for the metabolism of benzodiazepines. Increased fat proportion in older adult women combined with the declining activity of CYP3A4 and decreased oxidation in older adult men mean that older women generally have lower benzodiazepine levels than older men at comparable doses.

Diazepam. Diazepam is metabolized by CYP2C19, of which women show greater activity than men. Thus, women have a faster metabolism and a lower plasma concentration of diazepam. CYP2C9 also contributes to metabolism of diazepam, but sex differences have not been observed for CYP2C9 metabolism.

Lorazepam, Temazepam, and Oxazepam. The benzodiazepines lorazepam and oxazepam are metabolized by conjugation (phase II) reactions, which are generally slower in women than men resulting in lower clearance in women than men. Oral contraceptives also facilitate conjugation metabolism, so the coadministration of benzodiazepines with hormonal oral contraceptives needs to be considered carefully, and the dose should likely be adjusted.

Triazolam and Alprazolam. The clearance of benzodiazepines metabolized by oxidation, such as triazolam and alprazolam, are similar in both sexes. Some studies show alprazolam concentrations are higher in women than men, but this is likely due to weight differences rather than sex. Oral contraceptives inhibit the metabolism of oxidized benzodiazepines, and progesterone-containing oral contraceptives enhance the receptor binding of benzodiazepines, making triazolam much more potent.

Anticonvulsants and Antiepileptics

Anticonvulsants and antiepileptic drugs show some pharmacokinetic sex differences. Higher CYP3A4 isozyme activity in women compared to men may lower drug concentration of anticonvulsants such as carbamazepine. CYP2C9 metabolizes phenytoin, another anticonvulsant, but variation by sex has not been demonstrated in CYP2C9 metabolism. Gabapentin and pregabalin are drugs used to treat epilepsy and are highly sensitive to factors such as sex. Plasma levels obtained at the usual doses can vary more than a 100-fold depending on age, gender, and coadministered medications. The concentration-to-dose ratio of pregabalin is up to 42% higher in women than in men, and significant care should be taken in dose adjustment.

EFFICACY AND SAFETY

Efficacy

Evidence that there are sex differences in the pharmacokinetics of psychotropic drugs and that these drugs are modulated by gonadal steroid sex hormones is very well established. Evidence of sex differences in clinical outcomes, including efficacy and safety profiles of specific drugs, is much more sparse. Most of the work of sex differences in efficacy of psychotropic drugs evaluated antidepressants, but there is limited evidence of differences in antipsychotics and benzodiazepines, and it is likely many more are yet to be discovered. Table 33.17a–2 describes sex differences in efficacy and safety of psychotropic drugs.

Table 33.17a–2.
Sex Differences in Exposure, Efficacy, and Safety of Psychotropic Drugs

		Reported Sex Differences		
Drug	**Drug Type**	**Exposure**	**Efficacy**	**Safety**
Antidepressants				
Selective serotonin reuptake inhibitors (SSRIs)		F > M	F may respond better than M	F at greater risk of QT prolongation
Citalopram	SSRI	F > M	Premenopausal F responded better than M to citalopram	F at greater risk of QT prolongation
Fluoxetine	SSRI	M > F; F > M for metabolites	F responded better than M to fluoxetine vs. tricyclic antidepressant (TCA)	F at greater risk of QT prolongation; reduced dose recommended in F when adjuvant to olanzapine
Fluvoxamine	SSRI	F > M, but attenuated at high doses	M responded better than F for compulsive symptoms in obsessive-compulsive disorder (OCD)	
Paroxetine	SSRI	Conflicting data		
Sertraline	SSRI	F > M	F responded better than M to sertraline vs. imipramine	F at greater risk of QT prolongation
Serotonin and norepinephrine reuptake inhibitors (SNRIs)			F responded slightly better than M	
Duloxetine	SNRI	F > M		
Reboxetine	SNRI	F > M	Premenopausal F responded better than M to reboxetine	
Venlafaxine	SNRI	F > M for metabolites	Comparable response in M and F	F at greater risk of QT prolongation
Noradrenaline and dopamine reuptake inhibitors (NDRIs)				
Bupropion	NDRI	F > M		
Tricyclic antidepressants (TCAs)			M may respond better than F, but many studies show comparable response in M and F	Protein binding may make F more susceptible to toxic effects
Amitryptiline and nortriptyline	TCA	F > M		F at greater risk of QT prolongation
Clomipramine	TCA	Conflicting data	M responded better than F for compulsive symptoms in OCD	F at greater risk of QT prolongation
Dothiepin/dosulepin	TCA	Inadequate data		
Imipramine and desimpramine	TCA	F > M	M responded better than F; M had more sustained response	F at greater risk of QT prolongation
Tetracyclic antidepressants				
Mirtazapine	Tetracyclic antidepressant	F > M		
Serotonin-2 antagonists and reuptake inhibitors (SARIs)				
Nefazodone	SARI	F > M for older ages		
Trazodone	SARI	Conflicting data		F at greater risk of QT prolongation
Monoamine oxidase inhibitors (MAOIs)			F responded better than M	
Isocarboxazid	MAOI			
Phenelzine	MAOI		Older M responded better than older F	
Selegiline	MAOI	F > M maximum concentration		No consistent differences in M and F
Gamma-aminobutyric acid type A receptor–positive allosteric modulators ($GABA_A$ RPAM)				
Brexanolone and zulranolone	$GABA_A$R PAM	Currently only indicated for postpartum depression (PPD) in women		
Rapid-acting N-methyl-D-aspartate (NMDA) antagonist				
Ketamine and esketamine	NMDA antagonist	F > M	F mice responded better and at lower doses than M mice; F and M similar in human nasal esketamine trials	Nausea, dissociation, dizziness, and vertigo more frequent in F than M; F may be more susceptible to QT prolongation, tardive dyskinesia, and hyperprolactinemia

		Reported Sex Differences		
Drug	**Drug Type**	**Exposure**	**Efficacy**	**Safety**
Antipsychotics			**Greater response in F than M; Less likely to respond post-menopause**	**Weight gain, hyperprolactinemia, and cardiac effects may be more significant in F than M**
Chlorpromazine	Typical antipsychotic		Older M responded better than older F	
Haloperidol	Typical antipsychotic	F > M		
Aripiprazole	Second-generation antipsychotic (SGA)	F = M		F have greater risk of QT prolongation and tardive dyskinesia
Clozapine	SGA	F > M	Greater improvement in symptoms in F than M	Weight gain and metabolic syndromes are more frequent in F than M. F have higher risk of long QT syndrome than M. F may be at greater risk of neutropenia and tardive dyskinesia.
Olanzapine	SGA	F > M		Weight gain and metabolic syndromes are more frequent in F than M; F have higher risk of long QT syndrome than M; Reduced dose recommended in F when adjuvant to fluoxetine
Quetiapine	SGA	F = M		F have greater risk of QT prolongation, tardive dyskinesia, hyperprolactinemia, and reversible infertility
Benzodiazepines		**F > M**	**Greater effect in F than M**	**More potential sedation effects in F in similar doses to M**
Alprazolam	Benzodiazepine	F > M		
Diazepam	Benzodiazepine	M > F; volume of distribution F > M; free drug pregnant F or oral contraceptives (OCs) > F > M	Older M responded better than older F	
Lorazepam	Benzodiazepine	F > M		
Oxazepam	Benzodiazepine	F > M		
Temazopam	Benzodiazepine	F > M		
Triazolam	Benzodiazepine	F > M; progesterone containing OCs enhance receptor binding		
Anticonvulsants and Antiepileptics				
Carbamazepine	Anticonvulsant	M > F		Highly interactive with progestins; may cause breakthrough bleeding and reduced efficacy of progestin-containing contraceptives
Gabapentin, pregabalin	Antiepileptic	F >> M		
Valproic acid	Anticonvulsant	Protein binding decreases during pregnancy		
Mood Stabilizers				
Lamotrigine	Mood stabilizer	Estrogen increases clearance	Estrogen-containing contraceptives may decrease efficacy	Estrogen-containing contraceptives and therapies may cause increased side effects (dizziness, ataxia, diplopia) during placebo weeks due to decreased clearance
Lithium	Mood stabilizer	Clearance increased during pregnancy	No sex differences in response	F at higher risk of QT prolongation and hypothyroidism

Most antidepressants showed some evidence of greater efficacy in women than men, especially those that are serotonergic. This may be due to higher plasma levels in women, protein-binding specificity, or metabolic differences. There may also be pharmacodynamic differences, as women have steeper cortisol responses when exposed to SSRIs. A recent study of hospitalized patients treated for MDD (***n*** = 234) found women were more likely to achieve remission but also experience more comorbid metabolic abnormalities (i.e., hypercholesterolemia and low plasma uric acid). Greater response in females than males has been reported for SSRIs, particularly sertraline and fluoxetine, and also for serotonin and norepinephrine inhibitors (SNRIs) and MAOIs.

TCAs have been found to be more efficacious in men than women in some cases. Males responded better to imipramine and desipramine and had a more sustained response than females in both rodents and humans. Men also responded better than women with fluvoxamine and clomipramine for compulsive symptoms of obsessive-compulsive disorder.

Females are also more likely than males to experience improvement in symptoms with typical antipsychotics and the second-generation antipsychotic (SGA), clozapine, but there is not yet substantial evidence.

Most studies, however, particularly large observational studies and meta-analyses of randomized controlled trials (RCTs), find a comparable response in men and women. A large prospective sertraline utilization study (***n*** = 1,594 males, 3,858 females) found no sex differences in treatment response and also no differences in adverse effects or treatment termination. Other large observational studies have also found no sex differences in the efficacy of TCAs, MAOIs, fluoxetine, clomipramine, citalopram, paroxetine, and moclobemide. A meta-analysis of RCTs of SSRIs versus venlafaxine (***n*** = 2,045 patients with MDD) found response in men and women was comparable, and a large review of 30 RCTs of antidepressant efficacy (***n*** = 1,555 males, 2,331 females) found that TCA response was independent of sex.

There are significant challenges when evaluating sex differences in the efficacy of psychotropic drugs. As discussed, pharmacokinetics may vary across the life course and can be modulated by hormonal fluctuations. Differences have been demonstrated in the literature in that premenopausal and younger females have a better response to some antidepressants than postmenopausal females and males. Other studies have demonstrated a better response to diazepam in older men compared to older women and a better response to chlorpromazine in older men compared to women.

Studies of efficacy also generally fail to take adverse events and early discontinuation into account. Adverse effects are reported more frequently in women, which may result in early dropout. If a greater proportion of women who stayed in the study experienced a better response to a certain drug, then differences in effect by sex could be attenuated. Finally, current studies of sex differences in psychotropic drug efficacy are underpowered. Because genetic polymorphisms lead to much of the interindividual variability in pharmacokinetics, these studies are significantly underpowered to identify sex differences. When a weak effect of sex is identified, it may be dismissed as not being clinically significant, as there is also limited statistical power to detect sex differences in pharmacokinetic and safety profiles.

Safety

Adverse effects of pharmaceuticals, and particularly psychotropic drugs, are typically greater in women than men. Data from the national Adverse Events Reporting System administered by the U.S. FDA suggest that women experience more adverse events than men and that the adverse events are more serious. In a review by the U.S. Government Accounting Office of 10 drugs removed from the market over a 3-year period from 1997 to 2000, 8 of the 10 drugs were withdrawn due to a greater risk of adverse events in women. Since that time, the FDA has significantly improved surveillance of sex differences in adverse outcomes, particularly for potential QT-interval prolongation and drug-induced liver injury, for which women are at greater risk.

Women may experience more adverse drug events for a number of reasons. Due to differences in pharmacokinetics, females often experience a greater volume of distribution of lipophilic drugs, slower elimination, and differences in metabolism depending on the specific drug. Due to protein binding, the free fraction of many compounds is often greater in women, leaving a greater proportion of the active drug in the body. All of these differences may lead to exposure to higher drug concentrations in women compared to men, despite similar prescribed dosages. Most antidepressants are highly bound compounds and therefore produce a higher free fraction of drugs in women and may increase the risk of QT-interval prolongation, for which women are more susceptible. Benzodiazepines and other sedatives/hypnotics, which are lipophilic, typically have a more potent effect in women, and zolpidem (a nonbenzodiazepine hypnotic) was the first drug for which the FDA recommended sex-based dosing.

Women may also be more likely to experience adverse drug interaction effects. Overall, women take more medications and are more likely than men to be taking antidepressants, mood stabilizers, analgesics, contraceptives, and hormone replacements. In a large European study of psychotropic drug use by inpatients diagnosed with MDD between 2001 and 2017 (***n*** = 44,418), the use of monotherapy was more common among male patients, while female patients had a higher risk of being treated with four or more medications. Polytherapy of two or more antidepressants or the combination of an antidepressant and antipsychotic was similar between men and women, but women were more likely to be treated with antidepressants in combination with tranquilizers, hypnotics, or antiepileptics. Differences in protein binding and metabolism may make women more susceptible to drug interactions, particularly for psychotropic drugs, in which one may be used as adjuvant therapy to another. CYP2D6 inhibition is particularly of concern with psychotropic drugs. In addition, simultaneous administration of multiple drugs with elevated protein binding may cause one to be displaced, increasing the free amount of a drug and greater possibility of toxicity. Most SSRIs are highly bound compounds, as are anticonvulsants. Coadministration of psychotropic drugs with hormonal contraceptives and hormone replacement therapies must also be carefully considered, as oral contraceptives inhibit oxidative metabolism and enhance conjugation metabolism. For example, progesterone-containing oral contraceptives enhance the receptor binding of benzodiazepines and can significantly increase the effective dose of triazolam.

Overall, reported side effects are greater in women, but research investigating sex differences in the safety profiles of psychotropic drugs is still limited. Most comprehensive is the evaluation and review of SGAs, which found that weight gain, hyperprolactinemia, cardiac effects, metabolic syndromes, and long QT interval are more frequent in women taking clozapine and olanzapine than men.

CONCLUSION

There is strong evidence for sex differences in psychopharmacology, yet biologic sex is a variable that is far too often neglected, both in research and in clinical care. In general, women are more likely to be prescribed psychotropic medications, use a greater number of medications, have higher drug concentrations, and experience more adverse effects. Currently, most drugs lack sex-differentiated dosage data, and except for zolpidem, current guidelines and pharmaceutical manufacturer prescribing information do not provide dose adjustment for men and women, despite evidence that women should frequently receive lower doses than men. In addition to biologic sex, other factors such as body weight, oral contraceptive use, hormonal therapy, reproductive stage, and race/ethnicity may all contribute to differences in efficacy, safety, and tolerability of medications by sex. Continued research in sex differences in psychopharmacology is needed so that prescribing guidance and clinical care can evolve to meet the needs of each individual, rather than a one-size-fits-all approach.

33.17b Reproductive Hormonal Therapy: Theory and Practice

DAVID R. RUBINOW, M.D., AND PETER J. SCHMIDT, M.D.

The 19th-century medical literature contained several presumptions about the pathophysiology of mood disorders in women, largely based on anecdotal observations of reproductive endocrine dysfunction (e.g., amenorrhea) in psychiatrically ill women. These inferences, in turn, were translated into therapeutics. Thus, numerous reports also documented the beneficial effects on mood and behavior associated with medical or surgical manipulations of a woman's reproductive function. In addition to their interest in the role of reproductive function in psychiatric disorders, medical researchers in the late 19th century also developed a general interest in glandular secretions that potentially could modify physiology. Early experiments in humans with preparations derived from animal glands, including the thyroid, adrenal, ovary, testes, and spleen, provided the directions for the developing fields of endocrinology and immunology. In his seminal lecture in 1889, Charles-Édouard Brown-Séquard not only originated the formal study of endocrinology, he also reported the potential psychotropic effects of gonadal secretions. His description of the invigorating effects of testicular extracts resulted in a brief but widespread use of these compounds (as well as other interventions intended to increase the body's testicular or seminal fluid levels) in a variety of therapeutic settings. In addition to extracts of both testes and ovaries, investigators experimented with extracts of the thyroid and adrenal glands in psychiatric patients. This interest in the therapeutic use of thyroid and adrenal extracts enjoyed more enduring success with the recognition of their beneficial effects in the treatment of myxedema and Addison disease, respectively. However, the widespread use of gonadal extracts ultimately met with criticism due to some disappointing results and the realization that these extracts were not the "fountain of youth." Their subsequent clinical use was largely restricted to the treatment of menopause-related hot flushes (ovarian extracts). Nonetheless, the observation that ovarian extracts inhibited ovulation in rabbits was sufficient to maintain medical interest in the potential role of gonadal extracts in the control of human fertility. This process of promise and disappointment, passionate advocacy and evidence-based caution, is the story of both the birth and the ongoing existence of endocrinology. Many of the claims of the organotherapists were refuted by observations that most of the endocrine preparations were inactive when administered orally. Nonetheless, the so-called "practical men," the practitioners whose therapeutic zeal was not about to be extinguished by study results to the contrary, continued to claim the efficacy of endocrine preparations for all manner of illnesses. An additional source of the pendular swing of practice, and one particularly noteworthy for reproductive preparations, was the recognition of previously undiscovered side effects, a phenomenon that is particularly relevant for the therapeutic use of estradiol, the primary active substance in ovarian extracts. Efforts to improve techniques of extraction and purification of biologically active substances from the gonads were fueled by the hope that factors regulating reproductive function would be identified. By the late 1920s and early 1930s, many gonadal steroids were isolated and characterized, including estrone, estradiol, progesterone, and several androgens. Moreover, during the next 10 years, chemists identified modifications of the steroids that could alter their absorption (i.e., acetylation) and potency (e.g., the addition of an ethinyl group or removal of C-19 methyl groups). These findings initiated a resurgence in the medical use of gonadal steroids. Estrogen replacement therapy was used to treat menopausal symptoms in the 1950s, and oral contraceptives (i.e., mestranol and norethynodrel [Enovid]) were developed and first approved by the FDA in 1960. The use of gonadal steroids in women once again was widespread, and several papers were published reporting the therapeutic benefits of these compounds in involutional melancholia, premenstrual syndrome, and postpartum depression (PPD). However, their widespread usage was restricted—the pendular swing—after reports in the 1970s of increased rates of endometrial cancer secondary to unopposed estrogen replacement and increased rates of thrombosis and pulmonary emboli in women taking oral contraceptives. In the last two decades of the 20th century, the popularity of gonadal steroid therapy resumed due in part to the reports of the enhanced safety of both hormone replacement therapy (HRT) (due to the protective effect on the endometrium of the addition of progesterone) and oral contraceptives (due to the lower doses of estradiol and new progestins) and to the reported beneficial/disease protective effects of gonadal steroids on several tissues including the musculoskeletal system, cardiovascular system, and central nervous system (CNS).

The discovery of several other factors involved in the control of reproduction also led to new drug development. The decapeptide gonadotropin-releasing hormone (GnRH) was isolated and sequenced in the 1970s, and the observation that continuous GnRH infusion resulted in the downregulation of pituitary GnRH receptors led to the development of several GnRH agonists. These agonists were used to suppress reproductive endocrine function in a variety of medical conditions, including hormone-dependent cancers and endometriosis. In combination with gonadal steroids, preparations of GnRH agonists provided physicians with a strategy to control reproductive function and regulate the exposure to specific gonadal steroids without resorting to surgery. Thus physicians could selectively eliminate and/or replace reproductive factors considered to be the potential source of a medical or psychiatric problem.

More recently, however, reports of increased risk of breast cancer and, particularly, the Women's Health Initiative (WHI) demonstration of increased, not decreased, risks of both heart disease and dementia after hormone therapy (HT) have resulted once more in a mass exodus from reproductive HT. Subsequent findings suggest that the pendulum again may have swung too far (this time, in the direction of avoiding HT). Nonetheless, the conclusions that follow about the practical and potential applications of HT in psychiatric disorders must be viewed in the evolving context in which HT now resides.

Reproductive steroids are powerful and complex neuroregulators. If one is to knowledgeably, responsibly, and creatively employ reproductive steroids in the psychotherapeutic armamentarium, some familiarity with the structure and related complexity of activities of these compounds is required.

STRUCTURE AND ACTIONS

Gonadal steroids, like all steroid hormones, are derivatives of cholesterol, and all share a core four-ring structure. Despite the wide array of steroid hormones, the synthesis of individual steroids is performed by a much smaller number of enzymes with multiple sites of action in the hormone synthetic cascade. Indeed, during the 1980s, the cloning of the complementary DNAs (cDNAs) and genes of several steroidogenic enzymes led to the realization that multiple different steroids could serve as substrates for the same steroidogenic enzyme in most tissues. In the past two decades, there has been an explosion of findings that have demonstrated the enormous complexity of steroid synthesis. These findings include the identification of multiple isozymes for steroid synthetic enzymes (including at least 14 different isozymes of 17-beta hydroxysteroid dehydrogenase encoded by several different genes) and the presence of a range of alternate synthetic pathways leading to steroid production in both health and disease states (e.g., the "backdoor pathway" from progesterone to dihydrotestosterone without the usual androgen intermediates). In humans, plasma low-density lipoproteins are the major source of tissue cholesterol used for synthesizing steroids. The first step in steroid synthesis takes place in the mitochondria. The mechanism by which cholesterol is transported and deposited onto the outer mitochondrial membrane remains only partially understood. However, in steroidogenic cells, steroidogenic acute regulatory protein (STAR) and other members of the STAR-related lipid transfer family of proteins control the availability of cholesterol within the mitochondria, where it is cleaved in a series of steps by the P450 side chain cleavage enzyme (P450scc) to produce pregnenolone. Pregnenolone then serves as the precursor of the family of steroid hormones, individual members of which, as stated above, are generated through the actions of a relatively small number of enzymes with multiple sites of action (see Fig. 33.17b–1). The resulting end products of this cascade are determined by the tissue in which the metabolism is occurring and the enzymes present in that tissue. For example, testosterone in both men and women may be the end product and act directly at the androgen receptor, or it may be reduced to a form with greater affinity for the androgen receptor (dihydrotestosterone), converted to a form with less affinity for the androgen receptor (androsterone—also a neurosteroid active at the GABA receptor), or aromatized to estradiol and act through the estrogen receptor (ER). Recently, a new level of complexity has been introduced by the discovery of tissue-specific variations in the activity of steroidogenic enzymes. For example, 17-beta hydroxysteroid dehydrogenase exists in both oxidative and reductive forms: the type 2 isoform in the gut is oxidative and converts estradiol to estrone (thus “inactivating” orally administered estradiol), while the type 1 isoform in the ovary and placenta is reductive and “activates” estradiol via its conversion from the less potent estrone. Further, a genetic variation in 5-alpha reductase type 1, an enzyme that converts testosterone to dihydrotestosterone and is localized in skin and the CNS, has been associated with enhanced hirsutism in women with polycystic ovarian syndrome. Thus, polymorphic variants of steroidogenic enzymes can produce tissue-specific alterations in exposure to steroids with accompanying alterations in phenotype. Moreover, as an example of the multifunctional roles of steroidogenic enzymes, 5-alpha reductase also is the rate-limiting step in the conversion of progesterone to its neurosteroid metabolite allopregnanolone, which is active at the GABA receptor. Finally, given the structural similarities shared across different types of steroid hormones, steroids are classified by the particular receptor that mediates their actions rather than the structural elements of the hormone or the tissue of origin (see bioidentical hormone section below). By this classification, reproductive steroids are those that act via the androgen receptor, ER, or progesterone receptor (PR) systems.

FIGURE 33.17b–1. Synthetic pathways for steroid hormones. Circled numbers identify synthetic enzymes: 1, cytochrome P450 (CYP) 11A (P450 side chain cleavage enzyme); 2, 3β-hydroxysteroid dehydrogenase; 3, CYP21 (21-hydroxylase); 4, CYP11B2 (11β-hydroxylase, 18-hydroxylase, 18-oxidase); 5, CYP17 (17α-hydroxylase, 17,20-lyase); 6, 17β-hydroxysteroid dehydrogenase (or oxidoreductase); 7, aromatase; 8, 5α-reductase; 9, CYP11B1 (11β-hydroxylase). (Reprinted with permission from the American Journal of Psychiatry, 153:8 (Copyright © 1996). American Psychiatric Association. All Rights Reserved.)

The classic genomic action of steroid hormones occurs after the steroid binds (activates) its intracellular receptor, which, after undergoing phosphorylation, binds (usually as a dimer) to a hormone response element on a gene and directs or modifies transcription of that gene (see Fig. 33.17b–2). Note that in contrast to the membrane-bound receptors of neurotransmitters and neuropeptides, which act on the genome through a signal transduction cascade, the steroid hormone receptors are intracellular and are transcription factors that can directly bind to DNA. Further, once the ligand–receptor complex binds to the hormone response element (which is located on or near the promoter of the gene), the result can be either the initiation or repression of transcription of messages coding for an enormous array of proteins, including synthetic and metabolic enzymes for neurotransmitters, neuropeptides, receptor proteins, transporters, and second messengers; literally thousands of genes are so regulated.

Alas, while accurate, this mechanistic description is glaringly inadequate, and it is in the missing complexity that the explanation for so many ostensibly idiosyncratic responses to hormones lies. First, an additional source of transcriptional variance is found in the different forms of the gonadal steroid receptors. For example, isoforms (structurally varied products of the same gene) of the androgen and progesterone receptors exist that have different transcriptional effects, and two separate ERs, alpha and beta, have been identified and coded for by genes on the 6th and 14th chromosomes, respectively. These ERs have different distributions in the brain, different transcriptional actions, and even possess additional isoforms (e.g., insertional and deletional variants of ER beta). In addition, recent studies have identified splice variants of steroid receptors present in some disease states, including a splice variant in the androgen receptor that lacks a ligand-binding domain but is constitutively active (and, therefore, acts on the androgen receptor in the absence of steroid) and contributes to the development of hormone-refractory prostate cancer. In addition to the intracellular location of steroid receptors, receptors have been identified on the cell membrane; again, multiple forms of steroid membrane receptors have been identified. For example, membrane progesterone receptors exist in the following forms: the progesterone-adiponectin Q receptor (five subtypes), the membrane component progesterone receptor (three subtypes), and the classical PR. Second, the activated steroid receptor regulates transcription by binding protein intermediaries called coregulators. Some coregulators stimulate transcription while others inhibit it. The activities of these coregulators are tissue specific, and different types of coregulators interact with specific isoforms of the steroid receptors. Thus, the relative expression of coregulators and receptor isoforms within different tissues could underlie, in part, opposite effects of the same hormone in different tissues. Approximately 350 of these coregulators have been identified, with coregulators usually part of assemblies consisting of up to eight different regulators. Since the coregulator function is altered by covalent modification of its constituent amino acid residues, it has been estimated that there are 10^{13} possible different functional states that can be created in response to hormone activation. Third, steroid receptors can also indirectly associate with DNA through protein: protein interactions with other transcription factors—a process called **tethering**—to regulate the transcription of genes that do not have classical receptor binding sites—response elements—in the DNA.

Fourth, hormones display acute nongenomic actions; that is, they can, in a receptor isoform-specific fashion, allosterically modify the activity of neurotransmitter-gated ion channels, can directly bind and regulate ion channels, and can initiate signal transduction through the binding membrane rather than cytoplasmic or nuclear receptors. Fifth, hormone receptors can be activated, even in the absence of hormones, by a variety of neurotransmitters and growth factors. In this fashion, environmental stressors may amplify the response to even minimal levels of a hormone signal. Sixth, hormones may influence each other's activity by competing for cofactors or by producing opposite effects on genes regulated through integrator proteins. What are the practical implications of this biologic complexity? First, hormones of a given class (i.e., different hormonal preparations) are not going to produce similar effects on all tissues. For example, medroxyprogesterone (MPA) differs from progesterone in at least three ways: first, MPA interferes with the activity of the neurosteroid, $GABA_A$ receptor modulating metabolite of progesterone—allopregnanolone; second, MPA lacks the anti-inflammatory/neuroprotective effects of both progesterone and allopregnanolone; and third, MPA inhibits the enzyme that converts pregnenolone to progesterone (i.e., 3-beta hydroxysteroid dehydrogenase) thereby further decreasing substrate for the production of endogenous neurosteroids. At a cellular level, it is unlikely that the equine estrogens used so frequently in HRT produce the same conformational changes in the ER as estradiol and hence would have a different profile of actions. Indeed, the genetic effects of conjugated equine estrogens are not identical to those of estradiol. Second, hormone plasma levels are only part of the story. Hormone effects are context specific and reflect the constituents of the milieu that bathes the cell as well as the specific constellation of expressed proteins within the cell. Depending on one's genetic background, then, one might expect that the same hormone level would elicit a range of possible effects. This has been clearly demonstrated in animal studies in which exogenous estradiol exerts 100-fold differences in effects on reproductive development across rodent strains, accounting for far more of the variance than the plasma level of estradiol achieved. Third, recognition of the critical nature of intracellular proteins and hormone signaling/transcription suggests a strategy for future drug development, namely designing drugs that will facilitate or disrupt binding interactions between the receptor and specific cofactors. This strategy has already borne fruit in the development of selective estrogen receptor modulators (SERMs), as well as those for progesterone (SPRMs) and androgen (SARMs) receptors.

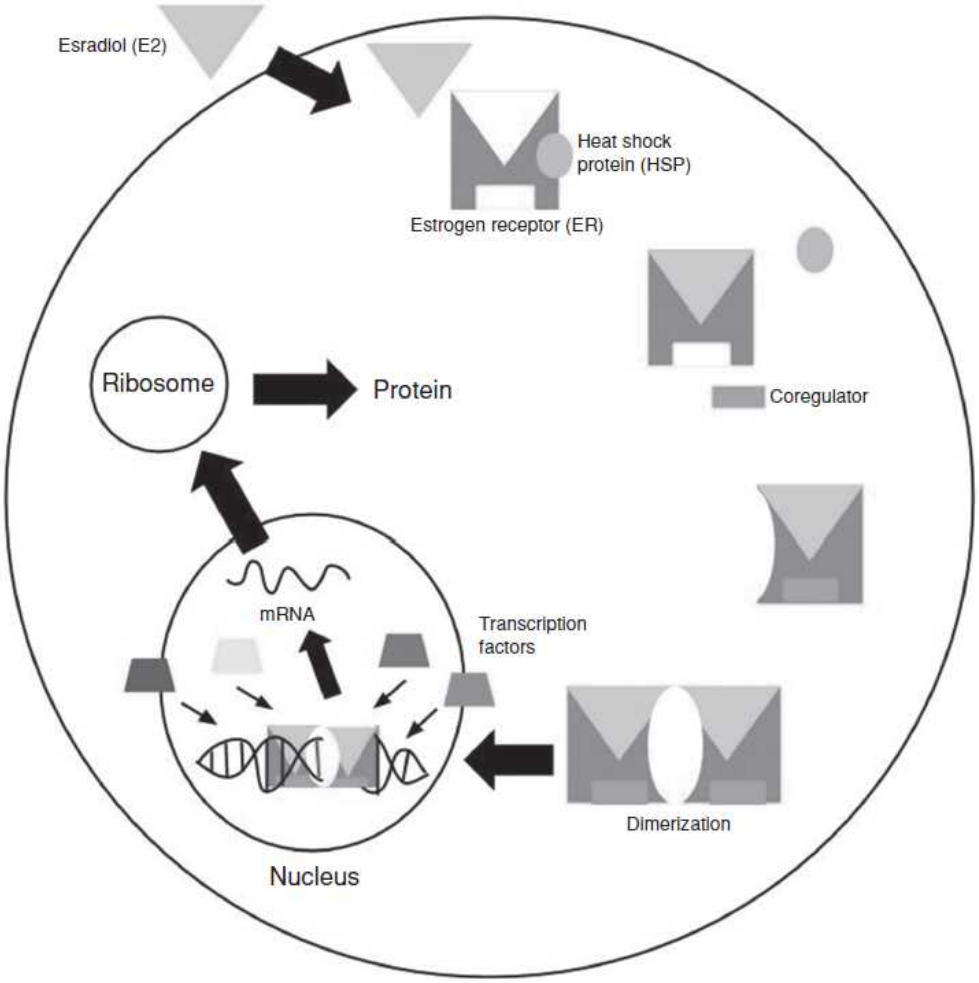

FIGURE 33.17b–2. Genomic action of steroid hormones. Estradiol acts by binding (activating) its intracellular receptor, which dissociates from heat shock protein. The activated receptor undergoes a conformational change that facilitates the binding of a coregulator (in this case, a coactivator) with enzymatic properties. The receptor dimerizes, and the receptor/coregulator complex both binds the DNA hormone response element and recruits a variety of transcription factors. The DNA is then remodeled to facilitate transcription of mRNA, which is exported to the cytoplasmic ribosome for protein synthesis.

WHY REPRODUCTIVE HORMONAL THERAPY?

It is biologically plausible that reproductive steroids might display psychotropic properties, as their pattern of neuroregulatory effects is highly convergent with those presumed to underlie psychotropic efficacy.

Indeed, wherever one finds a system believed to play a role in the etiology or treatment of depression, modulatory effects of gonadal steroids are observed as well. The neurotransmitter systems implicated in depression—serotonin, norepinephrine, dopamine, acetylcholine, gamma-amino butyric acid (GABA), glutamate—all are regulated by estradiol, as are other relevant processes like neuroplasticity, neuronal/glial survival (e.g., brain derived neurotrophic factor [BDNF], B-cell lymphoma 2 [Bcl-2]), signal transduction (e.g., mitogen-activated protein kinases [MAPK], Protein kinase B

[AKT]), and neuronal excitability (e.g., calcium and potassium ion channels). The effects of estradiol on these systems are similar to those of antidepressants and mood stabilizers (e.g., increasing the growth factors [BDNF] and signal transduction proteins [extracellular signal-regulated kinases (ERK), AKT] that promote neuroplasticity/neuronal survival and that are decreased in depression). Similarly, many areas of the brain that have been implicated in depression, including the prefrontal cortex (PFC), amygdala, hippocampus, striatum, and thalamus, contain ERs and are modulated by estradiol. More to the point, reproductive steroids regulate activity in multiple networks implicated in depression (e.g., salience, affective control, reward circuitry). Finally, the importance of gonadal steroids in affective regulation is suggested by studies demonstrating the role of estradiol in stress amplification, ER beta in anxiety in female rats, and ER alpha in arousal.

Progesterone is metabolized to the neurosteroid allopregnanolone, the levels of which have been shown to be decreased in depression and increased during treatment with a selective serotonin reuptake inhibitor (SSRI). Indeed, SSRIs increase the activity of the neurosteroid synthetic enzyme 3-alpha-hydroxysteroid oxidoreductase, and it has been hypothesized that the resultant increase in allopregnanolone may underlie the therapeutic efficacy of SSRIs in premenstrual dysphoria. Progesterone, through allopregnanolone, modulates both the conformation and the ligand sensitivity of $GABA_A$ receptors, with a role for allopregnanolone implicated in both the genesis and treatment of anxiety (depending upon the time course of administration) and in the sensitivity of $GABA_A$ receptor to the anxiolytic benzodiazepines. Notably, allopregnanolone, unlike benzodiazepines, modulates extrasynaptic (as well as synaptic) $GABA_A$ receptor activity, thus regulating tonic inhibition, critical for the “tuning” of neuronal excitability in the brain. Finally, allopregnanolone also exerts neuroprotective effects by reducing the expression of proapoptotic proteins and apoptotic DNA fragmentation, thereby reducing cell death and gliosis, which have been associated with depression. Neuroprotection may be mediated by immune regulation in depression, and both progesterone and allopregnanolone reduce the expression of the “proinflammatory” cytokine tumor necrosis factor (TNF)-alpha, which is elevated in individuals with major depression. Further, allopregnanolone has been shown to dramatically inhibit proinflammatory signaling through toll-like receptor pathways both peripherally and in the brain. Thus, allopregnanolone (or progesterone) may exert antidepressant effects by reducing the physiologic impact of stress, promoting neuroprotection, and protecting against the immune activation and cytokine hypersecretion associated with major depressive disorder. As such, both progesterone and therapies that target progesterone metabolism might be expected to modulate mood.

TYPES OF REPRODUCTIVE HORMONE THERAPY IN AFFECTIVE ILLNESS

Reproductive hormone therapies serve two principal functions. First, they potentially may replace traditional pharmacotherapies if the latter have proved ineffective or are accompanied by unacceptable side effects. Second, some reproductive hormone therapies can also serve as short-term trials to inform patients and their health care providers about possible links between the secretion of a particular hormone and the presence or exacerbation of symptoms (e.g., GnRH agonist–induced ovarian suppression in the menstrual cycle–modulated affective disorders, as described below).

Hormone Suppression in Premenstrual Dysphoric Disorder

A variety of hormonal therapies have been employed in premenstrual dysphoric disorder (PMDD). Currently, the best evidence of efficacy exists for GnRH agonists, compounds that reversibly suppress the pituitary secretion of the gonadotropins, follicle stimulating hormone (FSH), and luteinizing hormone (LH), and hence turn off ovarian steroid secretion. GnRH-induced ovarian suppression works in about two-thirds of women with PMDD, the same percentage (although not necessarily the same individuals) as are successfully treated by SSRIs. GnRH therapy should be considered for those women who do not respond to SSRIs, particularly if they have severe symptoms. While few predictors of therapeutic response to GnRH agonists exist, one report suggests that the presence of symptoms in the follicular phase predicts a lack of efficacy (although the women in this report would not meet the criteria for PMDD and more likely experienced a premenstrual exacerbation of a chronic depressive illness). Because of the largely unknown risk of compromising fertility and of nonreversible reduction in bone mass, this treatment should be reserved for those who do not intend to subsequently have children and should be administered only in consultation with a gynecologist and with full consideration of risks and benefits. Recently, concerns over the safety of long-term GnRH agonist–induced gonadal suppression in both fertility and bone health have been offset in part by reports of the return of normal reproductive function and bone mass in the majority of children with precocious puberty who were treated with these agents for several years. Nonetheless, prudent clinical practice would entail the use of GnRH agonists for not greater than 3 months without consultation with a woman's gynecologist and without consideration of the addition of bone-sparing adjunctive estradiol (which, if given continuously, would not be expected to reverse the efficacy of the GnRH agonist). One additional advantage to a therapeutic trial of GnRH agonist is that the results can determine the role of cyclical variation of steroid secretion in PMDD. If the patient does not respond to GnRH agonist–induced suppression (nonresponse is reported in about 30% of women with PMDD despite adequate ovarian suppression), it is unlikely that a reproductive hormone etiology is present or that a hormonal intervention will be successful. Other hormones studied as potential treatments for PMDD include progesterone and estrogen. Despite early claims to the contrary, the majority of studies overwhelmingly refute the efficacy of progesterone in PMDD.

Recently published data suggest that it is the change in hormone levels—rather than the levels themselves—that trigger the symptomatic state in PMDD. This is consistent with the possibility that it is the shortened pill-free interval that accounts for the efficacy of the drospirenone-containing oral contraceptive Yaz in PMDD. It should be noted, however, that several reports fail to demonstrate the efficacy of even continuous administration of oral contraceptives in PMDD. Three other studies are consistent with the hypothesis that differential sensitivity to changing hormone levels precipitates symptoms in women with PMDD. First, stabilizing neurosteroid levels across the menstrual cycle by inhibiting 5-alpha reductase type 1 (the rate-limiting enzyme for the conversion of progesterone to allopregnanolone) with the medication dutasteride results in the elimination of PMDD symptoms. Second, PMDD symptoms were significantly reduced following luteal phase administration of the isomeric antagonist of allopregnanolone (isoallopregnanolone; Sepranolone), which would prevent the effects of the rise in allopregnanolone during the luteal phase. Finally, efficacy specifically for mood (rather than physical) symptoms of PMDD was recently demonstrated for ulipristal acetate, an SPRM, which reduces both progesterone signaling and levels (through anovulation). These findings collectively hold great potential for understanding the role of progesterone and neurosteroids in PMDD but must be viewed with caution until larger trials with longer treatment duration can confirm these results.

While estradiol is described as superior to placebo in several studies, evidence to date must be regarded as preliminary and insufficient to support the recommended use of estradiol for the treatment of PMDD. Indeed, the doses of estradiol required to effectively treat PMDD suggest that in this condition, estradiol is acting to inhibit ovulation and interfere with normal cyclic ovarian hormone secretion. No studies have examined the therapeutic potential of GnRH antagonists, which have recently become available in an oral preparation.

Although not unrelated to the treatment of women with PMDD, a trial of GnRH agonist–induced ovarian suppression can be undertaken in some women who present with a recurrent affective disorder and in whom the clinical presentation suggests a menstrual cycle recrudescence of affective symptoms. In this clinical scenario, the results of the trial of ovarian suppression inform future decisions to include (or not) hormonal therapies to augment existing mood-stabilizing pharmacotherapy.

Estradiol Administration in Perimenopausal Depression and Postpartum Depression

Perimenopausal Depression

A 48-year-old gravida 2 para 2 married Caucasian female presented with an 8-month history of depressed mood, anhedonia, increased anxiety, tearfulness, avoidance of social activities, disturbed sleep, and decreased concentration. She did not feel that she was sad so much as, paradoxically, both more worried about even relatively trivial matters and less engaged by events in her life. She felt herself to be more emotionally reactive, finding herself becoming tearful in response to almost any emotionally laden situation. On questioning, the patient reported hot flushes, worse at night; however, daytime flushes were associated with marked anxiety, a racing heartbeat, and an enhanced sense of worry. Her menstrual cycle had been somewhat erratic in length for 2 years, and in the last year, she had skipped several menses with periods of amenorrhea lasting 2 to 3 months. The patient had no past personal or family history of depression. Laboratory testing revealed plasma FSH levels ranging from 25 to 40 IU/L and estradiol levels of 50 to 60 pg/mL. This typical case provides a springboard for highlighting elements of the diagnosis and treatment of perimenopausal depression (PMD).

For diagnostic purposes, FSH levels greater than two standard deviations above the mean for women of reproductive age combined with irregular menstrual cycles and amenorrhea characterize the menopause transition and the first year postmenopause (i.e., perimenopause). The most recent revision (2012) of the Stages of Reproductive Aging Workshop (STRAW +10) criteria emphasizes menstrual cycle variability with ≥7-day differences in length (i.e., either shortened or lengthened) of consecutive menstrual cycles (i.e., early menopause transition) and intervals of amenorrhea >60 days (i.e., late menopause transition) as the criteria for the perimenopause, with elevated plasma FSH levels >25 IU/L as confirmatory evidence only.

Several randomized, placebo-controlled trials of estradiol therapy (ET) in PMD (as well as those in perimenopausal women with depressive symptoms who may or may not have met diagnostic threshold criteria for major or minor depression) have demonstrated both short-term antidepressant efficacy and preventative benefits. In addition, low or declining levels of estradiol were shown to play a causal role in the appearance of depression in the subset of women with PMD; that is, under blinded and controlled conditions, acute estradiol withdrawal induced depressive symptoms in asymptomatic postmenopausal women with a past PMD but not in those without such a history. These findings support a role in maintaining stable levels of estradiol in women with or at risk for PMD. The small samples and short duration of treatment in trials of ET in perimenopausal depression notwithstanding, the best case for ET in the treatment of depression (either as monotherapy or as an adjunctive therapeutic agent) can be made in peri- rather than postmenopausal women. Of note, in a prospective placebo-controlled study, ET significantly decreased the risk of subsequent depression in perimenopausal women, with this effect most notable in those with a history of recent life stressors. Promising results notwithstanding, there are at present no clear predictors (including estradiol levels) of response to estradiol in women with perimenopausal depression. Further, the long-term risks of estradiol to endometrial and breast tissues continue to deter many women from its use. While initial reports suggested beneficial effects of estradiol on both cognitive performance (e.g., verbal memory) and cognitive pathology (i.e., Alzheimer dementia), consistent, perhaps, with its neuroprotective effects, subsequent reports demonstrate a far more restricted impact on cognition if any (e.g., limited to women with perimenopausal symptoms). The timing of starting ET relative to menopause has been proposed as one factor explaining the otherwise discordant observations (of the effects of ET on cognition) between the observational studies and the recent randomized controlled trials from the WHI. Thus, in several studies, women who take ET during the late menopause transition or early postmenopause have a lower risk of dementia than those starting ET later. This construct of a reproductive stage–dependent differential "risk" for both the benefits of ET on cognitive performance and the adverse effects in young peri- and postmenopausal women compared with older postmenopausal women has recently been tested. Two primary prevention, randomized, controlled trials examining the effects of ET on cognitive performance in younger and older postmenopausal women have recently been completed. Results of both the Kronos Early Estrogen Prevention Study (KEEPS) and the Early versus Late Intervention Trial with Estradiol (ELITE) showed that the effects of ET on measures of cognitive performance (including verbal and working memory) did not differ from those of placebo, nor did young postmenopausal women show more beneficial effects of ET on cognitive performance than older women. Thus, neither the therapeutic nor the prophylactic benefits of ET on cognition in postmenopausal women are supported by currently available data. Further, beliefs about other indications for the use of estrogen in the treatment of perimenopausal depression have been complicated by the HERS (Heart and Estrogen/Progestin Replacement Study) and WHI reports, which contradict the long-held view that estrogen protects against the development of heart disease in women. Since the cardioprotective effects previously reported were so substantial as to offset the increased risk of breast cancer after >4 years of use of estradiol, particularly given the efficacy of estradiol in the prevention of osteoporosis, many physicians recommended HT as prophylaxis against future heart and bone diseases. With the demonstration that, to the contrary, estrogen combined with the progestin MPA may increase the risk of coronary heart disease and stroke (during the first year of treatment), estradiol prophylaxis can no longer be recommended. However, estradiol treatment may still be indicated in women with perimenopausal symptoms (hot flushes, vaginal dryness) and depression, particularly in those who fail standard antidepressant treatment, who have a strong risk of osteoporosis, or who are intolerant of other acute treatments of perimenopausal symptoms. Indeed, recent analyses of the WHI demonstrate that the adverse effects of ET on cardiovascular outcomes were largely confined to older women (and those at a greater distance from menopause) compared with younger perimenopausal women, thus supporting the critical window or “gap” effect for the effects of estradiol on the cardiovasculature and providing some reassurance regarding the health effects of ET during the perimenopause.

The relationship between estrogen, both endogenous and exogenous, and the development of endometrial carcinoma has been suggested by several different lines of investigation. Numerous retrospective case-control studies published since 1975 have indicated that postmenopausal exposure to unopposed estrogens for more than 1 year results in a 2- to 12-fold increased relative risk for endometrial cancer. However, the addition of progesterone to ET decreases the risk of endometrial hyperplasia and endometrial cancer to equal or below that of women receiving no hormonal treatment. The optimal regimen to prevent hyperplasia and, thus, inferentially, the risk of carcinoma consists of 12 to 13 days of progestin treatment each month when estrogens are administered. There is an increased incidence of thromboembolism and stroke in women receiving ET and some SERMs; however, stroke is less likely in younger-aged perimenopausal women. Blood pressure, on average, appears to be unaffected by ET, although both increases and decreases have been reported. High doses of oral estrogens have been reported to elevate hepatocellular enzyme levels and, less commonly, cause cholestatic jaundice. The risk for gallstones and hepatocellular adenomas has been reported to be increased in association with oral contraceptive use, and although uncommon, these complications may also occur with the use of more physiologic doses of estrogen. Most studies have suggested an increased relative risk of breast cancer after 4 or 5 years of use, similar to the risk expected if the onset of menopause is delayed for a comparable length of time; recent analyses, however, suggest that the increased risk is related to current use and the risk normalizes after cessation of HT. In addition, it is recognized that ET (estrogen alone) is associated with considerably less risk of breast cancer than combined estrogen and progestin formulations. Indeed, a recent 20-year follow-up in the WHI reported that the use of estradiol alone (for an average of 7 years) was accompanied by a significant decrease in the risk of breast cancer. These data suggest that for some older women in whom estradiol stimulation of the endometrium is less of a clinical concern (e.g., in the presence of endometrial atrophy), continuous ET with appropriate endometrial monitoring (e.g., periodic vaginal ultrasounds) could be an acceptable longer-term therapy. Finally, the risk for breast cancer using HT for 5 years is associated with an increased "absolute risk" of only 0.67%, which some authors compare to the increased risk conferred by obesity and many other common exposures. For a more detailed review of the benefits and risks of menopausal ET, the reader is referred to recent updates from the Endocrine Society and the North American Menopause Society.

Estrogens may precipitate migraine headaches, and depression has also been reported to occur with the use of estrogens, but these reports are usually in the context of concurrent progestin use as in the oral contraception pill. If estradiol is to be used in the treatment of depression (see Table 33.17b–1), then one should consider using the 50-μg estradiol patch (transdermal estradiol [TE]). The patch delivers estradiol, the form of estrogen that mediates most of its physiologic effects, and does not cause an undesirable increase in the plasma proteins that mediate some of the adverse effects of estrogen. Levels achieved with this method are equivalent to levels in the early follicular phase and are slightly above the threshold necessary to preserve bone (60 pg/mL). In women without a uterus, estradiol may be given by itself and does not appear to have the risks associated with the combination of estradiol and progestin. Although ET does increase the risk of venous thromboembolism (VTE) and stroke, TE and low-dose estrogen are not accompanied by an increased risk of VTE. If a progestin is needed, micronized progesterone tablets may be used, which deliver progesterone rather than MPA. Of note, progestins may differ markedly in their molecular effects, physiologic effects, and side effects (as discussed above). For example, second-generation progestins (e.g., norethisterone or levonorgestrel) are more androgenic than third- (e.g., desogestrel) or fourth-generation (e.g., drospirenone) progestins but, as a consequence, are more able to oppose the adverse (inducing) effects of estradiol on the liver and are less likely to result in VTE. Finally, individuals can show 20-fold differences in the blood level achieved with the same form of estrogen, so one must be prepared to change doses or preparations if necessary after soliciting reports from the patient about side effects, adverse effects, or lack of efficacy.

Table 33.17b–1.
The Following Conditions Constitute Risk Factors or Contraindications* to Initiating Treatment With Estrogen

Women with a history of carcinoma of the breast*, or women with a family history of the following: premenopausal breast cancer or bilateral breast cancer in a first-degree relative; multiple family members (greater than three relatives) with postmenopausal breast cancer

Women with a history of uterine cancer*, endometriosis, ill-defined pelvic lesions*, particularly undiagnosed ovarian enlargement, undiagnosed vaginal bleeding*

(Active thrombophlebitis or thromboembolic disorders, or history of ischemic cardiac disease, pulmonary embolism, retinal thrombosis, or thrombophlebitis)*; (***risk factors for thromboembolic phenomena include cigarette smoking, varicose veins, prolonged periods of immobilization [including prolonged travel], and active heart disease***).

Known or suspected pregnancy*: Estrogens may cause fetal harm when administered to a pregnant women

Known hypersensitivity to estrogen or progestin (if prescribed) or the excipients (inactive compounds) contained within these medications. For example, Provera–calcium stearate, corn starch, lactose, mineral oil, sorbic acid, sucrose, talc; Alora–sorbitan monooleate, acrylic adhesive

History of cerebrovascular disease (stroke), epilepsy, hypertension, hypercalcemia

Cholecystitis or pancreatitis

Recurrent migraine headaches

Diabetes mellitus

History of familial hyperlipoproteinemia

Porphyria

Despite current concerns regarding ET and the requirement of adjunctive progestins for endometrial protection in women with an intact uterus, the specificity of actions of some of the newer SERMs and SARMs (and hence the promise of separating therapeutic from toxic effects) suggests that ER activators may occupy a useful niche in the future psychopharmacologic armamentarium. The recent introduction of tissue-selective estrogen complexes (TSECs), which combine estrogen with a SERM (some of which may be unable to enter the CNS), also holds promise for the delivery of individualized ET for those women who choose to employ hormonal therapies. Indeed, TSECs may have advantages over several SERMs (i.e., raloxifene and tamoxifen) since recent trials have documented that some TSECs (e.g., conjugated estrogen + bazedoxifene) are associated with a lower risk of VTE. These newer therapies could avoid the need for the addition of progestins (and the potential associated adverse effects) and could lead to therapies designed to optimize ER activity.

In the wake of the WHI report, interest in compounded bioidentical hormones as treatments for perimenopausal symptoms soared. Bioidentical means that the hormone is structurally and chemically indistinguishable from the same hormone in the human body. The purported benefits of this treatment class are increased safety and improved efficacy, both associated with the belief that these hormones are “natural” rather than "synthetic." There are several problems with these widely proclaimed benefits and inferences. First, as noted above, the effects—both therapeutic and adverse—are mediated through hormone receptors, which are sensitive only to the structure of the ligand, not to its source. Consequently, "bioidentical" progesterone that comes from a yam is, at the receptor level, indistinguishable from endogenous progesterone or FDA-approved micronized progesterone. If a hormone is bioidentical, the "natural" source is functionally irrelevant. Second, "natural bioidenticals" often begin with a chemical substrate from a plant that is subsequently modified in a lab to produce the final product (e.g., progesterone from diosgenin in the yam). Hence, even the "natural" hormone is synthetic. Third, bioavailability data for compounded products are exiguous at best, and results are inconsistent. As such, patients cannot reliably know the concentration of hormone to which their tissues are exposed. Fourth, FDA-approved bioidentical hormones exist, including micronized forms of estradiol and progesterone as well as a combination of estradiol and estriol. Many therapeutic benefits have been attributed in particular to estriol, a weak metabolite of estradiol and estrone, but confirmation of these benefits must await confirmation in adequately designed, controlled, head-to-head comparison trials with estradiol.
